## Lessons from the Past

Malcolm T. MCCULLOCH
ARC Coral Reef Centre of Excellence, Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia

Planet Earth is undergoing rapid environmental change at what is probably an unprecedented rate, even on geologic timescales of tens of millions of years. Coral reefs are at the forefront of these changes being extremely sensitive to the threats from both climate change and direct local human impacts on the marine environment. Locally, land-use changes in river catchments, wetlands, and estuaries, together with growing urbanisation of coastal zones, is leading to increased supplies of sediment and nutrients to inshore coral reefs. Degradation of water quality is also invariably accompanied by pressures from activities, such as trawling and overfishing. Further exacerbating the plight of coral reefs are the ever increasing effects from rapidly growing levels of anthropogenic CO2 emissions. This is not only causing global warming and the related impacts from coral bleaching, but is also directly changing the chemistry of the world's surface oceans by increasing the acidity, hence reducing the carbonate-ion concentration, upon which coral calcification is dependent. Sea levels are also rising at faster than predicted rates, although the effects on coral reefs are still relatively benign compared to those expected from catastrophic melting of the Greenland/West Antarctic ice sheets once critical CO2 thresholds are exceeded.
In addition to serving as immediate indicators of environmental change, corals also provide invaluable long-term information. Within the skeleton of long-lived massive corals, oxygen isotope and Sr/Ca, U/Ca ratios respond to changes in hydrologic and ocean temperature regimes. Increased sediment runoff and changes in water quality can be deduced from Ba, Mn, and rare earth element abundances. More recently it has been shown that boron isotopic variations preserved in coral carbonate skeletons mimic pH changes that control the distribution of carbonate/bicarbonate ions in seawater. Given that systematic measurements of seawater pH have only commenced during the past decade, coral-based pH records are essential to establishing the long-term response of coral calcification to increasing ocean acidity. Such records, however, also have some limitations since they are biologically mediated, hence coral calcification does not reflect a linear, passive response to external forcing. Furthermore, micro-scale variability within various skeletal components can mask larger-scale environmentally-driven signals. Despite these limitations, coral proxies are invaluable as in many cases they provide the only record of the natural 'baseline' and variability, against which the critical thresholds for irreversible human-induced environmental changes can be gauged. Such quantitative, scientifically-based data provides much needed guidelines to both reduce local human impacts on coral reef systems, and ensure their resilience to the poorly understood effects of global climate change.

## Coral Reef Fisheries: Three Thematic Challenges

Daniel PAULY
Sea Around Us Project, Fisheries Centre, University of British Columbia, Vancouver, Canada

This presentation is divided into three parts, each dealing with different sets of scientific challenges: (a) the identification of three types of coral reef fisheries, and the specific management regime each requires; (b) the estimation of global catches from reef fisheries, and (c) the potential impact of global warming on these catches.
Regarding (a), I see three types of major fisheries on reefs: (i) recreational fisheries in Florida, Australia and similar high-income areas; (ii) small-scale fisheries, such as traditional reef fishers and the fish suppliers of tourist resorts and the life-fish exporters, as well as a often competing and rapidly growing 'Malthusian' small-scale fisheries component, providing occupation of last resort to thousands of new entrants, often displaced coastal dwellers, e.g., in Southeast Asia or the larger Caribbean islands, and (iii) traditional reef fisheries, i.e., fisheries which are still managed under traditional-based rules in the South Pacific.
The question of how much fish is caught in coral reef fisheries is based on the assumption that, in the 21st century, it should be unnecessary to consult archives and unpublished or grey literature to derive time series of the world's coral reef catch, i.e., it should be part of global databases such as those maintained by the FAO. However, this is not the case, because coral reef fisheries are small-scale, and the FAO database covers mainly industrial fisheries. A series of authors have published independent estimates of the world catch from coral reef fisheries, but no consensus has emerged. An approach is presented here which documents an estimate, based on the assumed 'reefyness' assumed for various species in the catch reported to FAO by countries with coral reefs. The results, even less likely to generate a consensus, illustrate the need for country-specific catch reconstructions. An example is provided here, but these are discussed in more details in the presentations by Dirk Zeller and Jennifer Jacquet, who complement their catch reconstruction with fisheries-independent data, e.g., household food consumption data.
The third topic of this presentation is the future of coral reef fisheries, presently impacted by various stresses likely to increase in the next decades, such as increased turbidity and coastal development, and particularly global change-associated phenomena, illustrated here by quantifying the poleward shifts in the distribution range of reef-associated fish caused by warming at low latitudes, and their impact on the coral reef catches of 10 equatorial countries. This specific threat appears relatively small compared with the direct effect of warming (i.e., coral bleaching) and acidification, but it adds to what may be described, for coral reef systems, as 'death by a thousand cuts'.

## Photophysiology, Bleaching and Adaptation

Roberto IGLESIAS-PRIETO
Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Apartado Postal 1152, Cancún 77500 QR Mexico

During the last 200 million years scleractinian corals in symbioses with photosynthetic dinoflagellates have been responsible for the formation and maintenance of coral reefs. In these organisms, algal photosynthesis can provide more that a 100% of the basal metabolic requirements. The nutritional advantages that symbiotic invertebrates obtain from the translocation and consumption of algal photosynthates can explain why symbiotic corals possess significantly larger calcification rates relative to non-symbiotic invertebrates. In this context, algal photosynthesis is a key element in the formation of modern coral reefs. Considering the importance of algal photosynthesis for the well being of symbiotic corals, the study of the photobiology of these organisms has attracted significant attention. Symbiotic corals inhabit the entire photic zone and are subject to extraordinary variations in light intensity. I will review the characteristics of the photosynthetic apparatus of dinoflagellates and the physiological mechanisms employed by corals and their symbiotic algae to successfully harvest and utilize the available solar radiation. Based on comparative analyses of the differential responses of individual algal species to variations in growth irradiance in culture, or intact associations in nature, it has been postulated that the differential utilization of solar radiation is an important axis for niche diversification among reef-building corals. Recent analyses of the optical properties of intact coral surfaces using transmittance determinations indicate that due to the multiple scattering of solar radiation on the highly reflective aragonite skeleton, the specific absorption coefficients of the symbiotic algae are much higher that those obtained from freshly isolated algae, making symbiotic scleractinians one of the most efficient solar collector in nature. This efficiency results in significant competitive advantages, as symbiotic corals can collect the same amount of solar radiation as a green plant with approximately one order of magnitude less photosynthetic pigments concentrations. The role of the animal skeleton in modulating the absorption properties of the symbiotic algae has also profound implications for our understanding of the evolution of these organisms. Finally, I will discuss the role of multiple scattering of coral skeletons in the propagation of thermal stress, leading to coral bleaching and mortality.

## Population Connectivity Within and Among Reef Systems: Progress and Promising Directions

Robert COWEN
Marine Biology and Fisheries, University of Miami, RSMAS, Miami, FL

The study of population connectivity has evolved over the last decade to include a broad array of approaches to assess the scales and mechanisms over which successful larval dispersal operates among reef systems. Strong interest in this topic has been stimulated by a need to provide spatial management options to resource managers, often for resources that are in dire states. The major challenges in this effort are to provide a quantitative understanding of the processes and scales controlling successful larval dispersal and how connectivity influences the dynamics of the affected populations. Resolving the mechanisms controlling larval dispersal will involve a coherent understanding of the relevant physical processes and how organisms mediate the physical outcome. Multiple scales will be important, and therefore understanding how the processes are coupled across scales is essential. By the very nature of reef organisms initiating and ending their larval life within nearshore waters, new focus must be extended on the bio-physical processes operating within this environment. Identifying patterns will need to involve efforts that focus on a variety of species with different life histories across various environments. In concert, the problem is multidisciplinary, but one requiring interdisciplinary research effort. This talk will evaluate our progress to date, implications of mounting environmental challenges and suggest some promising new directions.

**Drivers of Coral Infectious Disease**

Drew HARVELL
Cornell University, Ithaca, NY

The rate of new infectious syndromes and disease outbreaks of gorgonian and scleractinian corals continues to increase. Evidence is developing that both global climate and local factors are contributing to this increase. The Coral Disease Working Group of the CRTR is investigating how these factors act synergistically to facilitate disease outbreaks, and developing tools and strategies for mitigating and managing disease impact. The focus of the Harvell laboratory is on understanding coral immunity to infectious agents, and most recently cellular and protein responses of Gorgonian sea fans to fungal infections. Our working hypothesis is that, in some cases, coral mortality during thermal anomalies is exacerbated by opportunistic pathogens whose virulence is enhanced by increased temperatures while host resistance is reduced. Required for testing this hypothesis is a tool for assessing coral immunity. Particularly promising is an assay measuring the temperature induced response of amoebocytes and production of prophenoloxidase in the Caribbean sea fan corals. Another important goal for the entire community is the development of practical management approaches for marine infectious diseases. This will require both the application of approaches developed to manage disease on land and new strategies that recognize the special biology of the coral holobiont.

## 1-1

**The R/v Alpha Helix Symbios Expedition: A Retrospective Analysis Of A Milestone in Coral Reef Research**

**Christopher F. D'ELIA***[1], Abbie Rae HARRIS*2

[1]Environmental Science and Policy, University of South Florida St. Petersburg, Saint Petersburg, FL, [2]College of Marine Science, University of South Florida, Saint Petersburg, FL

In the spring of 1971, a team of more than 20 marine scientists arrived at Enewetak Atoll in the Marshall Islands to conduct the most comprehensive study of a coral reef yet undertaken: the Symbios Expedition, using the R/V Alpha Helix for logistical support. While many coral reef researchers are aware that this team-oriented research program made significant contributions to the understanding of coral reef metabolism and function, neither a history of the Expedition has been done nor a formal assessment has been made on its impact on the field. This is not surprising, because scientists rarely concern themselves with documenting the history of the science they conduct or assessing the results of their research programs vis a vis the funding provided. Thus, we are typically left with only vague notions as to the scientific impact that a given project had and the factors that contributed. Clearly, science builds upon prior knowledge, and researchers recognize contributions to this knowledge by literature citations in their publications. Recently, citation analysis tools have become available to assess publication impact quantitatively. Using one such tool, Citespace II, together with quantitative and qualitative information gathered from historical reference materials and extensive interviews, we provide here a retrospective assessment of the Symbios Expedition that demonstrates its scientific impact and suggests some of the reasons for its success.

## 1-2

**Caribbean Coral Reef Communities in the 1970's: An Ecosystem Baseline Data Set for Assessing Current Regional Reef Health**

**Randolph BURKE*[1]**, Walter ADEY[2]

[1]Botany, Smithsonian Institution, Mandan, ND, [2]Botany, Smithsonian Institution NHB, Washington D.C., DC

Currently a great debate ensues among scientists about how well developed Caribbean reef communities were before the "crash" and exactly what changes occurred. Since the late 1980's, Caribbean coral reefs have been repeatedly struck by hurricanes, diseases, high temperatures, over fishing, and locally, recreational and pollution disturbance. For these reasons most scientists consider these reefs to be currently in a state of collapse, but none have a Caribbean wide, historical data base on which to base their beliefs.

A regional database, circum-Caribbean and Bahamas, consisting of still photographs (3350 frames, 60 mm and 35 mm; underwater and low altitude aerial) were taken over a two-week period in 1976. SCUBA diver measured transects of coral reef community data were taken concurrently during rest and refueling stops. Additionally, approximately 12 km of 16 mm motion picture film and 1650 still photographs (60 mm and 35mm; underwater and aerial) were taken between 1972 and 1987. This material was collected to support work on regional coral reef structure and ecosystem dynamics that resulted in numerous publications, but much of this supporting data has not been published. Current concerns about Caribbean coral reef health provided an opportunity to revisit this data.

The capability of accurately relocating individual reefs was demonstrated by digitally overlaying 1976 digitized photos on exactly the same reef location captured in USGS Orthoimages and Landsat 7 images using Google Earth. More than 80% of the aerial photographs can be accurately relocated within a meter or less using Landsat imagery. The large format (60 mm) allows for size resolution of objects 0.5m and less. This provides historical data on the regional distribution of *Acropora palmata*, currently on the endangered species list. This data set is uniquely valuable for evaluating changes of shallow-water, Caribbean wide coral reef communities in the last three decades.

## 1-3

**Estimating Live Coral Cover in Fossil Reefs: A Microboring Approach**

**Halard LESCINSKY*[1]**, Benjamin TITUS[1], Avinash MINHAS[1], Dennis HUBBARD[2]

[1]Department of Life and Earth Sciences, Otterbein College, Westerville, OH, [2]Department of Geology, Oberlin College, Oberlin, OH

The recent widespread decrease in Caribbean live coral cover points out the need for a valid ecological baseline for understanding modern reefs. Here we show that live coral cover, comparable to that measured in modern reefs, can be estimated in fossil reefs using microboring abundance and taphograde analysis. Subaerially exposed reefs may contain well-preserved corals that are topped by beds indicative of rapid burial. Since microborers infest coral skeleton within weeks of exposure, microboring analysis provides an objective way to identify corals with little post-mortem exposure and thus buried horizons of these corals can be censused to determine live coral cover in fossil reefs. We applied this technique to the Holocene (5-9,000 ybp) Enriquillo Valley reef in western Dominican Republic. A mud-rich event bed, characterized by *Madracis auretenra*, is found draping over corals for 125m within the massive coral zone at Cañada Honda. Field-estimated taphograde correlated with microboring intensity. The best preserved corals (grade 1) had little or no microboring suggesting immediate burial, grade 2 corals had surficial boring ($\leq$50$\mu$) suggesting minimal (days to weeks) post-mortem exposure, while grade 3-6 corals had more extensive borings and post-mortem exposure. We conclude that live coral cover in the massive zone averaged between 51% (grade 1) and 81% (grades 1 and 2) and was consistent along the transect, despite changes in coral composition and inferred depth over the 125m length. Live coral cover (grades 1 and 2) estimated elsewhere in the reef in the absence of event beds yielded lower, but still high, values: mixed zone 56%, massive zone 65%, platy zone 67%. An exact modern equivalent to these reefs is unavailable, but our results suggest much higher live coral cover in the recent geologic past of the Dominican Republic than is found today in most of the Caribbean.

## 1-4

**Historical Changes in Coral Communities Along A Gradient Of Land Use in Bocas Del Toro, Panama**

**Katie CRAMER*[1]**

[1]Marine Biology, Scripps Institution of Oceanography, UCSD, La Jolla, CA

The recent and historically unprecedented shift in the dominant hermatypic coral species on many Caribbean reefs has broadly been attributed to human disturbances such as overfishing, climate change, and/or land development. This study explored the relationship between changes on reefs and patterns of human alteration of nearby terrestrial habitats by comparing current and past coral community structure over the last few centuries at sites in western Panamá spanning a distance of 50 km. Modern living coral assemblages were surveyed by standard line transects, whereas historical communities were analyzed from dead coral rubble encountered along transect lines on the reef surface and by excavation of 0.25m x 0.25m quadrats to 0.25m depth. Radiocarbon dating and amino acid racemization were used to date coral rubble to determine the timing of community changes between neighboring terrestrial and reef habitats and among different reef sites. Patterns of community change were more complex than previous results reported from analyses of 3-inch cores from some of the same reefs. *Acropora cervicornis* and massive faviids were common to abundant in rubble assemblages from several reefs but absent from others just 1-10km apart, suggesting great variability in community structure among sites before the beginning of intense human disturbance. In general, relative abundance of branching growth forms (*A. cervicornis* and *Porites* species) declined, while that of massive (*Montastrea* and *Colpophyllia* species) and platy (*Agaricia* species) growth forms increased. The extent of community change was highly variable among reef sites, suggesting the importance of local disturbances on reef communities. Areas nearer to sources of land runoff have changed more dramatically than those further from these disturbances, highlighting the important role of land use activities in the observed recent demise of Caribbean coral reef ecosystems.

## 1-5

**The Effects Of Geology, Oceanography And Anthropogenic Activities On The Coral Reef Ecosystems Of The Pacific Remote Island Areas**

**Joyce MILLER*[1,2]**, Jamison GOVE[1,2]

[1]NOAA PIFSC Coral Reef Ecosystem Division, Honolulu, HI, [2]Joint Institute for Marine and Atmospheric Research -- Research Corp. Univ. of Hawaii, Honolulu

A wealth of geologic, oceanographic, and biological data collected since 2000 provides a unique opportunity to understand the coral reef ecosystems of the Pacific Remote Island Areas (PRIA). These data were collected by the National Oceanic and Atmospheric Administration and the U.S. Fish and Wildlife Service (FWS) during biennial cruises to seven PRIA: Howland, Baker, and Jarvis Islands, Kingman Reef, and Palmyra, Johnston and Wake Atolls. Detailed bathymetric maps show seven tiny, isolated peaks on anomalously shallow seafloor ranging in age from 120 to 83 Ma, but the four islands that have been dated were all formed about 70 Ma. Small submerged terraces from previous sea level stands can also be detected, providing insight into how sea level change may affect the PRIA in the future. From an oceanographic perspective, these islands and atolls are located in three distinct current regimes, providing an understanding of how current patterns affect the distribution and types of organisms found at each location. Oceanographic data also provide baseline information for understanding the effects of climate change, storms, and bleaching events. Although most of the islands are FWS National Wildlife Refuges and are currently uninhabited, anthropogenic effects from previous guano mining, military and construction activities, fishing, and shipwrecks also have recognizable impacts. Combining this information with biological data on the corals, algae, fish, and macroinvertebrates of the PRIA shows complex interactions that all influence the health of what are thought to be some of the least disturbed coral reef ecosystems in the world.

## 1-6

**Long-Term Records Of Reef Growth Under Terrigenoclastic Sediment Influence: Paluma Shoals, Central Great Barrier Reef, Australia**

**Suzanne E PALMER*[1]**, Chris T PERRY[2], Scott G SMITHERS[3]

[1]Environmental & Geographical Sciences, Manchester Metorpolitan University, Manchester, United Kingdom, [2]Environmental & Geographical Sciences, Manchester Metropolitan University, Manchester, United Kingdom, [3]Earth and Environmental Sciences, James Cook University, Townsville, Australia

Nearshore, turbid-zone reefs on the Great Barrier Reef (GBR) grow on the terrigenoclastic inner shelf and represent important analogues for understanding early-mid Holocene reef initiation on the GBR. They are recognised as ecologically and geologically significant, but knowledge of their development remains limited. The growth history of Paluma Shoals (Halifax Bay, north of Townsville) has been studied in detail to improve our understanding of inshore reef development. Paluma Shoals comprises two areas of active reef development. The reef structure displays distinct phases of reef initiation, reef accretion and reef 'turn-off', and the depositional sequence suggests 1) evidence for long-term reef accretion in association with terrigenoclastic sediment accumulation, and 2) phases of reef initiation, growth and burial influenced by nearshore sediment dynamics.

Reef growth began ~1200 cal years BP over coarse-grained, terrigenoclastic-dominated subtidal sands and/or Pleistocene clays. The reef sequence is up to 2.0-2.5m thick, comprising an unconsolidated framework of coral rubble within a terrigenoclastic-carbonate matrix. *In situ* massive corals (*Goniopora stokesi*, *Favites halicora*) within basal units are interpreted as shallow pioneer coral communities (the 'reef initiation' phase), now enveloped in mainly terrigenoclastic silts. Later reef growth was dominated by framework builders *Acropora pulchra, Turbinaria frondens* and *Montipora mollis*, infilled with fine- to medium-grained sands. Reef growth has been characterised by vertical accretion and then seaward progradation, followed by accumulation landward. Since ~250 years BP reef growth of the South Shoal exhibits little variation in framework builders and is characterised by well-established intertidal coral communities and carbonate-rich sands. In contrast, the Northern Shoal exhibits an increase of terrigenous sands, interpreted as a 'turn-off' phase in reef development driven by natural shoreline dynamics.

## 1-7

**Persistent Organic Pollutants And Trace Metals Associated With African Dust – Is There A Threat To Coral Reefs?**

**Virginia GARRISON*[1]**, Susan GENUALDI[2], William FOREMAN[3], Michael MAJEWSKI[4], Azad MOHAMMED[5], Staci SIMONICH[2]

[1]US Geological Survey, St. Petersburg, FL, [2]Oregon State University, Corvallis, OR, [3]US Geological Survey, Denver, CO, [4]US Geological Survey, Sacramento, CA, [5]University of the West Indies, St. Augustine, Trinidad and Tobago

Increasing quantities of African dust transit the Atlantic and impact the Caribbean and Americas. As part of an investigation into the effects of African dust on coral reef organisms and human health, we analyzed African dust for contaminants and compared levels of persistent organic pollutants (POPs) and metals between the source and downwind regions. Air samples from Africa (Mali) were found to contain a greater variety and a higher concentration of pesticides, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs) than downwind sites in the Caribbean (Trinidad and the U.S. Virgin Islands). To date, nine pesticides, 17 PAHs, and nine PCB congeners have been identified in air samples from the African Sahara/Sahel (Mali) and the Caribbean. One pesticide and four PAHs were detected only in samples from Africa. Of the more than 100 priority pollutant and common-use pesticides screened for in the samples, five pesticides (chlorpyrifos, dacthal, endosulfan I, hexachlorobenzene, and components of chlordane) were detected in samples from all sites. DDE (a breakdown product of DDT) was identified in Mali, USVI, and Trinidad samples. To date, DDT and chlorinated dioxins and furans have been detected only in samples from Mali. Eight and five PCB congeners were detected in Mali and Caribbean samples, respectively; of those, four congeners were detected in samples from both regions. Similarly, greater numbers of PAHs were detected in Mali than at downwind sites. Trace-metal concentrations in both regions were similar to crustal composition with slight enrichment of lead in Mali. Many of the identified POPs and metals are toxic to corals and other marine organisms and can interfere with reproduction, fertilization, and/or immune function. POP and metal contaminants commonly occur as mixtures that are likely to exhibit synergistic effects. Contaminant concentrations are sufficiently high to be of concern – for both marine organisms and humans.

## 1-8

**Bioturbation, Taphonomic Bias And Time-Averaging in Tropical Molluscan Death Assemblages: Differential Shell Half-Lives in Great Barrier Reef Sediment**

**Matthew A. KOSNIK*[1]**, Quan HUA[2,3], Darrell S. KAUFMAN[4], Raphael A. WÜST[5]

[1]Department of Paleobiology, Smithsonian Institution, Washington, DC, [2]Australian Nuclear Science and Technology Organization, Menai, NSW, Australia, [3]Australian Nuclear Science and Technology Organization, Menai, Australia, [4]Department of Geology, Northern Arizona University, Flagstaff, AZ, [5]School of Earth and Environmental Sciences, James Cook University, Townsville, Australia

Radiocarbon-calibrated amino acid racemization ages of 481 individually dated shells representing four molluscan taxa are used to quantify time-averaging and shell half-lives with increasing burial depth in the shallow-water carbonate lagoon of Rib reef, central Great Barrier Reef, Australia. The top 20 cm of sediment contain a distinct, essentially modern assemblage. Shells recovered at depths form 25 to 125 cm range in age from modern to 4,000 yrs old. They are age-homogeneous and significantly older than the surface layer. Taxon age distributions within layers indicate that the top 125 cm of lagoonal sediment is thoroughly mixed on a sub-century scale. The age distributions and shell half-lives of four taxa: *Ethalia*, *Natica*, *Tellina* and *Turbo* are found to be largely distinct. Shell half-lives do not coincide with any single morphological characteristic thought to infer greater durability, but they are related to a combined taphonomic score. These results illustrate the importance of bioturbation in tropical sedimentary environments, indicate that age estimates in this depositional setting are sensitive to specimen choice, and quantify a taxon-dependent bias in shell longevity and death assemblage formation.

## 1-9

**Coral Community Change Over A Cyclone Disturbance Gradient During The Quaternary in The Solomon Islands**

**Brian BECK*[1]**, Sean CONNOLLY[2], John PANDOLFI[1]

[1]ARC Centre of Excellence for Coral Reef Studies, University of Queensland, Brisbane, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, James Cook Univeristy, Townsville, Australia

Cyclones have a demonstrable impact on the short-term (<100 years) dynamics of coral communities, but we do not yet have a clear picture of the effects that such disturbances have on coral community dynamics over longer time scales (>100,000 years). It has been proposed that higher sea surface temperatures associated with projected changes in global climate might generate higher intensity storms with greater frequencies than in the recent past, and that these changes might adversely affect coral reefs. During the Pleistocene of the South Pacific, sea surface temperatures were higher than current temperatures. In this study, we investigated the effects of cyclones on coral communities over long time scales in the Solomon Islands. The Solomons have extensive raised reefs from the Pleistocene to the recent, and there has been a marked spatial gradient in cyclone frequency during this period; these characteristics allow an in depth look at how long-term community change is influenced by cyclone frequency. Taxonomic composition and diversity of coral communities were surveyed at several sites across a cyclone gradient, incorporating multiple levels of cyclone frequency and multiple stratigraphic ages, using a hierarchical sampling design. Coral diversity and growth form was examined over varying cyclone frequencies from the warm Pleistocene seas to the comparatively cooler seas of the Holocene. We found differences in the coral communities across cyclone gradients attributable to varying cyclone frequencies. These differences not only illustrate variation in community structure across a cyclone gradient within the same stratigraphic age, but also show how communities in similar cyclone frequency change with sea surface temperature change over time. These results are relevant in understanding how coral communities can change as sea surface temperatures and cyclone intensity varies.

## 1-10

**Reef slope failure in the northeastern corner of Male`, Maldives**

**Mahmood RIYAZ*[1]**, Kyung-Ho PARK[1]

[1]School of Engineering Technology, Asian Institute of Technology, Pathum Thani, Thailand

This study deals with the investigation of the reef slope failure occurred in the northeastern corner of Male`, Maldives on the 6th of February 2002. Malé is the capital of the Maldives with an area of 1.5m2 and a population of 130,000. Failed slope area was mapped and systematically investigated. Radiocarbon dates of rock samples from various depths were obtained. Aerial photograph and satellite image of Male reef 1969-2007 were compared to observe changes in the reef edge . The investigation shows that the reef-flat, cap-rock, consists of 2~3m thick slightly cemented coral rock and rubble, and beneath the cap-rock lays a 4~6m thick weakly cemented, highly erodible mixture of coral sand and coral rubble. Further down 10~30m deep the slope of 30o steep is built up by loose gravel and sand. The failure movement might have occurred during one single event and the rock mass was sliding 'en-block' which finally disintegrated into individual blocks in the block field. Radiocarbon dating of rock samples shows that the oldest is 8200 years at 20m depth, while the youngest is 6510 years at top reef, which indicates that with the rapid vertical reef growth the horizontal progression of reef played a more vital role in reef formation than the vertical growth. Aerial photographs and satellite images show four more reef failure areas on the northern side and concentrated in the areas of heavy weight and continuous vibration generation works. Due to the reef failure, the capping rock layer was removed and subsequently the weakly cemented highly erodible layer is exposed to further erosion. The eroded parts are expected to fall into atoll lagoon and cause further retreat of the reef edge. Proper remedial actions must be suggested for the overall stability and ground bearing capacity of the island.

## 1-11

**A 1500 Year Holocene Caribbean Climate Archive From The Blue Hole, Lighthouse Reef, Belize**

**Eberhard GISCHLER*[1]**, Eugene SHINN[2], Wolfgang OSCHMANN[1], Jens FIEBIG[1], Noreen BUSTER[3]

[1]Geosciences/Geography, Johann Wolfgang Goethe University, Frankfurt am Main, Germany, [2]College of Marine Science, University of South Florida, St. Petersburg, FL, [3]Florida Integrated Science Center, ETI Professionals Inc., St. Petersburg, FL

Aspects of historical climate change are becoming increasingly important in reef research. Common reefal climate archives include skeletons of corals and shells of mollusks among others. Pleistocene sinkholes in reefal limestone also have great potential as archives of climate data because they may act as sediment traps. Sediment cores (up to 6 m in length) from the bottom of the Blue Hole, a 125 m deep Pleistocene sinkhole located in the Lighthouse Reef Atoll, Belize, consist of undisturbed, annually layered biogenic carbonate muds and silts with intercalated coarser grained storm beds. Sedimentation-rate is 2.5 mm/yr on average, and the cores span the past 1500 yrs. Oxygen isotopes provide a late Holocene climate proxy: a high-resolution $\delta^{18}O$ time series traces the Medieval Warm Period, the Little Ice Age, and the subsequent temperature rise. Carbon isotopes ($\delta^{13}C$) decrease upcore and show the impacts of the decline of the Maya culture and the Suess Effect. Time series analyses of $\delta^{18}O$ and $\delta^{13}C$ reveal 88, 60, 52, and 32 year cyclicities, and suggest solar forcing. Storm event beds are most common during AD 650-850, AD 1000, AD 1200-1300, and AD 1450-1550. Major storm beds are rare during the past 500 years BP.

Holocene thickness in the Blue Hole is estimated to >20 m of annually layered sediment, given the average sedimentation rate of 2.5 mm/yr and the early Holocene marine inundation of the Lighthouse Reef lagoon. Because the Blue Hole probably formed not only during the previous but during several Pleistocene sea-level lowstands, we expect that similar, laminated sediments of previous Pleistocene highstands are present below the Holocene package. We plan to investigate this late Quaternary climate archive in a future larger scale core study.

## 1-12

**Environmental Factors Controlling Community Structure, Morphology And Linear Extension Of Mid-Holocene Reef Corals From Cañada Honda, Southwestern, Dominican Republic**

**David CUEVAS*[1]**, Clark SHERMAN[1], Wilson RAMIREZ[2], Dennis HUBBARD[3]

[1]Marine Sciences, University of Puerto Rico at Mayaguez, Lajas, Puerto Rico, [2]Geology, University of Puerto Rico at Mayaguez, Mayaguez, Puerto Rico, [3]Geology, Oberlin College, Oberlin, OH

The Mid-Holocene Cañada Honda (CH) fossil reef, located in southwestern Dominican Republic, provides a unique opportunity to examine a well-preserved fossil coral reef that thrived in a high-sedimentation environment between 9.0 to 5.0 ky ago. Growth rates of fossil Montastraea faveolata and Siderastrea siderea were determined in order to make comparisons with growth rate data of these same species from modern coral reefs. Also, assessments of coral species abundance and distribution, morphology, age, as well as reef sediment composition were completed in order to determine the paleoenvironment of reef accretion.

The CH reef is characterized by the high abundance of sediment-tolerant coral species and their tendency to form almost monospecific stands. Individual colonies have a propensity to grow as encrusting, dome-shaped, platy-like forms and colonies of Montastraea faveolata commonly contain bands of sediment incorporated within their skeletons. Calibrated radiocarbon ages of fossil corals range from 9,256±137 to 6,737±94.5 BP. Correlation of radiocarbon ages with well-established Holocene sea-level curves indicates that most corals on this reef developed at depths greater than 15m. Growth rates in CH varied from 0.09-0.44 cm/yr and are relatively low compared with growth rates from modern reef sites, suggesting reduced light penetration caused by either coral growth at great depths and/or under conditions of high turbidity. Reef sediment is characterized by more than 85% carbonate material. A significant portion of the carbonate is allochtonous and was derived from nearby Neogene limestones.

Our investigations indicate that the CH reef persisted for at least 3,000 years under conditions of high sedimentation. The reef was able to survive under these conditions because of the high carbonate content of incoming terrigenous sediment that would have allowed better light penetration and that storms probably occurred sporadically providing intervening low-sedimentation periods during which reef corals could respond and grow back, "keeping-up" with sedimentation.

## 1-13

**Unusual Serpulid/Tufa Bioherms Cap Corals of a Mid-Holocene Fringing Reef, Dominican Republic: Paleoenvironmental and Climatic Controls**

**H. Allen CURRAN*[1]**, Kelsey WINSOR[1], Lisa GREER[2], Bosiljka GLUMAC[1]

[1]Geology, Smith College, Northampton, MA, [2]Geology, Washington & Lee University, Lexington, VA

Meter-scale mid-Holocene serpulid/tufa bioherms in the form of mounds and terraces cap corals of the exposed fringing reef bordering much of the Enriquillo Valley, Dominican Republic. Composition of these unusual bioherms resembles that of two other localities described in the literature: Miocene mounds of the Paratethys Basin of Ukraine/Poland and Late Triassic deposits in the western Tethys of Italy. Rarity of such bioherms and their similarities indicate that their formation was the result of convergence of specific environmental conditions. In each case, restricted waters of less-than-normal marine salinity reduced ecological competition and favored opportunistic serpulid aggregation, as well as concentrated calcium carbonate for tufa precipitation. In the Enriquillo Valley, limited hard substrate, wave action, calcium carbonate-rich spring waters entering at the surface of ancient Lago Enriquillo, and periods of lake-level stability also contributed to bioherm formation. These contributing factors were a result of larger-scale climatic conditions characteristic of the mid-Holocene Caribbean, as well as local geological constraints. Around 5 ka, slowed sea-level rise, increased precipitation and resultant fluvial sedimentation owing to northward migration of the Intertropical Convergence Zone (ITCZ), and possible regional tectonic uplift restricted the mouth of the ancient Enriquillo seaway. This caused the demise of the Enriquillo fringing coral reef, and later the dead coral colonies commonly served as substrate for development of serpulid/tufa bioherms. Repeated changes in Lago Enriquillo water level and salinity created conditions that supported not only bioherm formation, but also diverse molluscan and ostracode faunas found within many bioherms. In late Holocene time, drier conditions prevailed as the ITCZ moved southward and water levels of Lago Enriquillo receded, exposing this spectacular fringing reef-serpulid/tufa mound and terrace complex.

## 1-14

**Is Acropora Cervicornis A Canary in The Global Warming Coal Mine? Lessons From The Mid-Holocene Dominican Republic**

**Lisa GREER*[1]**, Julia JACKSON[2], H. Allen CURRAN[3], Tom GUILDERSON[4], William P. PATTERSON[5], Lida TENEVA[6], Elizabeth RHEA[7], Jenny SHULTIS[8]

[1]Geology, Washington and Lee University, Lexington, VA, [2]University of Texas-Austin, Austin, TX, [3]Smith College, Northampton, MA, [4]Lawrence Livermore National Laboratory, Livermore, CA, [5]University of Saskatchewan, Saskatoon, SK, Canada, [6]Lamont-Doherty Earth Observatory, Palisades, NY, [7]Washington and Lee University, Lexington, VA, [8]RCHS, Lexington, VA

The recent, well-documented decline of *Acropora cervicornis* throughout the wider Caribbean region has been cause for considerable alarm, with the decline interpreted as a warning of greater coral reef devastation in the future. Elevated sea-surface temperatures, white band disease, anthropogenic stress, and storm activity have all been cited as potential causes for the decline. In order to understand the optimal conditions and threshold environmental range for *A. cervicornis* growth, an extensive mid-Holocene fringing reef located in the Dominican Republic was examined for evidence of paleoenvironmental variability during *A. cervicornis* dominance over a >3000 year period. Over 50 radiocarbon and 234U/230Th dates from an 11 m vertical exposure of *A. cervicornis* indicate continual accumulation between ~9.5 to ~7.3 ka with only minor reversals (mixing events). The species continued to thrive at the site until at least ~5.8 ka. This time range was marked by increasing regional sea-surface temperature to a mid-Holocene thermal maximum (HTM), a time comparable to, if not warmer than, present. δ13C and δ18O data from the fossil *A. cervicornis* specimens indicate high-magnitude changes in precipitation during reef formation with no resulting break in coral accumulation. Taphonomy and morphology data suggest the species thrived under high sediment stress, variable bioerosion, and differential exposure to wave activity. High-resolution δ13C and δ18O data from modern *A. cervicornis* growing at comparable depths off Barbados (2007 collections) show stable isotope 'signatures' most similar to corals that grew at the height of the HTM. *A. cervicornis* from the Dominican Holocene can be characterized as a relatively hardy survivor during highly variable environmental conditions. The data and inferences derived from this study indicate that the cause for recent *A. cervicornis* decline is not strictly due to rising sea surface temperature.

## 1-15

**The Emperor Has No Coral—An Inconvenient Truth?**

**Eugene SHINN*[1]**, Barbara LIDZ[2]

[1]College of Marine Science, University of South Florida, St. Petersburg, FL, [2]U. S. Geological Survey, St. Petersburg, FL

The Emperor Has No Coral—An Inconvenient Truth?

High-resolution subbottom profiling, reef drilling, and mapping of benthic habitats along the Florida Keys reef track demonstrate that moribund non-accreting coral reefs outnumber live accreting reefs about 100 to 1, based on reef-tract area. Sub-circular patch reefs restricted mainly to turbid nearshore areas in the lower Keys compose the majority of living/accreting reefs. Linear offshore shelf-edge areas are not accreting, and Holocene coral accumulation during the past 6 ka is generally less than 2 m thick. The thickest accretions consist mainly of coral spurs rooted directly on a Pleistocene unconformity at the platform margin. Less than 2% of Florida reefs have kept pace with the rise in Holocene sea level and are generally located shoreward of the platform margin. Such coral growth, or lack thereof, presents a paradox. Growth rates of all common coral reef species, especially the rapidly growing acroporids, should have kept pace with the well-documented rise in sea level over the past 6 ka. Why did so few reefs keep pace or accrete to present sea level? That Holocene coral growth has experienced setbacks before has been confirmed by 14C ages of fossil Acropora cervicornis fragments that are so common in backreef sands. Carbon-14 data reveal two 500-year periods of non-growth centered on 4.5 ka and 3 ka. The present period of rapid coral demise has spanned only about 30 years. Thus, past periods of non-growth indicate times of environmental crises that predated modern human invasion of the Florida Keys. These observations challenge the highly popular notion that the present declines in Florida, and elsewhere, are anthropogenic in origin.

## 1-16

**New Ideas About Caribbean Coral-Reef Development: A View From Ye Shoulders Of Giants**

**Dennis HUBBARD*[1]**

[1]Geology, Oberlin College, Oberlin, OH

Three cores from Lang Bank described at the 1977 ISRS Meeting set the direction of the coral-reef discussion for the next three decades. A perceived lag in reef initiation led to ideas about "inimical bank waters" and their control on reef building. High accretion rates reported for many Caribbean sites led us to ask why reefs capable of outpacing even the most rapid sea-level rise could be left behind. A possible gap in accretion on Lang Bank at 8,000 CalBP raised interesting possibilities. Dirty water flowing off the newly flooded bank or a sudden jump in sea level provided solutions to Schlager's "paradox". Combined with assurances that reef accretion should mirror coral growth, we developed our prevailing models. More recent studies suggest that some of the foundational ideas upon which these paradigms are built may warrant reexamination. Closer analyses of Caribbean cores reveal little variation in accretion rates down the forereef. New Lang Bank cores show that *A. palmata* reefs not only continued to build, but thrived across the "reef gap" that was attributed to "inimical bottom waters" in Miami and later to a jump in sea level. This was verified at other Caribbean/Atlantic sites. Reef building can be generally characterized as transgressive between 11,000 and 7,000 CalBP due to a steady but rapid sea-level rise, and regressive thereafter, as it slowed below ca. 4m/ky. Superimposed on this pattern are two enigmatic lapses in *Acropora,* starting at ca. 6,000 and 3,000 CalBP, well after sea level rise had slowed relative to reef accretion. Paradoxically, these events created gaps in the Caribbean *Acropora* assemblage that were not associated with earlier, documented SL jumps. The presentations at the 1977 Miami meeting were a watershed for valuable thought, and the return to Fort Lauderdale provides a fitting opportunity to take the next step.

## 1-17

**Holocene Reef Development At The Flower Garden Banks: Recent Surprises**

**William PRECHT*[1]**, Ken DESLARZES[2], Emma HICKERSON[3], G.P. SCHMAHL[3], James SINCLAIR[4], Richard ARONSON[5]

[1]Applied Coastal and Environmental Services, Battelle Memorial Institute, Miami Lakes, FL, [2]Marine Sciences, Geo-Marine Inc., Plano, TX, [3]Flower Garden Banks National Marine Sanctuary, NOAA, Galveston, TX, [4]Gulf of Mexico Region, Minerals Management Service, New Orleans, LA, [5]Marine Sciences, Dauphin Island Sea Lab, Dauphin Island, AL

The first living colonies of *Acropora palmata* were discovered on the Flower Garden Banks (FGB) in 2003 and 2005. Those discoveries, coupled with a known history of bank flooding since the last glacial maximum, led us to predict that *Acropora*-dominated reefs underlie and form the structural foundation of the living reef community at the FGB. In June 2006, while scuba diving on the southeast corner of the East FGB, we examined an open cave at 21 m depth, which exposed a 3-m vertical section of the reef subsurface just below the living community. Within that exposure we discovered large branches and trunks of *A. palmata* (>1 m in height) in growth position. Radiocarbon dating of a branch from a colony at the top of the section yielded a date of 6330 ± 60 14Cyr (radiocarbon years before 1950), corresponding to a calibrated age of 6780 calbp. Follow-up surveys in June 2007 revealed an *A. palmata* dominated under story dating between 10-6 ky on both banks. The discovery of fossil *A. palmata* has profound implications for understanding the history of reef development at the FGB. The banks supported a shallow, warm-water, reef-coral assemblage up until ~6000 years ago. This community lagged behind rapidly rising sea level in the middle Holocene. As sea temperatures cooled in the late Holocene the reef was capped by a eurythermal deeper-water assemblage dominated by massive corals, which persists to this day. During our 2007 surveys we also found the first fossils of *Acropora cervicornis* on the East FGB. This species appears to have persisted (and flourished) until the Little Ice Age in deeper water on the flanks of the Bank. Follow-up studies are proposed to document and explain the turn-on and turn-off mechanisms for *Acropora* reef development on these isolated reef complexes.

## 1-18

**Response Of *acropora* To Warm Climates; Lessons From The Geological Past**

**Clare WHITE*[1,2]**, Brian ROSEN[3], Dan BOSENCE[1]

[1]Earth Sciences, Royal Holloway University of London, Egham, Surrey, United Kingdom, [2]Palaeontology, Natural History Museum, London, United Kingdom, [3]Zoology, Natural History Museum, London, United Kingdom

Predictions about the future responses of modern coral reefs to global climatic change lack data from the deeper past. The geological record offers a storehouse of information which documents how reef coral palaeodistributions have been highly sensitive to climate change, modulated by the availability of suitable habitats. The geological record of one individual taxon, *Acropora*, illustrates how an important reef coral genus has responded to climate change, and additionally tectonics, through its Cenozoic history.

We have reconstructed *Acropora's* changing spatio-temporal distribution using museum specimens, literature reviews and databases, and plotted the data on a time-series of palaeogeographic maps and on 'Boucotgrams'. Unlike *Acropora's* widespread low-latitude distribution today, with its centre of diversity in the Indo-West Pacific, this coral was absent from this region in the Paleogene to early Neogene, but was common in Europe. Here we highlight (1) latitudinal changes in distribution in response to major climatic trends, and (2) the relatively late arrival of *Acropora* in the Indo-West Pacific, apparently in response to tectonically-driven rearrangement of Tethyan and Indo-Pacific seaways and land-masses around the end of the Paleogene. Focusing on a particular section of this record, the high palaeolatitude (48°N) occurrences in the Middle-Late Eocene (~48-33Ma) of southern England and northern France, we use taphonomic and geochemical analyses to reconstruct the palaeoenvironmental setting. This confirms that *Acropora* existed in tropical-like climatic conditions in Northwest Europe during the Eocene. This individual coral genus's latitudinal expansion, compared with modern distributions, illustrates "coral creep" as a response to the hot greenhouse setting of the early Cenozoic, and periods of extreme climatic warming of the Eocene, with sea-surface temperatures and ρCO2 higher than present. Hence this work shows how the geological record can provide information to complement predictions on the fate of modern coral reef genera with respect to climate change.

## 1-19

**Abrupt Drowning And Cooling 8.2-8.4 Ka Observed In A 0.8-M Diameter And 24-M Long Core Through A Hawaiian Coral Reef, Oahu, USA**

**Eric GROSSMAN*[1]**, Jody WEBSTER[2], Christina RAVELO[3], Jim BARRY[4], Stewart FALLON[5], Yael SAGY[1], Bruce RICHMOND[1], Mike TORRESAN[6], David CLAGUE[7]

[1]Coastal and Marine Geology Program, US Geological Survey, Santa Cruz, CA, [2]School of Earth and Environmental Sciences, James Cook University, Townsville, Australia, [3]Ocean Sciences Department, University of California, Santa Cruz, Santa Cruz, CA, [4]Sea Engineering, Inc., Honolulu, HI, [5]Research School of Earth Sciences, Australian National University, Canberra, Australia, [6]Coastal and Marine Geology Program, US Geological Survey, Menlo Park, CA, [7]Monterey Bay Aquarium Research Institute, Moss Landing, CA

Sediment collected in a 0.8 m diameter, 24 m long core at 18 m depth offshore of Pearl Harbor provide a geologic archive of reef response to the Holocene sea-level transgression on the island of Oahu, Hawaii. CHIRP seismic reflection data reveal a 5-15 m thick reef complex buried below the seafloor within a paleostream valley. An olivine-rich, black sand and rounded basalt cobble unit, inferred as an early Holocene delta occurs at the base of the core overlying a soil-stained, caliche-encrusted limestone dated to 124 ka. 14-C ages indicate a shallow-water coral reef assemblage comprised of encrusting *P. lobata* and branching coralline algae *P. gardineri* accreted until 8.4 ka, then was abruptly replaced by a mono-specific *P. compressa* reef between 8.4 and 8.2 ka and added 10 m to the reef by about 4.9 ka. Approximately, 4.5 m of carbonate-rich sand buried this reef complex and comprises the modern seafloor substrate at the site. The abrupt transition from shallow-water to deeper-water coral assemblages at 8.4-8.2 ka is coincident with rapid climate change observed in other reefs, lakes, and sedimentary records throughout the tropics. Reconstruction of paleowater depths at this transition indicates a rapid rise in sea level of at least 3 m, helping to explain preservation of a drowned erosional notch surrounding many shorelines of Hawaii at -24 m like a bath-tub ring. High-resolution measurements of δ18O and Sr/Ca ratios from three *P. compressa* corals 8.7-8.3 ka, indicate cooler surface water temperatures than today and a slight cooling during this event. Abrupt sea-level rise of several meters could explain the transition in coral community structure, the dominance of mono-specific *P. compressa*, and colder sea surface temperatures.

## 1-20

**Evidence of rapid sea-level rise from reef backstepping during the Last Interglacial highstand.**

**Paul BLANCHON*[1]**

[1]Inst. of Marine Sciences & Limnology, National University of Mexico, Cancun, Mexico

Investigation of reef development during the Last Interglaciation has focussed on flights of exhumed terraces in neotectonic terranes. But the timing of climatic cycles has taken precedence over reef response to sea-level change. As a result, we have no clear picture of highstand reef development nor sea-level changes that controlled it.

Here I report the facies architecture of a highstand reef from the NE Yucatan Peninsula that affords significant insight into reef development and sea-level behaviour during the Last Interglaciation. Excavations for a theme park (Xcaret) have exposed two coeval reef-tracts that are offset and at different elevations. The lower-tract crops-out along the coast and the crest facies reaches an elevation of +3.0 m amsl. One hundred metres in-land, the crest of the upper-tract reaches +5.7 m amsl. Crests in both tracts were true breakwaters, each consisting of large colonies of A. palmata and boulder-sized fragments with a suite of surf-zone encrusters. Lower-tract frameworks are occluded by crustose corallines, but those in the upper-tract remained open and were infiltrated by abraded sand during forced shoreface regression. This infiltration is clear evidence that the upper-tract was younger than the lower, and that reef backstepping occurred.

Backstepping was not related to shelf flooding to the north, because that had occurred during lower-tract development. But backstepping was accompanied by increased sediment flux that shifted lagoonal biofacies to a sediment-tolerant assemblage. Similar changes occurred in the strand-plain sequence to the north, but here it involved a switch from low- to high-energy coastal sedimentation. This energy switch and reef backstepping are both consistent with a +3 m sea-level jump at the end of the Last-Interglacial highstand.

## 1-21

**Coral Reef Development Along The Windward Platform Margin Since The Plio-Pleistocene: Southern Exuma Cays, Bahamas (Dedicated To Robert F. Dill, 1927-2004)**

**Paul J. HEARTY*[1]**, Donald F. MCNEILL[2]

[1]GeoQuEST Research Centre, School of Earth and Environmental Sciences, University of Wollongong, Australia (paulh@uow.edu.au), Wollongong, NSW, Australia, [2]MGG-RSMAS, University of Miami, Miami, FL

The surface geology and two 33-m cores from the Exmas contain 11 limestone-paleosol "couplets" (C1 to C11 – older to younger), revealing depositional cycles extending back to the Plio-Pleistocene. The couplets are composed of marine limestone and *terra rossa* paleosol-karst exposure surfaces. Amino acid racemization and paleomagnetic reversals provide a functional chronostratigraphy for the couplets. At the base of the more bankward Core #2, couplets C1 to C3 contain the coral *Stylophora*, generally associated with the Plio-Pleistocene. The overlying C4 complex consists of several meters of dense reddish paleosols and thin intertidal lenses. These C4 paleosols bracket the Brunhes-Matayuma boundary (0.78 Ma; MIS 19?), and collectively equate with the "Big Red Soil" recognized on Bermuda and Hawaii. This interval comprises a succession of much lower highstands reflecting more interglacial continental ice from 0.5-1.0 Ma. Younger units C5 through C11 were deposited 0.5 Ma to present, and record lesser-known middle Pleistocene sea levels (MIS 15 @ -15 m, MIS 13 @ -7 m, and MIS 7 @ -18 m). In contrast, important interglacials during MIS 11 and 9 left little sedimentary evidence, probably due to deep flooding of the platform, and the dearth of early Pleistocene antecedent topography on which to "hang" deposits.

Sea-level cycles across the Plio-Pleistocene show a general progression from reefal components to predominantly non-skeletal sands. Plio-Pleistocene highstands (3.0? - 1.0 Ma) are obscured below present sea level by subsidence. Corals are a key component of units C2, C3, C4 in Core #2 and unit C6 in the more seaward Core #1. A long period of subaerial exposure from 1.0-0.5 Ma was followed by several important mid to late Pleistocene highstand carbonate accretionary events during which the platform margin extended to its present position over 3 km eastward.

## 1-22

**Mid-Brunhes First High Amplitude Transgression(s): Platform Top and Siliciclastic Shelf Contemporaneous Re-flooding Recorded on the Slopes of Great Bahama Bank and Central Belize Barrier Reef**

**Andre DROXLER*[1]**, Brooke E. CARSON[2]

[1]Earth Science, Rice University, Houston, TX, [2]Shallow Marine Stratigraphy Team, Chevron Energy Technology Company, Houston, TX

Last 5 My ice volume variations recorded in stacked, globally distributed, benthic oxygen records, clearly show a systematic late Pliocene and early Pleistocene ice volume increase following an early Pliocene sea level highstand estimated to be 15 to 25 m higher than current sea level. This systematic ocean base-level fall was terminated by two mid Brunhes high amplitude transgressions at the MIS 16-15 and MIS 12-11 glacial to interglacial deglaciations. On the slopes of Great Bahama Bank (GBB) and central Belize Barrier Reef (BBR), a series of five-six stacked and contemporaneous highstand wedges are observed and identified as being linked to the MIS 15-13, 11, 9, 7, 5, and 1 interglacial stages. Each package is defined by high concentration and/or mass accumulation rates of bank derived fine aragonite sediment bounded by intervening late glacial intervals enriched in Mg calcite cement corresponding to marine hardgrounds on the western margin of GBB and intraclasts-rich levels with coarser grain concentrations on the slope off the BBR. The highstand wedges are overlying an interval in both areas with lower bank-derived aragonite concentration and/or mass accumulation rates, higher pelagic calcite concentrations, and overall lower sedimentation rates. Based upon these observations, the two mid-Brunhes major MIS 16-15 and MIS 12-11transgressions correspond to first a partial and then a full re-flooding of GBB top and the siliciclastic fluvial plain established at lower base level during the late Pliocene and early Pleistocene sea level regression in Belize. These two mid-Brunhes transgressions have most likely triggered also the onset of modern barrier reefs along the Queensland and New Caledonia margins, the Florida Keys, and globally modern atolls. The MIS 12-11 transgression marks the first time interglacial atmospheric CO2 concentrations reached late Brunhes values between 280-295 ppm which has been suggested to be related to the global neritic carbonate re-establishment.

## 1-23

**Late Miocene To Recent Coral Community Dynamics in The Gulf Of California**

**Ramón LÓPEZ-PÉREZ*[1]**

[1]Instituto de Recursos, Universidad del Mar, Puerto Angel, Mexico

Hermatypic coral studies in the Gulf of California have focused mainly on the distribution, abundance, ecology, and biogeography of modern species, but relatively few of these works have studied fossil corals. Miocene to Pleistocene coral communities in the Gulf of California were targeted in order to assemble a detailed geologic and taxonomic framework for already known and new coral bearing units. In general, coral bearing units are small and represent single spatio-temporal growth episodes ranging in age between late Miocene to late Pleistocene. Identification of recently collected specimens reveals that previously recognized coral species probably represent ~ 50 % of the Gulf of California fauna. Cluster analysis, multidimensional scaling and analysis of similarity of presence/absence and relative abundance data demonstrated that Gulf of California coral reef assemblages experienced larger temporal differences in species composition and relative abundance than expected by chance. Coral species originated and were added to the species pool during late Miocene-early Pliocene and Pleistocene. Gulf of California assemblages consisted of locally originated Caribbean-like species between late Miocene and late Pliocene when extinction peaked at the Plio-Pleistocene transition. During the Pliocene assemblages consisted of a mix of extinct and living species co-occurring within and among localities, but immediately after the demise of pre-turnover taxa, living Indo-Pacific immigrant species dramatically increase in number and relative abundance ruling out ecological replacement as the key factor in pre-turnover species extinction. The turnover is unique in that pre-turnover species origination resulted from the formation of the Gulf of California, and instead of reducing species richness, the extinction event triggered the long-distance colonization of species. More data and better resolved age dates are necessary to understand the cause of faunal turnover, and the relative importance of biological and environmental factors in the faunal change.

## 1-24

**Caribbean Coral Reef Types From A Mixed Siliciclastic-Carbonate Setting: Miocene-Pliocene Of The Dominican Republic**

**Donald MCNEILL*[1]**, James KLAUS[2], Ann BUDD[3]

[1]Marine Geology & Geophysics, Rosenstiel School - University of Miami, Miami, FL, [2]Department of Geological Sciences, University of Miami, Coral Gables, FL, [3]Department of Geoscience, University of Iowa, Iowa City, IA

Geologic models of ancient Caribbean coral reefs that occur in predominantly siliciclastic settings have developed and diversified since the 3rd Coral Reef Symposium in 1977. The objective of this study is to characterize the styles of reef development in these mixed siliciclastic-carbonate settings from the exceptionally well-preserved fossil reef deposits in the Cibao Basin, northern Dominican Republic. Building on the mixing classification of Mount (1984), we recognize three main styles (geometries) of "in situ" carbonate (reef) deposition within siliciclastics. These include: 1) late Miocene stacked patch reefs-these reefs occur as isolated patches approximately 20-30 m thick and 300-400 m wide as part of a shallow clinoformal shelf. Lowered sea level and initial transgression provided conditions favorable to patch reef initiation and development; 2) late Miocene-early Pliocene bedded coral in mud-these reefs occur as either thick beds (3-6 m thick) of mud with abundant coral and coral fragments scattered throughout, or as distinct, cyclic coral beds (0.5-1 m thick) interbedded with mud beds (<1 m thick). Corals beds first accumulated as part of a prograding shelf clinothem (corals in mud matrix), and then under progressive deepening water depths during transgression (cyclic coral-mud beds); and 3) early Pliocene-late Pliocene reefal clinothems-coral-rich clinothems with well-defined foresets and topsets associated with transgression and highstand. Siliciclastic muds in these reefal clinothems occur predominantly as a matrix component and as occasional <1-m thick distinct beds. Our findings suggest that these reef geometries are closely tied to the prevailing sea level regime. On a Caribbean-wide basis, many Miocene to middle Pleistocene mixed-system reefs assessed have similar geometrical configurations that mimic these "in situ" mixing types.

**Paleoecology Of Mio-Pliocene Free-Living Corals in The Northern Dominican Republic And Neogene Evolutionary Patterns Of The Caribbean Region**

**James KLAUS*[1]**, Ann BUDD[2], Donald MCNEILL[3], Scott ISHMAN[4]

[1]Department of Geological Sciences, University of Miami, Coral Gables, FL, [2]Department of Geoscience, University of Iowa, Iowa City, IA, [3]Rosenstiel School of Marine and Atmospheric Science, Marine Geology and Geophysics, University of Miami, Miami, FL, [4]Department of Geology, Southern Illinois University, Carbondale, IL

Periods of accelerated origination and extinction have played a disproportionate role in shaping the structure and ecology of Cenozoic coral communities in the Caribbean region. This is most evident in the late Pliocene faunal turnover event in which approximately 80% of Mio-Pliocene corals became extinct and more than 60% of species now living in the region originated. Free-living meandroid corals were particularly hard hit during this interval; only two species survive in the region today, *Manicina areolata* and *Meandrina brasiliensis*. Diversity patterns based on new collections and compiled records from the Caribbean region show that the diversity of free-living meandroid corals increased throughout the Neogene. Two free-living meandroid corals are known from the early Miocene, and diversity accumulated slowly during the middle and late Miocene. During the latest Miocene and early Pliocene diversity more than doubled from 11 to 24 species, before falling abruptly between 2 and 1 Ma from 22 late Pliocene species to the two modern species. To better understand the ecology of free-living corals as well as their pattern of abrupt origination proceeding catastrophic extinction, over 1,300 free-living coral specimens were collected from 21 localities in the northern Dominican Republic ranging in age from 6.2 to 3.4 million years ago. Preliminary results integrating benthic foraminifera and other environmental indicators suggest that unlike modern *M. areolata* and *M. brasiliensis*, which are typically associated with very shallow water grassflat environments, free-living corals of the northern Dominican Republic had a much wider habitat range from grassflats to deeper forereef environments. Given these environmental constraints we evaluate the patterns of origination and extinction within the context of Neogene paleoceanographic events.

## 1-26

**Cenozoic Photic Reef And Carbonate-Ramp Habitats: A New Look Using Paleoceanographic Evidence**

**Pamela HALLOCK*[1]**, Luis POMAR[2]

[1]College of Marine Science, University of South Florida, St Petersburg, FL, [2]Departament de Ciencies de la Terra, Universitat de les Illes Balears, Palma de Mallorca, Spain

Understanding biological and geochemical processes associated with modern coral reefs is essential to interpreting fossil reefs and carbonate sedimentation. Yet recognizing the limitations of uniformitarianism is equally crucial. Cenozoic carbonate-producing ecosystems emerged from the remnants of Cretaceous biotas, evolving in the warm alkaline oceans of a Greenhouse world, then modifying in response to developing Icehouse conditions. The latter included stronger latitudinal and bathymetric temperature gradients, declining carbon dioxide concentrations in the atmosphere and declining calcium concentrations and alkalinity in the oceans. Paleocene-Eocene photic-dependent carbonates tended to be dominated by calcitic coralline red algae and larger benthic foraminifers (LBF), with aragonitic corals and calcareous green algae more restricted temporally and spatially. Conceptual models suggest that episodic changes in ocean circulation and thermocline stratification that accompanied high latitude cooling during the Cenozoic provided impetus for turnover in chlorozoan biotas. For example, comparison of Eocene through Miocene paleotemperature data on surface to thermocline gradients with the history of LBF assemblages indicates that the latter were most diverse and productive when deeper waters were warmest and gradients were weakest. Higher extinction rates corresponded with times when surface to thermocline gradients increased. In contrast, zooxanthellate corals, while relatively diverse in the Eocene, were restricted as reef builders. As Icehouse conditions emerged, aragonite production by corals and calcareous algae became more widespread, with a setback in the early and middle Miocene when coralline algae again dominated. Moreover, the proliferation of reef-building coralline algal taxa into shallow-water habitats in the late Miocene paralleled the emergence of shallow-water corals and new clades of zooxanthellae, indicating co-evolution of these critical reef taxa. Implications of these observations support the hypothesis that deeper photic-zone (30-100 m) carbonate systems will survive anthropogenically driven changes in ocean chemistry.

## 1-27

**Photosymbiosis is a Major Theme in the History of Mesozoic to Cenozoic Reef Systems**

**George STANLEY JR.*[1]**, B. VAN DE SCHOOTBRUGGE[2]

[1]Paleontology Center, University of Montana, Missoula, MT, [2]Institute of Geosciences, Goethe University Frankfurt, Frankfurt, Germany

Symbiotic partnerships between photosynthetic dinoflagellates (zooxanthellae) and corals provide enhanced nutrition and calcification and partly explain the reef phenomenon. They elucidate the success and failure of many reefs today and in the geologic past. Here, we review the geologic record of 240 million years of hexacoral evolution. It reveals the origin of the group from soft-bodied anemone-like ancestors of the Paleozoic, the first appearance of calcifying scleractinians in Middle Triassic time, and their subsequent rise to dominance. Middle Triassic corals did not diversify or move into roles of reef building until Late Triassic time, some 14 ma later. The co-occurrence of these early scleractinians with the earliest dinoflagellates represented by suessiacean cysts and their subsequent expansion into roles of reef-building in the Late Triassic, coincides in space and time. Furthermore, stable isotopes confirm photosymbiosis in Late Triassic (Carnian-Norian) corals. We propose that this was the time of their coevolution with zooxanthellae. The end-Triassic mass extinction disrupted this ecological relationship, and a lengthy Early Jurassic post-extinction recovery led to coral reefs of the Middle to Late Jurassic. The Cretaceous records high diversity among corals but a subordinate role relative to rudistid bivalves. This is best explained by differential responses to climate warming, especially during the Late Cretaceous greenhouse time. The end-Cretaceous mass extinction removed the last surviving rudistids. Zooxanthellate corals later resumed dominance on Paleogene reefs. The coral expansion among Neogene reefs led to ecologically modern coral reefs. The resilience of Miocene-Holocene corals in the face of major oceanographic and climate change is explained by the ecological flexibility of the zooxanthellae-coral symbiosis, especially the ability of corals to switch clades of zooxanthellae in response to environmental change. This may not have been the case in older zooxanthellate corals.

## 1-28

**Early Cenozoic Recovery Of Caribbean Reef Coral Communities**

**Thomas STEMANN*[1]**

[1]Department of Geography and Geology, The University of the West indies, Kingston, Jamaica

There is some controversy over the extent to which the K-T extinctions affected coral reef communities at global and regional scales. Recent collections from latest Maastrichtian successions indicate that diverse Caribbean reef coral communities persisted up until the very end of the Cretaceous. The fate of this reef fauna is unclear, however, because early Cenozoic Caribbean reef corals are so poorly known.

The present study examines new collections of early Cenozoic corals from Jamaica that provide insight into Caribbean reef communities immediately following the K-T boundary. Extensive sampling from sites in three units in the Paleocene of eastern Jamaica yields an average of <5 coral species from each sample site and total sampled richness that is lower than at any time in the Cenozoic or late Cretaceous. Less than 5% of the Jamaican Cretaceous corals range into the Cenozoic. Coral abundance and richness rises slightly in the early - middle Eocene but remains low compared to typical levels found in later Cenozoic units. Endemism is high in the early Cenozoic but ecologic diversity is low with communities composed only of thin branching colonies or small solitary corals. Dense accumulations of reef corals including large massive, branched and plate shaped colonies do not become common until the late middle Eocene.

The results here are similar to reports from throughout the Caribbean and suggest significant coral species turnover regionally at the K-T boundary followed by a protracted recovery time. This contrasts markedly with the rich faunas recorded from Europe, Africa and Asia in the Paleocene –middle Eocene. After significant extinctions at the end of the Cretaceous, coral community recovery is slow in the Caribbean and faunas in this region remain species poor and ecologically simple considerably longer than elsewhere in the world.

## 1-29

**Evolution Of The Coral Reef Ecosystem Under A Jurassic Perspective: From Mixotrophy Towards Superoligotrophy**

**Reinhold LEINFELDER*[1]**, Ulrich STRUCK[1]

[1]Museum of Natural History Berlin, Berlin, Germany

Scleractinian reefs rapidly evolved and expanded during the Jurassic. Many Jurassic scleractinian calical structures were nearly as complex as in modern star or brain corals and thus appear modern. However, a much greater variety of coral reef types and coral reef settings existed than today. During the Jurassic, the adaptation to nutrient restriction by photosymbiosis was only one of several adaptational strategies, including other adaptational pathways to terrigeneous and even brackish settings. Many mid and late Jurassic corals exhibit good indicators for the existence of photosymbionts (integrated calical growth shapes, depth zonation, typical growth banding with high and low-density bands and, in some examples, non-linear clustering of C/O stable isotopes). Nevertheless, even density-banded corals and most pure coral reefs mostly grew under terrigeneous influence. On the other hand, typical low-nutrient settings such as the 1000 km broad Arabian shelf or intra-tethydian platforms were dominated by stromatoporoid sponges with or without scleractinian corals. Taxa distribution shows provincialism of many stromatoporoids. Jurassic coral taxa distribution data are not yet statistically significant but also point to differences between near-coast and intra-ocean platforms, indicative of splitting of the coral reef window into a mesotrophic to mildly oligotrophic subset dominated by mixotrophic corals and a superoligotrophic subset dominated by stromatoporoids together with strongly photosymbiontic corals.

The Bahia Almirante coral reefs from Panama may represent a “Jurassic-type” modern example for mixotrophy of corals. These reefs are adapted to both reduced salinity and to sewage-related, slightly elevated nutrients. This is shown by the C/O and N stable isotope pattern, signalling that certain phototrophic coral species consumed considerable proportions of zooplankton and, possibly, even terrigeneous plant debris.

## 1-30

**$Co_2$-Concentrating Mechanisms, Harmful Blooms, And Late Devonian Reef Extinction 375 Million Years Ago**

**Robert RIDING*[1]**

[1]Earth and Planetary Sciences, University of Tennessee, Knoxville, Knoxville, TN

Late Devonian Mass Extinction caused the largest change experienced by reef biotas in the entire Phanerozoic. Stromatoporoid-coral communities that had dominated metazoan reefs since the mid-Ordovician disappeared. In the extinction’s immediate aftermath they were replaced by microbial reefs. By the Early Mississippian rimmed shelves had given way to ramps dominated by carbonate mud mounds. The Mass Extinction selectively eliminated shallow marine organisms, including acritarch phytoplankton as well as reef biotas.

Here I suggest induction of $CO_2$-concentrating mechanisms (CCMs) in marine phytoplankton as a factor in Late Devonian Mass Extinction. CCMs help maintain photosynthesis when levels of dissolved inorganic carbon are low. Late Devonian decline in atmospheric $CO_2$ level was sufficient to induce CCMs in aquatic algae and cyanobacteria. This is likely to have had several geologically recognizable effects. Firstly, CCMs promote phytoplankton productivity and bloom conditions by helping to overcome carbon limitation. Productivity enhances organic matter burial, and harmful blooms kill shallow-water reefs and pelagic organisms. Secondly, conditions favouring photosynthetic groups with effective CCMs can promote community restructuring, resulting in extinction of some phytoplankton groups. Thirdly, cyanobacterial CCMs can stimulate calcification, both in the water column as ‘whitings’, and in benthic mats as *in situ* microbial carbonates.

The Late Devonian marine realm underwent marked changes in addition to Mass Extinction. Organic carbon-rich sediments, microbial carbonates, and carbonate mud mounds significantly increased in abundance. These, at first sight disparate, developments all have potential links to CCM induction in phytoplankton. Harmful blooms could have contributed to extinction of shallow marine metazoans, and increased phytoplankton productivity would have increased organic carbon-rich sediments. Phytoplankton community restructuring could have led to acritarch extinction. Combination of increased microbial productivity and enhanced cyanobacterial calcification would have promoted both microbial carbonate and carbonate mud mound development. These possibilities do not exclude the likely involvement of additional causative factors.

## 2-1

**Hopping Hotspots: Global Shifts in Marine Biodiversity**

**Willem RENEMA*[1]**, David BELLWOOD[2], John PANDOLFI[3], JC BRAGA[4], K BROMFIELD[3], R HALL[5], KG JOHNSON[6], Peter LUNT[7], CP MEYER[8], L MCMONAGLE[9], RJ MORLEY[10], A. O'DEA[11], John TODD[6], FP WESSELINGH[12], MEJ WILSON[13]

[1]Nationaal Natuurhistorisch Museum Naturalis, Leiden, Netherlands, [2]2School of Marine and Tropical Biology, JCU, Townsville, Australia, [3]Centre for Marine Studies, Brisbane, Australia, [4]Universidad de Granada, Granada, Spain, [5]SE Asia Research Group, London, United Kingdom, [6]NHM, London, United Kingdom, [7]Murphy Oil, Kuala Lumpur, Malaysia, [8]UC Berkeley, San Francisco, CA, [9]University of Durham, Durham, United Kingdom, [10]Palynova, Cambridge, United Kingdom, [11]STRI, Panama, Panama, [12]NNM Naturalis, Leiden, Netherlands, [13]Curtin University, Perth, Australia

Hotspots are a dominant feature of global biodiversity patterns. Many coral reef groups reach their greatest diversity here . Recent fossil and molecular evidence reveal at least three marine biodiversity hotspots during the past 50 million years. These hotspots have moved across almost half the globe, with their timing and locations coinciding with major tectonic events. The birth and death of successive hotspots highlights the link between environmental change and biodiversity patterns. The molecular and fossil evidence from a range of taxa rejects the notion of Pleistocene origins of the modern marine IAA fauna and flora, and point to the presence of a high diversity of extinct and extant lineages from at least the Miocene onwards. Fossil data further establish that the IAA has not always been the centre of marine biodiversity, but that earlier 'centers of marine biodiversity' occurred in at least two additional places during the past 50 Million years. The future of modern biodiversity hotspots can now be placed in a historical context.

## 2-2

**Evolution Of Carbonate Factories For The Last 100 Million Years Based On Investigations On Shallow-Water Carbonate Deposits On Seamounts in The Northwestern Pacific Ocean**

**Yasufumi IRYU*[1]**, Hideko TAKAYANAGI[1], Tsutomu YAMADA[1], Motoyoshi ODA[1], Tokiyuki SATO[2], Shun CHIYONOBU[1], Akira NISHIMURA[3], Tsutomu NAKAZAWA[3], Satoshi SHIOKAWA[4]

[1]Institute of Geology and Paleontology, Graduate School of Science, Tohoku University, Sendai, Japan, [2]Institute of Applied Earth Sciences, Faculty of Engineering and Resource Science, Akita University, Akita, Japan, [3]AIST (Advanced Industrial Science and Technology ), Tsukuba, Japan, [4]JOGMEC (Japan Oil, Gas and Metals National Corporation), Kawasaki, Japan

Evolution of carbonate factories for the last 100 million years were delineated by investigating lithology, biotic and abiotic compositions, and depositional ages of shallow-water carbonates collected from 25 sites on 21 seamounts in 6 sea areas (Amami Plateau, Daito Ridge, Oki-Daito Ridge, Urdaneta Plateau, Kyushu-Palau Ridge, and Ogasawara Plateau) in the northwestern Pacific Ocean. There are significant differences among Cretaceous, Eocene, and Oligocene to Pleistocene shallow-water carbonates. The shallow-water carbonate deposits examined in the present study can be roughly divided into three types based on their composition: Cretaceous, Eocene, and Oligocene to Pleistocene types. The Cretaceous type is characterized by abundant occurrence of rudists, microencrusters, solenoporacean algae, and calcareous sponges. The Eocene type includes shallow-water carbonates predominated by *Halimeda* or nummulitid and discocyclinid larger foraminifers. The Oligocene to Pleistocene type includes abundant corals, nongeniculate and geniculate coralline algae, and miogypsinid, lepidocyclinid, and amphisteginid larger foraminifers. These indicate that carbonate factories comparable with modern coral reefs were initiated in the Oligocene, which corresponds to the timing of the transition from Calcite II to Aragonite III. These changes in the composition of the shallow-water carbonates from the Cretaceous onward is in accordance with those shown in previous studies, which have been considered to reflect a shift in seawater chemistry. Our investigation shows that large amounts of shallow-water carbonates were deposited on the seamounts in Oligocene, although it was a relatively cool period in the Cenozoic. Whereas Early Miocene shallow-water carbonates are limited, although it was a relatively warm period. These suggest that deposition of shallow-water carbonates on seamounts in the northwestern Pacific Ocean was not necessarily controlled by climatic conditions but related with volcanism and tectonics which served foundations for reef/carbonate-platform formation.

## 2-3

**The Influence Of Global And Regional Environmental Change On Cenozoic Carbonates in The Indo-Pacific**

**Moyra WILSON*[1]**

[1]Applied Geology, Curtin University, Perth, Australia

The SE Asian carbonate record allows insight into the poorly known response of equatorial marine systems to regional and global change during the Cenozoic. There is a marked change from larger benthic foraminifera to corals as dominant producers in SE Asia around the Oligo-Miocene boundary. The Early Miocene acme of coral development in SE Asia lags Oligocene coral development in the Caribbean and Mediterranean. Changing $CO_2$, oceanography, nutrient input and precipitation patterns are inferred to be the main cause of this lag. Moderate, although falling level of $CO_2$, $Ca^{2+}$ and Ca\Mg when combined with the reduced salinities in humid equatorial waters probably all contributed to reduced aragonite saturation hindering reefal development compared with warm more arid regions during the Oligocene. By the Early Miocene, atmospheric $CO_2$ levels had fallen to pre-industrial levels. Although this was a relative arid phase globally, in SE Asia palynological evidence indicates the Early Miocene experienced everwet, but more stable and less seasonal conditions than periods before or after. Tectonic convergence truncated deep through-flow of cool nutrient-rich currents from the Pacific to Indian Ocean around the beginning of the Miocene, thereby directly, and perhaps indirectly (though less seasonal conditions) reducing nutrients. Aragonitic reefs were promoted where previously the waters had been more acidic, more mesotrophic, more turbid, and less aragonite saturated. Extensive reefal development resulted in an order of magnitude expansion of shallow carbonate areas through buildups and pinnacle reefs in the Early Miocene. Tectonics via increased habitat partitioning and reducing distances to other coral-rich regions may also have contributed to enhanced reefal development. Implications of this study are that with anthropogenically induced environmental changes it will be the diverse reefs of SE Asia that are likely to be amongst the first and hardest hit as oceanic aragonite saturation decreases and terrestrial nutrient runoff increases.

## 2-4

**Scleractinian Coral Diversity in The Oligocene Of Sabah, Borneo.**

**Laura MCMONAGLE*[1,2]**

[1]Earth Sciences, Durham University, Durham, United Kingdom, [2]Palaeontology, Natural History Museum, London, London, United Kingdom

The modern Indo-West Pacific is characterised by the highest global species diversity in reef-corals and associated biota, but the origins and long-term history of this important biodiversity hotspot remain poorly studied, with most work on the corals derived from collections made in the late 19th Century. The extant biota may have appeared during a diversification event that took place slightly before the Oligocene-Miocene boundary, marked by a change in the style of carbonate deposition in the region. This may also have coincided with a reduction in the deep-water throughflow between the Pacific and Indian Oceans and marine incursions in the area. To better constrain the timing, magnitude, and environmental context for this diversification, a previously undescribed reef-coral fauna has been documented from extensive new collections taken from Oligocene patch-reef facies in the Gomantong Formation of Sabah, Malaysia. Study of nannofossil assemblages suggests that sections range from biozone NP23 (Early Oligocene) to NP25 (Late Oligocene), with the majority falling within nannofossil zone NP24 (late Early to early Late Oligocene). This study has more than doubled the number of coral species previously known from the Oligocene of Borneo, and suggests that the apparent paucity of Paleogene corals from SE Asia could be a result of sampling bias, rather than true lack of diversity. These results show that coral diversification was already underway by the Early Oligocene, rather than occurring at the Oligocene/Miocene boundary. This would indicate that if changes in the Indonesian Throughflow caused increased diversification, then these changes occurred earlier than has so far been suggested. Alternatively it could mean that other factors controlled reef-coral diversification in the Indo-West Pacific during the Oligocene.

## 2-5

**Differential response of Southeast Asian and Caribbean reef ecosystems to global environmental change during the Oligocene/Miocene Transition**

**Kenneth JOHNSON*[1]**

[1]Palaeontology Department, Natural History Museum London, London, United Kingdom

The paleoceanographic record contains several intervals during the Cenozoic in which apparently rapid global change in the open ocean also had effects on tropical coastal marine ecosystems. One example is the Oligocene/Miocene transition (OMT) that occurred approximately 25-20 Ma. This interval is associated with the termination of a Late Oligocene warm interval by a 'snap' glaciation and development of a stable globally-cooler climate phase during the Early Miocene. These changes are contemporaneous with the initial constriction of deep water connections across the Indonesian Throughflow as Australia collided with Eurasia. A database of specimen-based occurrences of reef corals was assembled from both new and existing collections to document the history of coral diversity and the regional extent of reef development in the Caribbean and Southeast Asia during the OMT. All specimens were examined to verify taxonomic identifications and collections were placed within a consistent stratigraphic framework. During the Late Oligocene there was widespread reef building by a moderately diverse biota in the Caribbean. Both diversity and the extent of reef building had crashed by the Early Miocene in response to increased regional surface productivity. In contrast, there was little reef building and low diversity of reef builders in the Late Oligocene of SE Asia. Instead both reef-building and reef-coral diversity in the region increased during the OMT. Therefore, the effects of global change caused a decline in reef-coral diversity and reef-building in the Caribbean but an increase in reef building and radiation of reef-corals in Southeast Asia. The fact that regional biotic responses were out of phase in Southeast Asia and the Caribbean indicates that the ecological signal of global environmental change is modulated by local to regional-scale biotic and oceanographic history.

## 2-6

**Indo-Pacific Coral Growth Forms Through The Miocene To The Pliocene**

**Kate BROMFIELD*[1]**, John PANDOLFI[1]

[1]University of Queensland, Brisbane, Australia

One of the most intriguing questions for the evolution of the modern Indo-Pacific coral reef fauna is the antiquity of modern branching-dominated coral assemblages. The Miocene (21-6 Ma) of the Indo-Pacific is a period of pronounced first occurrences of reef coral species, and a complete reorganisation of coral communities has been proposed; from a Miocene fauna dominated by massive growth forms, to reef domination by corals with branching morphologies in the Pliocene. Many genera of modern reef corals (order Scleractinia), are thought to date from the early Pliocene (5.6-3.2 Ma), around 5.3 Ma. This study tested the Miocene/Pliocene growth form transition hypothesis from uplifted reefs at three sites along a longitudinal gradient: Vanua Balavu (16.9-6.7 Ma) in Fiji; New Britain (14.8-12.3 Ma) in Papua New Guinea; and Selayar (5.8-1.4 Ma) in Indonesia.

The collection includes 121 coral species, fifteen of which are new, though now extinct. The highest percentage (25%) of newly recorded, extinct species occurred in the late Pliocene (5.8-3.4 Ma) reef deposits of Selayar. Newly described extinct species from the Miocene deposits of Fiji and Papua New Guinea averages 6%. The data shows no significant change in either the relative abundance or the presence versus absence of growth forms among the three sites and times. Miocene assemblages contained 27% abundance of branching individuals and the Pliocene contained 23%. This challenges the premise that reefs underwent a transition from those dominated by massive forms to those dominated by branching forms during this period. However, our study corroborates the previously proposed model of an origination event in reefal corals in the early Pliocene.

## 2-7

**Biodiversity And Biogeography Of Mollusca During The Cenozoic: A Database Approach To The Assessment Of Spatial Patterns And Their Relationship To Global Environmental Change**

**Austin HENDY*[1]**

[1]Geology and Geophysics, Yale University, New Haven, CT

A focal point in the Phanerozoic trajectory of global biodiversity has been its apparent rapid increase since the end-Cretaceous extinction. The interval stimulates additional interest through the availability of chronologically well-constrained information on changing global paleoenvironments. This knowledge aids understanding of how the Cenozoic diversification of marine invertebrate faunas was influenced by developing global paleogeography, major tectonic shifts, and related climatic transitions.

An extensive dataset (http://paleodb.org) of fossil molluscan occurrences permits analysis of how spatial components of global biodiversity vary through the Cenozoic, specifically how faunas are partitioned biogeographically and how these biogeographic units relate to one another. On a global scale, sampling-standardized diversity appears to have increased at most only 50% over the course of the Eocene-Pleistocene, showing small drops during the Early Oligocene and a slight decline since the Middle Miocene. Nevertheless, there is remarkable stage-to-stage independence in the shape of diversity curves at the regional scale, reflecting both regionally distinct environmental controls and variable data quality, related to reduced sample size. A multivariate analysis of global biogeography reveals that provinciality has increased only slightly during this interval, peaking in the Plio-Pleistocene, although this patterns is strongly influence by spatial sampling intensity. A strengthening latitudinal gradient of diversity is observed through the Neogene, reflecting an increased in not only tropical diversity but also a decline in the richness of faunas from temperate and polar latitudes.

Fluctuations in regional endemism and biogeographic similarity between regions appear related to the opening and closing of major oceanic gateways. Nevertheless some aspects of global and regional diversity patterns reflect Cenozoic-scale climatic transitions, expressed by an Early Oligocene decline. The influence of deteriorating global climate through the Neogene appears to be offset by a steepening latitudinal diversity gradient and an associated increased late Neogene provinciality.

## 2-8

**Molluscan Biodiversity in Shallow Carbonate Platforms (Indonesia)**

**Frank WESSELINGH*[1]**

[1]Geology, Naturalis, Leiden, Netherlands

A pilot study into the spatial distribution of mollusc taxa in the shallow carbonate platform, the Spermonde Archipelago (Sulawesi, Indonesia) is presented. The very high species numbers and the unresolved taxonomical status of the far majority of these mollusc species should cripple such a documentation. However, by using taxa groups with an as low as possible taxonomic rank, very clear distribution patterns and associations are found. This study shows that molluscan associations probably are a very good tool for study of communities, facies and biodiversity in ancient carbonate platform settings as well.

## 2-9

**Escaping The Heat: Range Shifts Of Reef Coral Taxa In Coastal Western Australia**

**Benjamin GREENSTEIN*[1]**, John PANDOLFI[2]

[1]Geology, Cornell College, Mount Vernon, IA, [2]Centre for Marine Studies and Department of Earth Sciences, University of Queensland, Brisbane, Australia

One of the most critical challenges facing ecologists today is to understand the changing geographic distribution of species in response to current and predicted global warming. Coastal Western Australia is a natural laboratory in which to assess the effect of climate change on reef coral communities over a temporal scale unavailable to studies conducted solely on modern communities. Reef corals composing Late Pleistocene reef assemblages exposed at five localities along the west Australian coast were censused and the results compared to coral occurrence data published for the modern reefs offshore of each locality. The resulting comparative data set comprises modern and Late Pleistocene reef coral communities occurring over approximately 12º of latitude. This gradient includes the zone of overlap between the modern Dampierian and Flindersian Provinces.

Modern reef coral communities show a pronounced gradient in coral composition over the latitudinal range encompassed by the study, while the gradient in community composition is not as strong for Pleistocene communities. Tropical-adapted taxa contracted their ranges north since Late Pleistocene time, emplacing two biogeographic provinces in a region in which a single province had existed previously.

Beta diversity values for adjacent communities also reflect this change. Modern reefs show a distinct peak in beta diversity in the middle of the region; the peak is not matched by Pleistocene reefs. Beta diversity is correlated with distance only for comparisons between modern reefs in the north and the fossil assemblages, further supporting change in distribution of the biogeographic provinces in the study area. Coral taxa present in modern communities clearly expanded and contracted their geographic ranges in response to climate change. Those taxa that distinguish Pleistocene from modern reefs are predicted to migrate south in response to future climate change, and potentially persist in "temperature refugia" as tropical reef communities farther north decline.

## 2-10

**Ecological Dynamics Of Pleistocene Reefs During Sea-Level Lowstand**

**John PANDOLFI*[1]**, Danika TAGER[2], Jody WEBSTER[3], Don POTTS[4], Willem RENEMA[5], Juan-Carlos BRAGA[6]

[1]Cente for Marine Studies and School of Physical Sciences, University of Queensland, St. Lucia, Australia, [2]Centre for Marine Studies, University of Queensland, St. Lucia, Australia, [3]School of Earth and Environmental Sciences, James Cook University, Townsville, Australia, [4]Earth & Marine Sciences, University of California, Santa Cruz, Santa Cruz, CA, [5]Nationaal Natuur Historisch Museum, Leiden, Netherlands, [6]Estratigrafía y Paleontologia, Universidad de Granada, Granada, Spain

Reef ecosystems built during sea level rise have shown remarkable persistence in coral community structure but little is known of the ecological characteristics of reef communities during periods of low sea stands or sea level falls. We sampled the relative species abundance of coral, coralline algae and foraminifera communities from eight submerged carbonate reefs in the Huon Gulf, Papua New Guinea, that formed during sea level fall and lowstand over the past ~416 ky. We found that dissimilarity in coral species composition increased significantly with time on these reefs. However, neither coral diversity nor the taxonomic composition of foraminifera and coralline algae assemblages vary significantly over time. The taxonomic composition of coral communities from lowstand reefs was significantly different from that of highstand reefs previously reported from the nearby Huon Peninsula. We interpret the community composition and temporal dynamics of lowstand reefs as a result of shifting energy regimes in the Huon Gulf, and differences among low and highstand reefs as a result of variation between the Huon Gulf and Huon Peninsula environments. Regardless of these trends our study represents the first glimpse into the ecological dynamics of coral reefs during low sea level stands when habitable reef area was much less than present day. One major issue associated with present climate change is a possible order of magnitude reduction in coral reef habitat as low latitude reefs succumb to mortality events associated with temperature-induced bleaching events. Reduced areal extent of Pleistocene coral reefs during sea level lowstand may provide an analogue for such a future scenario.

## 2-11

**Spatial and Temporal Variations in Pleistocene Coral Assemblages in the South and Central Ryukyu Islands**

**Marc HUMBLET*[1]**, Yasufumi IRYU[1]

[1]Institute of Geology and Paleontology, Tohoku University, Sendai, Japan

In order to study spatial and temporal variations in Pleistocene coral assemblages in the South and Central Ryukyus, taxonomic composition and morphology of corals were investigated using the quadrat method in Irabu-jima (South Ryukyus), Okinawa-jima (southern Central Ryukyus), and Kikai-jima (northern Central Ryukyus). Cluster analysis was conducted to identify groups of taxa which tend to co-occur (coral associations) and groups of quadrats with similar taxonomic compositions. We recorded 40 genera and 84 species in Irabu-jima, 35 genera and 72 species in Okinawa-jima, 33 genera and 65 species in Kikai-jima. The cluster analysis produced 4 coral associations in Irabu-jima, 6 in Okinawa-jima and 4 in Kikai-jima. Some of these associations contain taxa indicating a specific depth range, while others, composed exclusively of cosmopolitan taxa, do not point to any particular reef zone. The analysis of taxonomic similarities among quadrats resulted in the segregation of 2 groups of quadrats in Irabu-jima, 5 in Okinawa-jima and 4 in Kikai-jima. In the cluster diagrams, the segregation of coral assemblages indicative of a same reef zone into distinctive groups or single branches reflects within-reef-zone variability. Upper reef-slope assemblages display a high spatial variability in taxonomic and morphological compositions over several meters to several kilometers. Conversely, middle to lower reef-slope assemblages display a low variability in taxonomic and morphological composition over meters to tens of meters. Temporal changes in Pleistocene coral assemblages within several-meter-thick sections of coral limestone reflect various types of coral successions. Transitions from one reef zone to another are likely due to sea-level fluctuations. Small-scale abiotic and/or biotic disturbances may result in successions of distinctive coral assemblages with overlapping depth ranges reflecting within-reef-zone variability.

## 2-12

**Reef Building At High Latitudes (34° N, Japan)**

**Hiroya YAMANO*[1]**, Kaoru SUGIHARA[2], Tsuyoshi WATANABE[3], Michiyo SHIMAMURA[4], Kiseong HYEONG[4]

[1]Center for Global Environmental Research, National Institute for Environmental Studies, Tsukuba, Japan, [2]Fukuoka University, Fukuoka, Japan, [3]Hokkaido University, Sapporo, Japan, [4]Korea Ocean Research & Development Institute, Ansan, Korea, Republic of

At Iki Island, Japan (33° 48' N), the world's highest-latitude coral-reef formation has been observed (Yamano et al., 2001, Coral Reefs, 20, 9-12). Following the discovery at Iki Island, we set up an international project funded by JSPS and KOSEF under the Japan-Korea Basic Scientific Cooperation Program in order to examine high-latitude corals around Japan and Korea. In the project, another reef-like mound structure over 5-m thickness was found at Tsushima Island, ca. 40 km north of Iki Island. We took two cores from the structure, which indicated that the inside of the mound was dominated by corals and mud. Similar as the coral reef at Iki Island, faviid corals, also dominant in modern coral community at Tsushima Island, were observed most frequently and abundantly throughout the cores. These characteristics are significantly different from those at tropical reefs that are dominated by acroporid corals. It is the highest latitude reef-like mound structure formed over a few thousands of years. We describe the distribution, timing of the formation and the growth rate of the mound in combination with those of the coral reef at Iki Island. We also discuss the significance of reef building at high latitudes in terms of geological reef evolution.

## 2-13

**Millennial-Scale Episodes Of Reef Accretion And Degradation Determined By U-Series Dating Of Coral Death Assemblages in Moreton Bay, Se Queensland, Australia.**

**Matt LYBOLT*[1]**, Jian-xin ZHAO[2], David NEIL[3], Yue-xing FENG[2], Ke-fu YU[2], John PANDOLFI[4]

[1]Centre for Marine Studies, University of Queensland, St. Lucia, Australia, [2]Centre for Microscopy and Microanalysis, University of Queensland, St. Lucia, Australia, [3]School of Geography Planning and Architecture, University of Queensland, St. Lucia, Australia, [4]Centre for Marine Studies / Department of Earth Sciences, University of Queensland, St. Lucia, Australia

The sub-tropical marginal reefs of Moreton Bay were characterized by diverse mid-Holocene communities that dramatically declined in the absence of major anthropogenic disturbance. We examined the nature and timing of changes in surficial coral death assemblages from Moreton Bay reefs to gain insight to the interplay of local and global changes. Corals were selected throughout the Bay across a depth range from 1 m above high tide to 5 m below low tide. Uranium-series age determinations (n=57) were made by Uranium-series thermal ionization mass spectrometry. The oldest sample was found atop *in situ* reef accretions at the highest elevation sampled, so Moreton bay reefs initiated before 6.82 ka and sea level must have reached its Holocene maximum prior to that time. Since the oldest cohort of corals was not buried by younger ones we conclude that coral accretion since 5.5 ka has been minimal. Coral accretion occurred in discrete episodes rather than continuously, and depths of accretion, corrected for palaeo-sea-level, became deeper through the Holocene. Major coral accretion episodes are 0-0.3 ka (19% of samples dated), 1.3-1.7 ka (11%), 4.3-4.7 ka (11%), and 5.5-6.8 ka or older (51%). Conspicuous episodes with no accretion are 0.4-1.1 ka and 4.7-5.5 ka. Sea-level fell from its Holocene high in a series of oscillations which coincide with episodes of accretion (stable/rising) and no accretion (falling). Greater extremes of temperature and salinity would result from a lower volume of water in the Bay, and decreased tidal volume would increase the residence time of river-discharge amplifying the sea-level-driven episodes. The hyposaline wedge associated with increased flooding since ENSO re-establishment ~3.5 ka likely forced younger accretions into deeper water. Because European colonization coincides with an episode of accretion we have an excellent opportunity to isolate historical causes of reef decline from novel anthropogenically-induced causes of decline.

## 2-14

**Holocene To Recent Foraminifera Assemblages Of Moreton Bay, Queensland, Australia: Assessing Modern And Historical Estuarine Habitats, Degradation And Foraminiferal Responses To Environmental/faunal Changes**

**Yogeeta Roshni NARAYAN*[1,2]**

[1]Earth Sciences, University of Queensland, Brisbane, Australia, [2]Centre for Marine Studies, University of Queensland, Brisbane, Australia

Moreton Bay (MB) is internationally (Ramsar), nationally (EPBC Act) and State (Marine Parks and Fisheries Habitat Reserves) recognized for its biodiversity, socio-economic and historical significance. The Bay and its large (21,220 km$^2$) catchment area are on the doorstep to Queensland fastest developing urban centre. The increasing population pressures and coastal development, coupled with the effects of climate change, have raised concerns over current conservation and management of critical habitats (i.e. seagrass meadows, fringing reefs) and biodiversity. At present, the MB Marine Park is undergoing assessment of the Bay's diverse habitats, compiling existing knowledge of the Bay's ecosystem and assessing the sustainability of ongoing activities. Investigations of the foraminiferal (foram) assemblages, which span the mid-Holocene (~6,500 years before present, ybp), through European colonization (~200 ybp) to the Recent, is timely with the above Action Plan.

The mid-Holocene was a time of climatic optimum. Coral communities flourished and were dominated by the fast-growing *Acropora* species. Since the mid-Holocene, oscillations in climate and the environment have influenced species diversity and composition. European settlement introduced anthropogenic inputs, furthering deterioration of habitats from increased sedimentation and pollution. This study aims to; 1) assess decadal changes in diversity and distribution of forams since the 1970's (Geological Survey of Queensland datasets); 2) survey assemblages from the Holocene through European colonization and correlate with concurrent coral community studies; and 3) evaluate sea-grass associated forams as a proxy for historical seagrass distribution and changes in water quality, in the last 200 years. Adequate understanding of the faunal changes, overtime, whether influenced by natural and/or anthropogenic impacts, is crucial in understanding long-term habitat degradation and providing baseline studies for future ecosystem management. Moreton Bay is an exceptional location for such a study and foraminfera play a valuable role in decadal and millennial scale investigations of biotic change in estuarine environments.

## 2-15

**Historical Collapse Of Acroporid Corals At Pelorus Reef, Inshore Great Barrier Reef**

**George ROFF*[1]**, Tara R CLARK[2], Jian-xin ZHAO[2], John M PANDOLFI[1]

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia, [2]Centre for Microscopy & Microanalysis, University of Queensland, Brisbane, Australia

Since European settlement of the Queensland coastline in the mid-18th century, extensive changes in land usage within in the Great Barrier Reef (GBR) catchment region have occurred, resulting from increases in grazing, agriculture and land clearance. Evidence is accumulating that inshore reefs of the GBR are undergoing persistent phase shifts, with losses of previously dominant acroporid communities and local removal of coral species. Despite this, considerable difficulty exists in determining the extent and magnitude of the decline, primarily due to a lack of historical data on coral communities. To address this issue, we conducted palaeoecological reconstructions of coral communities through surveys of modern coral communities in conjunction with extensive collections of in-situ surface coral rubble (death assemblages) at Pelorus Reef (central GBR). Comparisons of sites with low modern coral cover (<5%) revealed a remarkable disparity between the composition and diversity of modern coral communities and death assemblages, with substrate dominated by extensive in-situ dead acroporid rubble. High-precision U-series dating of acroporid fragments by thermal ionization mass spectrometry revealed that the majority of acroporid mortality occurred much earlier than previously assumed, following the onset of European Settlement (~1860 AD) and prior to 1950 AD. In contrast, one site with a high cover of modern dominant coral genera (Pavona & Goniopora spp.) with in-situ death assemblages showed remarkable similarity in community composition and diversity, implying temporal stability of community structure. Representative dating of corals from the death assemblage using the high precision U-series method supports this, with mortality bracketed to within the last two decades. Our results suggest a long-term decline on previously dominant acroporid corals on the inshore reefs began long before the advent of monitoring in the late 1980's.

## 2-16

**Traits Of Surficial Carbonate Sediments At Reef Islands: Implications Of Climate Change To Island Fauna.**

**Mariana FUENTES*[1]**, John DAWSON[1], Scott SMITHERS[1], Mark HAMANN[1]

[1]EES, James Cook University, Townsville, Australia

Predicted intensification of climatic processes and changes in sea level and sea surface temperature, can greatly impact reef islands, their reef platform and its resident reef building organisms. This can affect island morphology and structure, as well as production, transportation and delivery of sediment to islands, potentially distressing island stability and the fauna that depend on them. Assessing the overall vulnerability and impacts of climate change to different reef islands is complex. Not only does an islands' sensitivity vary greatly, but also islands can be affected by a variety of natural and climate change stressors, which may also differ on temporal and spatial scales. Thus it is necessary to collect site specific data. Sedimentological traits from seven islands in the Great Barrier Reef (GBR) were characterised, these islands are not only the most important rookeries for the nGBR green turtle population, but also significant rookeries for seabirds. Sedimentological traits were used to investigate how these islands may adjust as impacts of climate change affect surrounding reefs and reef organisms. Differences in carbonate sediment structure were identified between each rookery. Distinctions include: i) highest concentrations of foraminifera at Bramble Cay; ii) significantly more molluscs at Milman Island, Sandbank 7 and Sandbank 8, iii) significantly more coral and coralline algae at Raine Island and Sandbank 8; and iv) Dauer Island being the only island with terrigenous material. Dissimilarities indicate that each site may be affected differently by climate change progresses. Affects of climate change to the islands studied here, which are used as nesting grounds for sea turtles and birds, will affect their populations through loss off eggs and reduction of optimal nesting habitat. This paper highlights the importance of understanding reef island vulnerability to climate change for an effective management of fauna that dependent on them.

## 3-1

### A Tropical Surface Water Calcium Carbonate Saturation History For The Late Pleistocene

**Bradley OPDYKE*[1]**, Stephen EGGINS[2]

[1]Research School of Earth Science, Australian National University, Canberra ACT, Australia, [2]Research School of Earth Science, The Australian National University, Canberra ACT, Australia

Knowing the history of the surface water calcium carbonate saturation in tropical waters is critical to understanding the dangers posed to Coral Reefs by declining saturation states in the future due to increased CO2 inputs from anthropogenic sources. We present here the first paleo- saturation record from the Indo-Pacific Warm pool region, specifically the Timor Sea, south of the Island of Timor. Near surface dwelling (0-50m) planktonic foraminifera Globigerinoides ruber were measured for the time intervals spanning 6-63Ka and 130 to 110Ka. Mg and Sr were measured employing a novel approach; laser ablation inductively coupled mass spectrometer (LA-ICP-MS). This method allows for precise determination of the chemistry of foraminifera tests in depth profiles of their trace element content. A stratigraphy was constructed from the MD 982167 core.

From each layer sampled, fifteen to twenty G. ruber per were analysed and the average value determined. In was discovered that Sr/Ca increases in Globigerinoides ruber at higher surface water saturation state and Sr/Ca peaks at 1.6 (mmol/mol) in the Early Holocene (8ka) and dips to 1.5 (mmol/mol) during colder time intervals back to Stage 5e (128ka) where the ratios return to Holocene values. Coral Reefs, also respond strongly to changes in temperature and calcium carbonate saturation state. Combining these data with paleotemperature data will allow us to predict where and how vigorously coral reef communities would have thrived going back in time. These paleo-saturaturation data not only allow us to put future changes of the chemistry of the surface sea water in context but will allow more accurate modeling of coral growth histories around the globe.

## 3-2

### The Darwin Point: a Conceptual and Historical Review

**Richard GRIGG*[1]**

[1]Oceanography, University of Hawaii, Honolulu, HI

The term “Darwin Point” is defined as the geographic or depth limit (threshold) beyond which vertical growth or net accretion of reef building corals is zero or negative. Consequently, coral reefs and/or atolls that exist at, below or beyond a Darwin Point threshold would be expected to undergo drowning under conditions of constant sea level. If present ecological conditions were to change, for example, due to a rise or fall in sea-level, or geophysical uplift or subsidence, or due to Global Climate Change, the geographic location or depth limit of a Darwin Point would correspondedly change. In this paper, the history of the Darwin Point concept is reviewed and several examples are given of reefs and atolls that have drowned having exceeded a Darwin Point threshold. Such appears to be the case for: 1) guyots beyond the northwestern end of the Hawaiian Archipelago, 2) atolls that crossed equatorial latitudes due to plate movement in the Pacific during Cretaceous Time, and 3) many drowned reefs extant at the present time; a result of sea-level rise since the last Glacial Maximum 21,000 years ago.

## 3-3

### Declining Coral Calcification in Massive Porites in Two Nearshore Regions Of The Northern Great Barrier Reef

**Timothy F COOPER*[1,2]**, Glenn DE'ATH[1], Katharina E FABRICIUS[1], Janice M LOUGH[1]

[1]Australian Institute of Marine Science, Townsville, Australia, [2]School of Marine and Tropical Biology, James Cook University, Townsvile, Australia

Temporal and spatial variation in skeletal density, linear extension and calcification rate in massive *Porites* from two nearshore regions of the northern Great Barrier Reef (GBR) were examined over a 16 year study period. Calcification rates declined by approximately 21% in the two regions, which are ~450 km apart. This is a function primarily of a decrease in linear extension (~16%) with a smaller decline in skeletal density (~6%). These changes were linear over time. Averaged across colonies, skeletal density declined over time from 1.32 g $cm^{-3}$ (SE = 0.017) in 1988 to 1.25 g $cm^{-3}$ (0.013) in 2003, equivalent to 0.36% $yr^{-1}$ (0.13). Annual extension declined from 1.52 cm $yr^{-1}$ (0.035) to 1.28 cm $yr^{-1}$ (0.026), equivalent to 1.02% $yr^{-1}$ (0.39). Calcification rates (the product of skeletal density and annual extension) declined from 1.96 g $cm^{-2}$ $yr^{-1}$ (0.049) to 1.59 g $cm^{-2}$ $yr^{-1}$ (0.041), equivalent to 1.29% $yr^{-1}$ (0.30). Mean annual seawater temperatures had no effect on skeletal density but a modal effect on annual extension and calcification with maxima at ~26.7ºC. There were minor differences in the growth parameters between regions. A decline in coral calcification of this magnitude with increasing seawater temperatures is unprecedented in recent centuries based on analysis of growth records from long cores of massive *Porites*. This talk will discuss the decline in calcification within the context of known environmental controls on coral growth. Although these findings are consistent with studies of the synergistic effect of elevated seawater temperatures and *p*CO2 on coral calcification, further data on seawater chemistry of the GBR are required to better understand the links between environmental change and effects on coral growth.

## 3-4

### Declining Calcification Rates Of Bermudan Brain Corals Over The Past 50 Years

**Anne COHEN*[1]**, Nicholas JACHOWKSI[2], Ross JONES[3], Struan SMITH[4]

[1]Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, [2]Stanford University, Palo Alto, CA, [3]Bermuda Institute of Ocean Sciences, St Georges, Bermuda, [4]Georgia State University, Atlanta, GA

We used ScionImage (freeware) to quantify greyscale variability in CT-scan images of twenty colonies of the brain coral Diploria labyrinthiformis, collected live from four sites on Bermuda. The average colony age, determined from counts of annual high/low density couplets, was 45 years, spanning the time period 1959-2004 AD. A 233 yr-old colony, collected live, was also included in the analysis. 6cm-wide slabs, cut from the center of each colony were scanned alongside a series of Ca-hydroxyapatite standards of known density. The CT images (*.dicom) were manipulated to expose the appropriate (upward) orientation and slice thickness, in our case, 7.5 mm. Using ScionImage, greyscale variability (x-ray intensity) was quantified along a minimum of 10 tracks down the length of each colony, averaged and converted to density (g/cm3) using the standard calibration. Skeletal extension rates were determined from the distance (in mm) between successive high-density bands, and calcification rates as the product of extension and density.

Our data indicate that skeletal extension and calcification rates of D. labyrinthiformis across the reef declined significantly between 1959 and 2004. On average, annual skeletal extension rates decreased by more than 25%, from 4.2 (±0.2) mm/yr to 3.1 (±0.1) mm/yr, while annual calcification rates decreased by 25%, from ~4 g/cm2/yr to 3 g/cm2/yr. The last 45 years of growth of the 233-yr old coral reproduced these trends, indicating that ontogenetic processes were not a factor in the trends observed in the younger colonies. That documented changes in oceanographic conditions in the subtropical North Atlantic over the past 50 years - including rising SST, changes in circulation patterns linked to NAO and decreased saturation state of the surface ocean - may have individually or collectively influenced the skeletal growth of Bermuda’s corals, will be discussed.

## 3-5

**Reduced Skeletal Growth in The Scleractinian Coral *porites Lutea* From Southern Thailand – A Consequence Of Climate Change Over The Last Two Decades?**

**Jani TANZIL*[1]**, Barbara BROWN[1], Sandy TUDHOPE[2], Hansa CHANSANG[3]

[1]Newcastle University, Newcastle, United Kingdom, [2]Edinburgh University, Edinburgh, United Kingdom, [3]Phuket Marine Biological Centre, Phuket, Thailand

Of the few studies that have examined in situ coral growth responses to climate change, none have done so in equatorial waters already subject to relatively high temperatures (average >27°C). Comparison of coral growth of *Porites lutea*, a major reef building coral in the eastern Andaman Sea, sampled from eight sites on an inshore-offshore gradient around Phuket, South Thailand were made at two time periods (Dec 1984–Nov 1986 and Dec 2003–Nov 2005). Results revealed a significant decrease in coral calcification (~11%) and linear extension rates (~18%) in recent samples compared with those collected in the mid 1980s, while skeletal bulk density remained unchanged. Over this period, sea temperatures (SST) in the area have risen at a rate of 0.16°C per decade (current temperature range 28-30°C) and regression analyses of coral growth data, acquired at regular intervals over the period 1984-2005, suggest a link between rising temperature and reduced linear extension. These results contrast with earlier studies from reefs at higher latitudes, where sea temperatures are lower (average ~25–27°C) and where a positive relationship between linear extension and SST was found. The apparent sensitivity of linear extension in *P. lutea* to increased SST suggests that corals in the Andaman Sea may already be subjected to temperatures beyond their thermal optimum for calcification.

## 3-6

**Simulation And Observations Of Reef Corals Calcification Associated To Ocean Warming**

**Juan P. CARRICART-GANIVET*[1]**, Aimé RODRÍGUEZ-ROMÁN[2], Susana ENRÍQUEZ[2], Guillermo HORTA-PUGA[3], José D. CARRIQUIRY-BELTRÁN[4], Roberto IGLESIAS-PRIETO[2]

[1]El Colegio de la Frontera Sur, Unidad Chetumal, Chetumal, Q. Roo, Mexico, [2]Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología, UNAM, Cancún, Q. Roo, Mexico, [3]Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, Tlalnepantla, Edo. México, Mexico, [4]División de Geociencias Ambientales, Instituto de Investigaciones Oceanológicas, UABC, Ensenada, Baja California, Mexico

Reefs achieve positive carbonate balances when the calcification rates of reef-building corals and other organisms are larger that the rates of physical and biological erosion. We characterize the effects of short-term exposures to different temperatures on the calcification rates of the scleractinian Montastraea faveolata. Calculations of calcification rates under a modeled sea surface temperature (SST) future scenario for the West Atlantic indicate that increases in SST will result in significant reductions in coral calcification. Analyses of historical variations in calcification rates during the last 20 years of M. faveolata, growing in Veracruz, southern Gulf of Mexico, and massive Porites, growing in Rib Reef, Central Great Barrier Reef, are consistent with the experimental data, indicating negative associations with temperature. We found evidence that the local ocean warming trends have already resulted in significant reductions in calcification of both species, indicating that increases in temperature alone would severely compromise the abilities of corals to form and maintain reefs and their services. The observed reductions in calcification rates of M. faveolata in Veracruz are larger that the predictions of the physiological model, suggesting that other forcing processes in addition to increases in SST are responsible for the observed reductions in calcification. We show that relative small changes in the optical properties of the seawater are sufficient to explain the observations.

## 3-7

**Raman Spectroscopy of the Initial Mineral Phase of Coral Skeleton**

**Brent CONSTANTZ*[1]**

[1]Geological and Environmental Sciences, Stanford University, Stanford, CA

Recent studies suggest that the mineralogy of the scleractinian skeleton has been phenotypically plastic over geological time, varying with ocean chemistry, and dominated by physiochemical processes, under low levels of biologic control. Isotopic studies have demonstrated that scleractinian corals strongly fractionate carbon and oxygen from seawater during their skeletal mineralization process. Skeletal chemical studies have shown that that minor and trace elements in coral skeleton are also out of equilibrium with seawater. Furthermore, the degree of chemical fractionation is highly variable throughout the skeleton, but relatively consistent within particular anatomical structures. Mineralization of the scleractinian exoskeleton is initiated at centers of calcification located at the calcioblast ectodermal interface with the skeleton. The initial mineral phase of scleractinian coral skeletal has long been assumed to be the orthorhombic polymorph of calcium carbonate, aragonite. Past work has included crystallographic analysis using selected area electron diffraction of ion thinned specimens and various microanalytical chemical analyses that have shown that the initial mineral phase at the centers of calcification differs chemically and crystallographically from the aragonite fiber bundles comprising most of the skeleton. Due to the intricate microstructural anatomy, most studies have failed to properly locate the centers of calcification, and sample preparation artifacts have further complicated our understanding of the crystallographic character of the centers of calcification. Raman microscopy allows live coral skeleton to be observed in the physiologic state, controlling for both microstructure as well as mitigating sampling artifacts. Results to date indicate that highly unstable amorphous phases predominate the initial phase of mineralization in the scleractinian centers of calcification. These findings help explain why the crystallographic identity of the centers of calcification have to date been unclear. The new information from Raman microscopy has important implications with respect to the potential impact of ocean acidification on scleractinian skeletal formation.

## 3-8

**Daily Banding in Coral Septa.**

**Ian SANDEMAN*[1]**

[1]Biology, Trent Umiversity, Peterborough, ON, Canada

Fine banding has previously been described from different regions of coral skeletons. If present in septa, daily growth increments have the potential to provide, with a non-destructive technique, a record of recent growth. Sections of septa from eight coral species were mounted on glass microslides with thermo-setting resin, ground (10-20μ), and polished on both sides. With phase contrast optics, alternating light and dark laminations are apparent in the crystalline areas of the sections. The separation of the bands varied from 2-4μ in *Agaricia agaricites* to 10-15μ in *Meandrina meandrites*. In some septa (e.g. *M. meandrites*) banding is robust, in others banding was confined to the central part of the septa (e.g. *Montastrea*) and in some species banding was not seen at all (e.g. *Acropora cervicornis*). Small *A. agaricites* colonies were held in seawater with alizarin R (20mg/L) for two periods separated by four days. Two lines of stained skeleton confirmed that the laminations are diurnal and indicated that the darker bands (optically denser) are formed during the day and the lighter bands at night. Ground polished and stained sections of fixed *A. agaricites* mounted in epoxy resin showed, particularly in areas with high calcification, many bunches of spherical bodies (Golgi apparatus?) in the calicoblastic layers. These bodies are probably involved in the secretion of the organic matrix. A model of calcification is presented which suggests a mechanism by which the banding is produced. Following Vago et al (1997) physical extension takes place in the evening as a new layer of matrix is secreted and during the day calcium carbonate is deposited in the new matrix layer. In large septa the series of laminations representing several months of growth can be followed.

## 3-9

**Are Abiogenic Processes Sufficient To Describe The Formation Of Coral Skeletons?**

**Michael HOLCOMB*[1]**, Anne COHEN[1], Rinat GABITOV[2], Jeffrey HUTTER[3]

[1]Woods Hole Oceanographic Inst., Woods Hole, MA, [2]California Institute of Technology, Pasadena, CA, [3]The University of Western Ontario, London, ON, Canada

Microscale analytical and imaging techniques were used to compare morphological features and chemical signatures of abiogenic aragonites precipitated experimentally from seawater, and the aragonitic skeleton of scleractinian corals. Morphological features shared between abiogenic aragonites and coral aragonites include the spherulitic morphologies of the crystal bundles, the occurrence of granular crystals in nucleation regions and fibrous crystals in growth regions, and the presence of fine bands, composed of granular crystals, oriented perpendicular to the direction of fibrous growth. Fusiform-shaped crystals, morphologically similar to those found in corals, were also produced experimentally. Under experimental conditions, crystal morphology appears linked to saturation state. Only under highly supersaturated conditions were fusiform crystals formed (Omega > 25), at slightly lower saturation states, granular crystals with morphologies similar to those found in the centers of calcification of coral skeletons were produced. Aragonite fibers with morphologies similar to those found in fiber bundles in coral skeletons were produced at moderate supersaturation states, while at the lowest saturation states (Omega 4-5), the aragonite fibers formed were much broader and more widely separated than those found in coral skeletons. In both abiogenic aragonites and coral skeletons, the granular nucleation regions are characterized by high Mg/Ca ratios compared with the fibrous growth regions. Further, abiogenic aragonite and coral skeletons show similar patterns of fluoresence when stained with acridine orange, with regions of granular crystals appearing to fluoresce more intensely. These data suggest that many features of coral skeletons are also characteristic of abiogenic aragonite grown from seawater. Based on these observations, cycles in the saturation state of the coral's calcifying fluid is proposed as a plausible explanation for many of the features observed in coral skeletons.

## 3-10

**Coral Skeletons: From Calcium Carbonate To Intricate Architecture**

**Elizabeth GLADFELTER*[1]**

[1]Marine Policy Center, Woods Hole Oceanographic Institution, Woods Hole, MA

A coral skeleton is an intricate architecture of aragonite forming a scaffolding to support the soft tissues of the animal. Our understanding of the inorganic and organic chemical processes that result in these beautiful and elaborate structures is still evolving. This is due partly to the fact that many studies of coral skeletal growth and calcification are complicated by the role of zooxanthellae in enhancing rates of calcification. Another important aspect is reconciling the physical (and temporal) scales at which various studies were conducted. Some recent papers have emphasized the role of an organic matrix in coral calcification, while others have focused on the essentially inorganic processes of crystal nucleation and growth that can be produced without organic input. A model of biomineralization must address the chemistry operative between collections of inorganic atoms (e.g., nucleation centers; crystal faces) and the multiple arrays of molecules arranged across organic surfaces (e.g., insoluble proteins, lipid membranes). We need to understand how molecular-based interactions are integrated into higher levels of organization and dynamics.

In this work, I examine two key elements of a biomineralization model: (1) the morphology and site of deposition and growth of the various types of crystals that compose the skeleton; and (2) the role of organic macromolecules in controlling the synthesis, construction and organization of the architecture of the skeletal form. The result is a model of biomineralization of corals that recognizes the production of the skeleton as an example of "organized-matter chemistry" involving chemical composition, synthesis and emergence of organized architectures and complex forms. This model identifies critical areas for further research to better understand this crucial process, i.e. coral calcification, in coral reefs.

## 3-11

**Large-Scale, In-Situ Measurements Of Coral Reef Community Metabolism Using An Integrated Control Volume**

**Cameron MCDONALD*[1]**, Robert DUNBAR[2], Jeffrey KOSEFF[1], Stephen MONISMITH[1], Ove HOEGH-GULDBERG[3], Matthew REIDENBACH[4]

[1]Civil and Environmental Engineering, Stanford University, Stanford, CA, [2]Geological and Environmental Sciences, Stanford University, Stanford, CA, [3]Center for Marine Studies, University of Queensland, Brisbane, Australia, [4]Department of Environmental Sciences, University of Virginia, Charlottesville, VA

In-situ, ecosystem level measurements of inorganic carbon fluxes in a coral reef are critical to understanding how the reef functions and interacts with the surrounding ocean; furthermore, ongoing monitoring of this community metabolism will be essential to assess the effects of ocean acidification on reef health and net community calcification. Traditional methods for measuring reef metabolism have had some limitations, for example: constraints on location and flow regime, and lack of spatial or temporal resolution. The method presented here utilizes a combined Eulerian-Lagrangian control volume approach wherein carbon system parameters are monitored in place, under natural flow conditions. This enables calculation of inorganic carbon fluxes on time-scales of minutes to hours in almost any reef sub-environment. A 20m by 40m Integrated Control Volume was deployed on the fore-reef of Heron Island, Australia (23° 27' S, 151° 55' E) as a test of the ICV concept. Carbon system parameters were measured continuously by pumping seawater from 6 different depths at each corner of the volume. To measure seawater fluxes the hydrodynamic field within and adjacent to the ICV was characterized using 1200 kHz Acoustic Doppler Current Profilers, high frequency (25 Hz) Acoustic Doppler Velocimeters, and thermistor strings set at different distances down the reef slope. We measured clear gradients in carbon system parameters, vertically, along the flow, and also in the cross-shelf direction. The most consistent gradients were in the cross-shelf direction with total dissolved inorganic carbon (TDIC or ΣCO2) lower inshore during the day and higher at night. Night sampling showed a strong respiration signal. Periods of both net dissolution, and net calcification were observed. The ICV method shows promise for in-situ monitoring of reef metabolism; potentially allowing determination of the relationships between primary production, carbonate saturation state, and rates of net community calcification.

## 3-12

**Studies Of The Calcfication Rate Of The Coral Reefs in The Bight Of Parguera, Puerto Rico**

**Chris LANGDON*[1]**, Jorge CORREDOR[2]

[1]MBF, Uni. of Miami/ RSMAS, Miami, FL, [2]Dept. of Marine Science, Uni. of Puerto Rico, Mayaguez, Puerto Rico

Little is known about how the calcification of coral reefs in the Caribbean has changed in the past 30 years. As a result it is not possible to document how this important reef-building and sustaining process has changed in response to increasing sedimentation, eutrophication, outbreaks of disease, collapse of Diadema, overfishing, bleaching events and increasing ocean acidification. With the saturation state of the surface ocean currently declining at a rate of -0.013 to -0.025 units $y^{-1}$ we can expect a decrease in calcification of 0.4 to 0.8% $y^{-1}$. If a warming rate of 0.02 to 0.06°C $y^{-1}$ is factored in based on IPCC's low emission (B1) and higher emission (A1F1) scenarios the rate of decline could increase to 0.9 to 2.2% $y^{-1}$ and these calculations only consider the direct effect of temperature on calcification. Corals also exhibit a thermal threshold of 2-3°C above the normal summer ambient temperature at which point calcification abruptly shuts down. In response to a clear need to establish both a baseline and to better understand the response to climate change a study of the community calcification of the coral reefs in the Bight of Parguera, Puerto Rico has been undertaken. Results indicate that in May 2007 salinity normalized total alkalinity (NTA) decreased from 2278 uEquiv $kg^{-1}$ offshore to 2247 at the outer rank of reefs to 2130 at the reefs closest to shore. With a detailed knowledge of bathometry and the residence time of the waters the spatial distribution of NTA could be turned into a map of the community calcification of the region. If the average draw down of NTA relative to offshore source water is taken as 74 uEquiv $kg^{-1}$, the mean water depth as 3 m and the average residence time as 14 days then the average community calcification rate would be 8 mmol $CaCO_3$ $m^{-2}$ $d^{-1}$ or about 30% of the average complete reef-system rate established by Kinsey (1985).

## 3-13

**Dissolution of Calcium Carbonate in Coral Reefs**

**Hajime KAYANNE*[1]**, Atsushi WATANABE[2], Makoto TERAI[1], Shoji YAMAMOTO[1], Tatsuki TOKORO[1], Ken NOZAKI[3], Ken KATO[3], Akira NEGISHI[3]

[1]Department of Earth and Planetary Science, University of Tokyo, Tokyo, Japan, [2]Hydroshperic Atmospheric Research Center, Nagoya University, Nagoya, Japan, [3]National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

Acidification of the ocean by anthropogenic $CO_2$ absorption leads to decrease in the saturation state of calcium carbonate, and thus calcification in the ocean. Dissolution of calcium carbonate is predicted to occur in the high-latitude ocean, where aragonite saturation state will become under-saturated during the 21st century. On the other hand, coral reefs distributed in the tropical ocean have high saturation state, and is not thought to be dissolved by the acidification. However, on-site continuous monitoring of alkalinity in reef water at Shiraho Reef in the Ryukyu Islands showed that dissolution actually occurred during nighttime as shown by increase in total alkalinity. Even during the time of the dissolution, aragonite saturation state never decreased below one. When the aragonite saturation state decreased below 3, net calcification becomes 0 and dissolution occurred below this value. During nighttime, aragonite saturation state in pore water of the reef sediment decreased below 2, which is lower than the saturation state of the water column but still over-saturated for aragonite. We thought magnesian calcite contributed to the dissolution, as it is generally soluble than calcite and aragonite but little information has been obtained so far. We conducted a laboratory experiment to examine its dissolution. Magnesian calcite started to dissolve under aragonite saturation state of 2.0. Based on the field monitoring and laboratory experiment, we hypothesided that saturation state decreases below this threshold value in pore water of the sediment, and magnesian calcite starts to dissolve even at present condition. The results suggest that coral reefs are more soluble than has been thought and may act as a large buffer against $CO_2$ increase.

## 3-14

**Use Of Replicated Coral Reef Mesocosm Studies To Establish The Potential Impact Of Ocean Acidification.**

**Paul L. JOKIEL*[1]**, Ku'ulei S. RODGERS[1], Ilsa B. KUFFNER[2], Andreas ANDERSSON[3], Fred T. MACKENZIE[4], Evelyn F. COX[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI, [2]Florida Integrated Science Center, U. S. Geological Survey, St. Petersburg, FL, [3]Bermuda Institute of Ocean Sciences, St. George, Bermuda, [4]Department of Oceanography, University of Hawaii, Honoloulu, HI

A mesocosm facility designed to conduct long term controlled experiments on the consequences of ocean acidification on coral reefs has been developed at the Hawaii Institute of Marine Biology. The facility uses replicated continuous flow coral reef mesocosms flushed with unfiltered sea water from the adjacent reef in Kaneohe Bay, Oahu, Hawaii. The mesocosms are located in full sunlight and experience diurnal and annual fluctuations in temperature and sea water chemistry characteristic of the adjacent reef. In the initial long term (10 month) experiment the treatment mesocosms were acidified to midday pCO2 levels exceeding control mesocosms by approximately 365 µatm, which is a level expected later in this century. Under these conditions crustose coralline algae (CCA) developed 25% cover in the control mesocosms and only 4% in the acidified mesocosms. Free-living associations of CCA known as rhodoliths that were held in the control mesocosms increased at the rate of 0.6 g buoyant weight yr-1 while those in the acidified experimental treatment decreased in weight at a rate of 0.9 g buoyant weight yr-1. CCA play an important role in the growth and stabilization of carbonate reefs, so future changes of this magnitude could have great impact on these systems. Coral calcification decreased by 14% to 26% under acidified conditions. Coral rate of calcification per unit of linear extension decreased by 6% to 8% in the acidified treatment, indicating that corals were laying down a somewhat more fragile skeleton at higher pCO2. On the other hand, various other calcifying organisms such as barnacles and oysters showed little or no response to the acidified treatment. No differences were observed in coral gamete production by Montipora capitata and coral recruitment by Pocillopora damicornis. Advantages and disadvantages of the mesocosm approach are discussed.

## 3-15

**Nutrient Loading Affects the Relationship Between Coral Calcification and Aragonite Saturation State**

**Pascale CUET*[1]**, Marlin ATKINSON[2], Aline TRIBOLLET[3], James FLEMING[2], Daniel SCHAR[2], James FALTER[2]

[1]ECOMAR, Universite de la Reunion, Saint-Denis, France, [2]Hawaii Institute of Marine Biology, Kaneohe, HI, [3]IRD, Marseille, France

Coral calcification (G) is proportional to the ambient sea water saturation state of aragonite (ΩA). It has also been established that G is reduced by high nutrients, but it is not apparent how nutrient loading and ΩA interact. Experiments were conducted to determine the effect of nutrient loading on the ″G - ΩA relationship″. Coral communities comprised of *Montipora capitata*, *Porites compressa* and *Pocillopora damicornis* were placed in a wave flume in which temperature, light, water motion, nutrient loading and initial ΩA were controlled. The flume was closed over 4 to 5 day periods, resulting in a decrease in ΩA from 4 to 1. Gross primary production and community respiration were respectively 320 ± 37 and 406 ± 55 mmolC m-2 d-1. Independent of the nutrient loading, we observed a decrease in the calcification rate with a decrease in ΩA, with no net 24H - calcification occurring at ΩA ≈ 1 - 1.5. Calcification rate of the high nutrient loading (1 mmolP m-2 d-1 and 24 mmolN m-2 d-1), however, was 2 times higher than the low one (0.06 mmolP m-2 d-1 and 0.3 mmolN m-2 d-1) at ΩA = 3 (respectively 186 and 100 mmolCaCO3 m-2 d-1). The range in calcification was similar to that in the field, and the high nutrient loading was near the upper limit of nutrient uptake. Our results are contrary to the established view that nutrients reduce calcification, and indicate that there is an optimal nutrient loading that enhances calcification. It is likely that constant nutrient uptake is required to offset nutrient release from basic metabolism. The high nutrient corals showed a relatively high calcification at ΩA between 2 and 4. Therefore, further experiments should simulate nutrient loading of the field to improve our understanding of the G - ΩA relationship.

## 3-16

**Aragonite Saturation State And Seawater Ph Do Not Predict Calcification Rates Of The Reef-Building Coral Madracis Mirabilis.**

**Christopher JURY*[1]**, Robert WHITEHEAD[2], Alina SZMANT[3]

[1]Biology and Marine Biology, University of North Carolina Wilmington, Wilmginton, NC, [2]Center for Marine Science, University of North Carolina Wilmington, Wilmington, NC, [3]Biology and Marine Biology, University of North Carolina Wilmington, Wilmington, NC

The calcification rate of corals has been found to decrease under experimental conditions with reduced seawater aragonite saturation state (Ωarag), but it is unclear how this relates to changes in seawater chemistry due to anthropogenic CO2 enrichment. The reduction of carbonate concentration ([CO32-]) has been suggested to drive this response, but physiological data suggest that bicarbonate ion (HCO3-) and not CO32- serves as the carbon source for coral calcification. Reduced pH has also been suggested as the cause of reduced coral calcification but no study to date has adequately separated the effects of these two parameters. This study tested whether seawater pH, [CO32-], or both affect rates of calcification in corals. *Madracis mirabilis* nubbins were incubated in one of four treatment chemistries (produced by manipulation of pCO2 and total alkalinity): 1) pHT = 8.06, [CO32-] = 260 µmol kg-1 (control), 2) pHT = 7.77, [CO32-] = 150 µmol kg-1 (low pH, low [$CO_3^{2-}$]; 3x pre-industrial pCO2 conditions), 3) pHT = 7.77, [CO32-] = 260 µmol kg-1(low pH, normal [$CO_3^{2-}$]), and 4) pHT = 8.06, [CO32-] = 150 µmol kg-1(normal pH, low[$CO_3^{2-}$]). Relative to the controls, Treatment 2 resulted in a ca. 10 % increase in calcification; Treatment 3 in a ca. 21 % increase in calcification; and Treatment 4 in ca. 43 % reduction in calcification. The results indicate that rates of calcification in the coral *Madracis mirabilis* are not correlated to either seawater pH or [CO32-]. Instead, calcification is better correlated with [HCO3-] in all experimental treatments. These results imply that projected changes in Ωarag or pH may not offer appropriate models of coral responses to ocean acidification and that not all corals may be negatively affected by acidification.

## 3-17

**The Effect Of Depressed Aragonite Saturation State On Larval Settlement, Post-Settlement Survivorship, And Growth Of The Brooding Coral *porites Astreoides* And The Broadcast-Spawning Coral *montastrea Faveolata***

**Rebecca ALBRIGHT*[1]**, Benjamin MASON[1], Chris LANGDON[1]

[1]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

In conjunction with the projected increases in *p*CO2 of the coming century, adult coral growth and calcification are expected to decrease significantly. However, no published studies have investigated the effect of elevated *p*CO2 on earlier life history stages of corals. As coral recruitment, post-settlement survivorship, and growth are critical to reef persistence and resilience, it is of timely importance to better understand the repercussions on such factors. Larvae and gametes of *Porites astreoides* and *Montastrea faveolata* (respectively) were collected from reefs in Key Largo, Florida, fertilized (*M. faveolata*) and settled and reared in controlled saturation state seawater. The effect of treatment water on settlement and post-settlement growth was examined. Three treatment levels were targeted based on present (380 ppm) and projected *p*CO2 scenarios for the years 2065 (560 ppm) and 2100 (720 ppm). Corresponding saturation states of treatment water were obtained using 1M HCl additions: $\Omega = 3.19 \pm 0.13$ (control), $2.59 \pm 0.08$ (mid), and $2.16 \pm 0.12$ (low). Larvae were introduced to their respective treatments and allowed one week to settle onto pre-conditioned limestone tiles. Percent settlement was determined by examination under a dissecting microscope. Settled larvae were placed in flow-through treatment aquaria (25°C) and growth rates were analyzed over the course of twenty-one days, using high magnification photographs and SPOT© Softwareto monitor changes in total surface area (mm2). Results indicate that saturation state had no significant effect on percent settlement of *P. astreoides* or *M. faveolata* larvae. Skeletal extension rates of *P. astreoides* spat exhibited a positive correlation with saturation state, while tissue growth rates of *M. faveolata* spat were not significantly affected.

## 3-18

**Monitoring Oceanic And Coastal Variability in Carbonate Chemistry: Tracking Ocean Acidification in The Greater Caribbean Region**

**Dwight GLEDHILL*[1]**, R WANNINKHOF[2], F.J. MILLERO[3], C. M. EAKIN[4], C. LANGDON[3], J. HENDEE[2], T.R.L. CHRISTENSEN[1], A.E. STRONG[4], W.J. SKIRVING[4], J.A. MORGAN[1], G. LIU[1], S.F. HERON[4]

[1]IMSG at NOAA Coral Reef Watch, Silver Spring, MD, [2]NOAA OAR AOML, Miami, FL, [3]Rosenstiel School, University of Miami, Miami, FL, [4]NOAA Coral Reef Watch, Silver Spring, MD

The surface oceans serve as an important natural sink for increasing atmospheric carbon dioxide (CO2) concentrations. As this CO2 reacts with seawater it reduces pH (acidification) and redistributes inorganic carbon species. Ocean acidification decreases the availability of carbonate ions that are vital to biocalcification processes, including those of prominent reef building organisms. Mapping and monitoring the distribution of such changes provides an important context for understanding the potential impacts of ocean acidification and identifying the most susceptible regions. Using satellite remote sensing and modeled environmental parameters, we have extended *in situ* observations obtained from Volunteer Observing Ships (VOS) and multiple geochemical surveys to derive estimates of the oceanic changes in sea surface carbonate chemistry throughout the Greater Caribbean Region. The results reveal considerable spatial and temporal variability throughout the region transposed over a strong secular decrease in aragonite saturation state (Ωarg) at a rate of ~ $-0.12 \pm 0.01$ Ωarg decade-1 ($r2 = 0.97$, $P<0.0001$). This rate is comparable to that estimated from recent geochemical models for Atlantic subtropical surface waters and as recorded at the nearby Bermuda Atlantic Time-Series station. Sustained observations of CO2 partial pressure (pCO2) from autonomous systems deployed at two reef sites in the region reveal considerable seasonal variability relative to oceanic waters as a consequence of benthic metabolic activity. We will present an examination of these seasonal variations in carbonate chemistry for the Greater Caribbean Region in both oceanic and coral reef occupied coastal waters.

## 3-19

**Remote Sensing Of Changes in Carbonate Production On Reefs: The Florida Keys**

**Christopher MOSES*[1]**, David PALANDRO[2], Serge ANDREFOUET[3], Frank MULLER-KARGER[4]

[1]College of Marine Science, University of South Florida, Saint Petersburg, FL, [2]Florida Fish & Wildlife Research Inst., Saint Petersburg, FL, [3]Institut de Recherche pour le Développement (IRD), Noumea, New Caledonia, [4]Univ. Massachusetts Dartmouth, New Bedford, MA

Using satellite remote sensing, it is possible to scale-up *in situ* observations of carbon and carbonate production on coral reefs from habitat scales ($10^{-1}$-$10^{0}$ km$^2$) to regional ($10^{3}$-$10^{4}$ km$^2$) estimates. Multi-spectral satellite imagery from Landsat, with 30 m spatial resolution, is both sufficiently accurate and cost effective for performing such scaling-up exercises. Using a time series of Landsat 5 Thematic Mapper (TM) and Landsat 7 Enhanced Thematic Mapper Plus (ETM+) spanning 18 years from 1984-2002, it is possible to quantify changes in the spatial extent of reef habitats (e.g., dense live cover) in the Florida Keys. This study focused on the shallow (<6 m) backreefs, reef flats, and forereefs along the length of the Upper, Middle, and Lower Florida Keys.

Twenty-eight georectified images were subjected to atmospheric and water column corrections, then calibrated to remote sensing reflectance ($R_{rs}$) for change detection analyses. Published values for production were applied additively to estimate overall changes in production. A decline in cover of coral habitat of >50% is observed both *in situ* and by satellite between 1996-2002, and is reflected in changes in production estimates. Similar approaches could be applied over other areas with good temporal availability of remote sensing imagery validated by *in situ* observations. Using remote sensing as a tool for scaling-up *in situ* measurements of production has potential applications for monitoring synoptic scale environmental impacts, such as the broad reaching effects from ocean acidification.

## 3-20

**Comparative Microarray Analysis During Onset Of Calcification In The Phylogenetic Distinct Scleractinian Coral Species Acropora Millepora And Montastraea Faveolata.**

**Alejandro REYES*[1,2]**, Chris VOOLSTRA[1], Lauretta GRASSO[3], David HAYWARD[3], Eldon BALL[3], Alina SZMANT[4], Roberto IGLESIAS[5], David MILLER[2], Monica MEDINA[1]

[1]Natural Sciences, UC Merced, Merced, CA, [2]Molecular Sciences, James Cook University, Townsville, Australia, [3]Research Shool of BIological Sciences, Australian National University, Camberra, Australia, [4]Biology and Marine Biology, University of North Carolina Wilmington, Wilmington, NC, [5]Instituto de Ciencias del Mar y Limnologia, Universidad Autónoma Nacional de México, PuertoMorelos, Mexico

In reef building corals, cells from the calicoblastic ectoderm secret and mature an organic matrix. In this matrix, calcium ions are concentrated and calcium carbonate crystals incorporated into the massive exoskeleton. These calcareous structures not only provide protection for coral polyps, they also constitute the framework of the reef ecosystem. Current concerns, that rising atmospheric CO2 may inhibit the biological deposition of calcium carbonate in the marine environment, have directed attention to the way in which coral reefs will respond to climate change.

Although it is likely that conserved molecular mechanisms regulate skeleton deposition in scleractinian corals, there is evidence suggesting that differential organic matrix composition and physiological plasticity might be responsible for species-specific responses to environmental perturbations. To test this idea we are comparing gene expression microarray data from two phylogenetic distant hermatypic coral species: Acropora millepora (Complex clade), and Montastrea faveolata (Robust clade).

Microarray analysis for each species included non-calcifying aposymbiotic planulae, calcifying aposymbiotic primary polyps as well as adult symbiotic calcifying samples. In both cases a number of extracellular membrane matrix proteins, carbonic anhydrase, carbohydrates transporters and cytoskeleton regulators were differentially expressed in calcifying stages when compared to non-calcifiyng samples. The identification of species-specific gene expression patterns might help understand calcification related processes that are either conserved or coral clade-specific.

## 4-1

**Coralline P/Ca: Evidence For A New Seawater $PO_4$ Proxy**

**Michèle LAVIGNE*[1]**, Robert M. SHERRELL[2], M. Paul FIELD[1], Eleni ANAGNOSTOU[1], Kim COBB[3], Andréa G. GROTTOLI[4], Braddock LINSLEY[5], Gerard M. WELLINGTON[6]

[1]Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, [2]Institute of Marine and Coastal Sciences and Department of Earth and Planetary Sciences, Rutgers University, New Brunswick, NJ, [3]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA, [4]School of Earth Sciences, The Ohio State University, Columbus, OH, [5]Department of Earth and Atmospheric Sciences, University at Albany, State University of New York, Albany, NY, [6]Biology and Biochemistry, University of Houston, Houston, TX

A proxy for surface water nutrient concentrations, recorded in coral skeleton, would provide novel records of sub-seasonal to centennial variations in nutrient dynamics and primary production in the past. Records of tropical euphotic zone nutrient supply and uptake could link decadal-centennial scale climate oscillations to low latitude carbon fixation more directly than can be achieved using available paleo-SST/upwelling proxies alone. A coral proxy for seawater phosphate would complement records from established but quantitatively uncertain surface water upwelling proxies in coral such as Cd/Ca and Ba/Ca. Using solution phase and laser ablation HR-ICP-MS methods, we have found that average skeletal P/Ca in surface corals growing in regions with distinct nutrient regimes (Gulf of Panamá (*Pavona gigantea*), Martinique (*Montastrea faveolata*), Pacific Line Islands and Rarotonga (*Porites lutea*)) are positively correlated with mean local surface phosphate concentrations. Further, a 4-year record along the growth axis of the *Pavona gigantea* coral growing under seasonally varying nutrient levels in the upwelling regime of the Gulf of Panamá shows repeated annual cycles of P/Ca (~75 -230 µmol/mol), with maxima occurring during cool upwelling periods, following the ~3 fold seasonal variations of surface water phosphate (LaVigne et al., in review). Based on rigorous solution cleaning and soluble reactive phosphate analyses of drilled powders, we hypothesize that the P/Ca signal measured by ICP-MS reflects a combination of inorganic and organic intracrystalline phases, incorporated in proportion to ambient seawater phosphate. We plan to further investigate the skeletal P incorporation mechanism and test the validity of this new proxy in corals of different ages and nutrient environments. Modern cores from the Pacific Line Islands (~160ºW, 2-4ºN) will be used to evaluate coralline P/Ca (preliminary range ~30-60 µmol/mol) for reconstructing tropical Pacific nutrient availability in relation to past ENSO-driven changes in equatorial upwelling.

## 4-2

**U/ca As A Possible Proxy Of Carbonate System in Coral Reef**

**Alrum ARMID*[1]**, Yuki TAKAESU[1], Tanri FAHMIATI[1], Hiroyuki FUJIMURA[1], Tomihiko HIGUCHI[1], Eiko TAIRA[2], Tamotsu OOMORI[1]

[1]Department of Chemistry, University of the Ryukyus, Japan, Nishihara, Japan, [2]Aqua Culture Okinawa, Japan, Nishihara, Japan

Increasing carbon dioxide in the atmosphere and absorption into the ocean will modify the carbonate chemistry of the surface ocean. The atmospheric $CO_2$ level has already increased from the concentration of 280 ppm in the pre-industrial age to 380 ppm in 2007, and it is predicted to reach 560 ppm before the end of the 21st century. Ocean acidification influences calcium carbonate ($CaCO_3$) equilibrium of the ocean due to the decrease in carbonate ($CO_3^{2-}$) ion concentration. During calcification process of marine carbonates (such as coral), some trace elements can be incorporated into carbonate skeleton. Since the elevated atmospheric $CO_2$ reduces the oceanic pH, and the alteration of oceanic pH governs both the ocean carbonate chemistry and the speciation of elements, the mechanism of trace elements incorporated into coral skeleton will be also affected.

In seawater, $UO_2^{2+}$ forms complex ions such as $UO_2CO_3^0$, $UO_2(CO_3)_2^{2-}$, and/or $UO_2(CO_3)_3^{4-}$. Uranium is thought to be incorporated into carbonate as uranyl ($UO_2^{2+}$) ion. However, the mechanism of their incorporation into coral skeleton based on the pH changes is poorly understood. Therefore, study of such complex uranyl ions incorporated into coral skeleton is significantly needed to establish basic concept of uranium uptake by coral.

Incorporation of uranium into coral skeleton was investigated in the labotatory incubation under the controlled $pCO_2$ at 27°C. Distribution coefficient, $\lambda UO_2$, between coral skeleton and seawater was measured, which varies from 2.6 to 0.6 with the change in $CO_3^{2-}$ ion activity in seawater.

## 4-3

**A Rayleigh-Based Approach To Coral Thermometry: Seeing Through The "Vital Effect"**

**Glenn GAETANI*[1]**, Anne COHEN[1], Zhengrong WANG[1,2]

[1]Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, [2]Yale University, New Haven

Paleotemperature proxy records are typically derived from coral skeleton using empirical relationships between elemental ratios and water temperature. While this approach has produced significant advances in our understanding of Earth's climate system, its accuracy is limited by the impact of physiological processes ("vital effects") on compositional variability within the skeleton. Several recent studies have identified the importance of Rayleigh fractionation in producing "vital effects" in coral skeleton, providing the basis for a new approach to coral paleothermometry. In contrast with conventional paleothermometry, this approach does not rely on calibrations involving living corals, and no prior knowledge of water temperature is required. By combining analyses of multiple elemental ratios (Mg/Ca, Sr/Ca and Ba/Ca) from a given coral skeleton with experimentally determined partition coefficients for abiogenic aragonite, a mathematically overconstrained system of Rayleigh equations can be constructed that describe element fractionations during coral biomineralization. While these equations cannot be solved explicitly for temperature, global minimization techniques can be used to derive ocean temperatures. The accuracy and precision of this approach was tested on aragonite skeletons from two coral species grown in significantly different environments: (1) *Acropora* sp., a symbiont-bearing tropical coral grown at 21 to 29°C by Reynaud et al. (2007, Geochim Cosmochim Acta,71:354-362) and (2) *Lophelia pertusa*, an asymbiotic, cold-water coral collected from a depth of 129 m on the Tisler Reef, NE Skagerrak, where water temperature ranges from ~5 to ~9°C. Results from these corals show that our approach is yields ocean temperatures that are both accurate and precise to within a few tenths of a degree, and that it is applicable both across species and to corals growing in vastly different environments.

## 4-4

**Identification And Calibration Of Proxies For Thermal And Disease Stress From Lipid Biomarkers**

**Jessie KNEELAND*[1]**, Konrad HUGHEN[1], James CERVINO[2,3], Erich BARTELS[4]

[1]Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA, [2]Pace University, New York, NY, [3]Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, [4]Mote Marine Laboratory, Summerland Key, FL

New lipid biomarkers indicative of thermal and disease stress on corals are important for assessing coral health, and lipids also have the potential for preservation in coral aragonite. To identify such stress biomarkers, we cultured *Symbiodinium* zooxanthellae clade subtypes A, B, C1 and D1 at one-degree temperature increments (24-32 degrees C), with and without introduction of *Vibrio* pathogens, for 1 to 5 weeks. We also performed analagous incubations of whole coral samples of *Montastraea faveolata* from Summerland Key, Florida. Lipids were extracted from the cells using a Bligh and Dyer protocol, and were analyzed by gas chromatography and mass spectrometry. Triplicate cultures under each set of conditions were analyzed up to three times each to ensure a reproducible signal. Resulting indices are calculated as ratios of lipids, providing a robust measure that is not sensitive to total lipid abundance and non-constant sample size. The ratios of fatty acid to sterols, and unsaturation ratios in the fatty acids respond strongly to both increasing temperatures and length of exposure. Comparisons between cultured *Symbiodinium* lipids and coral tissue, and comparisons between diseased and non-diseased samples, demonstrate the potential for biomarkers as thermal and disease stress proxies.

## 4-5

**Coral Record of Ba/Ca from the Southern Gulf of Mexico and its Relationship to Fluvial Discharge**

**Guillermo HORTA-PUGA*[1]**, José D. CARRIQUIRY[2]

[1]Facultad de Estudios Superiores Iztacala, UBIPRO, Universidad Nacional Autónoma de México, Tlalnepantla, México, Mexico, [2]Instituto de Investigaciones Oceanológicas, Universidad Autónoma de Baja California, Ensenada, Baja California, Mexico

The Ba/Ca ratio in the annual growth bands of Montastraea faveolata from the Veracruz Reef System was used to record long-term environmental change associated to anthropogenic activity in the Southern Gulf of Mexico (SGM). Annual samples, from cores of two colonies collected at Anegada de Adentro and Isla Verde reefs, were cleaned to quantify both the total and the Ca-sustitutive Ba/Ca ratios by ICP-OES. The total and the Ca-sustitutive Ba/Ca records from the Anegada de Adentro reef were similar for the period 1835-2002, ranging from 5.9 to 10.2 µmol/mol with averages of 7.8 µmol/mol. As no significant statistical differences were found between records, it is concluded that almost all Ba is incorporated in the Ca-sustitutive fraction. The Ba/Ca ratio average increased from 7.4 µmol/mol in the 1835-1920 period to 8.2 µmol/mol in the 1920-2002 period. As the human population in the SGM increased >600% in the last period, it is probable that the sediment load of river waters also increased due to higher erosion rates enhanced by human activities, which also caused and increase of about 10% in the concentration of Ba in the seawater of the SGM. The 62-yr record of Ba/Ca from Isla Verde reef (1941-2002), showed a significant correlation with the Jamapa River total annual discharge for the periods 1957-1974 ($r=0.78$, $p<0.05$) and 1988-1996 ($r=0.54$, $p<0.05$). Thus, most of the coral Ba content derives from suspended sediments delivered to the SGM by the river. The periods when correlation (with the river's discharge) decreased abruptly are coincident with peaks of high barite production in the USA, in 1975-1985 and 1995-2002. This suggests that barite, a component of drilling-muds used in oil industry in the northern Gulf of Mexico, could be transported by surface ocean currents, becoming and additional source of Ba in the SGM.

## 4-6

**Mg Isotope Fractionation in Corals: Developing A Promising Paleothermometer**

**Zhengrong WANG*[1]**, Anne COHEN[2], Glenn GAETANI[2], Rinat GABITOV[3], Stanley HART[2]

[1]Geology and Geophysics, Yale University, New Haven, CT, [2]Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, [3]Division of Geological and Planetary Sciences, Caltech, Pasadena, CA

We report a systematic study of Mg isotope fractionation that reveals temperature-correlated annual δ26Mg cycles in coral skeletons. δ26Mg ratios were measured in the skeleton of the massive reef corals and in experimental abiogenic aragonites precipitated from seawater. Clear annual cycles in δ26Mg were observed in two *Montastrea* and one *Porites* coral colonies that experienced seasonal SST changes of 4 oC and 7 oC, respectively. We tested for "vital effects" by comparing δ26Mg along 'bumps' and 'valleys' of the same *Montastrea* coral. δ26Mg values were consistent between 'bumps' and 'valleys', whereas Sr/Ca ratios showed significant differences. We empirically calibrated the temperature-dependence of Mg isotope fractionation between corals and seawater. This fractionation factor has a linear relationship to inverse absolute temperature, corresponding to a temperature sensitivity of about 0.10 per mil/oC for both corals, which is slightly larger than the measurement precision of our improved analytical technique to resolve degree-level sea surface temperature variation (c.a. 0.09 per mil for ~ 1 mg sample). Moreover, the Mg isotope fractionation between abiogenic aragonite slowly precipitated in the experiment and seawater at 25oC falls along *Montastrea* coral calibration curve. All of these results suggest the possible lack of 'vital effects' on Mg isotope fractionation between seawater and coral skeletons, and indicate the temperature dependent Mg isotope fractionation could be developed as a potential paleothermometer.

## 4-7

**Records Of Past Thermal And Disease Stress From Lipid Biomarkers in Coral Aragonite**

**Konrad HUGHEN*[1]**, Jessie KNEELAND[1], James CERVINO[1,2], Jessica CARILLI[3]

[1]Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA, [2]Pace University, New York, [3]Scripps Institution of Oceanography, La Jolla, CA

Coral reefs are being threatened by combinations of stressors including global climate change and local environmental degradation. In order to predict the future response of corals to on-going environmental stress, we need accurate data quantifying the response of corals to a wide range of adverse conditions. A rich source of such information can be found in past records of coral bleaching and disease outbreaks, and the environmental conditions that preceded them. However, although numerous proxies exist for quantifying environmental parameters, there are currently no quantitative proxies for coral stress, such as caused by elevated temperatures or disease. Here we report new records of past coral stress constructed from lipid biomarkers in coral aragonite. Experiments with Symbiodinium zooxanthellae and Montastrea faveolata corals grown in culture were used to develop new proxies for thermal and disease stress. Samples exposed to elevated temperatures for periods up to 5 weeks, and those inoculated with Vibrio bacterial pathogens, showed distinct changes in lipid biomarker concentration and distribution. Lipids responding to thermal stress changed as a function of both temperature and duration of exposure. The same lipid biomarkers used to develop stress indices in cultured samples are found in adequate abundance for quantification in intracrystalline coral aragonite. Coral drill cores up to 1.2m long were obtained from four locations in the Mesoamerican Reef – Turneffe Atoll, Sapodilla Cayes, Utila Island and Cayos Cochinos Islands. Yearly density bands were identified from x-rayed slabs, and samples were cut and cleaned for analysis at annual resolution to construct records of coral stress over the past 100-150 years. Locations in the southern Mesoamerican Reef have a well-documented history of recent mass bleaching events, providing a verification period to test the accuracy of these new biomarker stress proxies.

## 4-8

**Foraminifera As Bio-Indicators? The History Of Foram Communities From The Wet Tropical Inshore Reefs, Great Barrier Reef**

**Claire REYMOND*[1]**, John PANDOLFI[1]

[1]ARC Centre of Excellence in Coral Reef Studies, Centre for Marine Studies, University of Queensland, Brisbane, Australia

As a result of land based activities there is an increasing need to develop marine bio-indicators for effective monitoring programs within coastal marine regions. Benthic foraminifera are prolific unicellular marine organisms, which are regarded as powerful indicators of environmental perturbation. Reef coral and foraminiferal assemblages are found in close association and exhibit distinctive local and regional patterns. We present a historical reconstruction of foraminiferal communities from the Great Barrier Reef (GBR) inshore wet tropical region based on ten 5-meter cores collected from the back reef habitats of Pandora Reef and Havannah Island. Community similarity is up to 75% for over 1,500 years. Fourteen key species differentiate two community types within the core. There is a positive correlation in the abundance of *Quinqueloculina philippinensis* and *Elphidium craticulatum*, and a negative correlation in the abundance of *Calcarina mayori* and *Peneroplis pertusus*, both endosymbiont-bearing species. It is clearly not the most abundant or the rare species that are differentiate these communities down core, more so it is the species with intermediate abundances. Highly abundant species are commonly distributed throughout the core. Understanding the nature of foraminiferal biology and sensitivity to environmental change is important when comparing modern day assemblages with assemblages from the last millennium.

## 4-9

**Long-Term Caribbean Nutrient Perturbations Recorded by Gorgonian Corals**

**David BAKER*[1]**, Kirby WEBSTER[2], Eduardos VALAITIS[3], Kiho KIM[2]

[1]Department of Ecology & Evolutionary Biology, Cornell University, Ithaca, NY, [2]Department of Biology, American University, Washington, DC, [3]Department of Mathematics & Statistics, American University, Washington, DC

Over the last century the Wider Caribbean has experienced dramatic changes from human activities. Widespread land-use change to agriculture, the concomitant removal of coastal mangrove forests, and recently accelerated population growth has led to perturbation of aquatic ecosystems. Of particular concern is increasing amounts of anthropogenic nutrients, and their effect on coastal marine habitats. Coral reefs are particularly sensitive to nutrification, and there is an abundance of reports on the deleterious effects of nitrogen (N) on these systems. However, the paucity of historical nutrient pollution data inhibits our understanding of the full scope of the problem. Fertilizer and sewage-derived N represent opposing end-members across the natural range of $\delta^{15}N$ from near zero to > 20 ‰, respectively. The relative proportion of N from these and natural sources dictates the resulting $\delta^{15}N$ of any mixture. Thus, in the absence of information about the relative contributions of fertilizer and sewage derived N, interpretation of $\delta^{15}N$ values is problematic. In this study, we use fertilizer use and human population data in a cointegration model to tease apart their respective contributions to long-term changes in N inputs to the Wider Caribbean. We analyzed four species of gorgonians collected from 10 regions within the past 155 years as an integrator of N sources. We show that $\delta^{15}N$ values of gorgonian corals are positively correlated with population, and negatively correlated with fertilizer consumption. Trends in gorgonian $\delta^{15}N$ since 1851 indicate a minimum inflection value in the 1970's, after which $\delta^{15}N$ increases. We conclude that widespread land-use change to agriculture has historically perturbed N dynamics in coastal Caribbean environments however, recent population growth has offset fertilizer isotope signals in corals, and suggests that the interplay between fertilizer and sewage derived N on coral $\delta^{15}N$ may lead to underestimation of their respective contributions.

## 4-10

**Identification Of Bleaching Events In Coral Skeletal Records Using High-Resolution Stable Isotope And Trace Element Records**

**Abbey CHRYSTAL*[1]**, Andrea GROTTOLI[1], Lisa RODRIGUES[2]

[1]School of Earth Sciences, The Ohio State University, Columbus, OH, [2]Department of Geography and the Environment, Villanova University, Villanova, PA

Coral skeletal stable oxygen isotopes (δ18O) reflect changing seawater temperature and salinity, while stable carbon isotopes (δ13C) reflect metabolic and kinetic fractionation. These isotopic changes may provide a record of past bleaching events. The effects of bleaching and subsequent recovery on skeletal isotopes in the mounding coral *Porites lobata* were experimentally investigated by inducing bleaching in outdoor tanks via increased water temperature (30°C). Control fragments from the same parent colonies were separately maintained at ambient seawater temperature (27°C). After one month all were returned to the reef for 20 months of recovery. Alizarin red staining was used to mark specific dates throughout the 21 months. Isotopes were measured by Kiel-SIR-MS at 0.1 mm increments along the major axis of growth for one bleached and one control fragment. Skeletal δ18O did not differ between the bleached and control fragments during the month of elevated temperatures, nor during recovery under natural reef temperature variations. However, δ13C decreased dramatically relative to the control several weeks into recovery, recovered to control levels after 4 months, and showed a negative departure again the following summer. The initial lag in δ13C depletion suggests that while *P. lobata* is fairly resistant to initial physiological effects of bleaching, it continues to be affected by the stress event during the first few weeks of recovery. Lower $\delta^{13}C$ values the second summer suggest that the bleached fragment was more susceptible to thermal-stress from a second moderate warming. Overall, high-resolution skeletal $\delta^{13}C$ has potential as a proxy for past bleaching events in this species independent of $\delta^{18}O$ variability. Skeletal trace element analyses in both bleached and control fragments are underway and will also be presented.

## 4-11

**Coral Growth Records From Southeast Florida: A History Of Anthropogenic Influence**

**Kevin P HELMLE*[1]**, Richard E DODGE[1], Peter K SWART[2], J Harold HUDSON[3]

[1]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Dania Beach, FL, [2]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [3]Florida Keys National Marine Sanctuary (ret.), National Oceanic and Atmospheric Administration, Key Largo, FL

Coral skeletal growth records of extension, density, and calcification from Southeast Florida reveal a three-decade period of stress spanning ca. 1940 to 1970. The period is characterized by dramatically decreased annual extension rate and increased skeletal bulk density. No similar periods of growth departures of this intensity or duration are present in locally collected corals dating back to 1694. Coral growth from a total of 80 corals exhibits strong correlation with master chronologies indicating a common growth response to one or a combination of environmental limiting factors. Near-shore shallow-water corals in Southeast Florida are affected by a number of stresses including freshwater drainage and coastal runoff. The 30-year period of high skeletal densities and low extension rates matches with a 30-year period of increased freshwater discharge, at times, an order of magnitude greater than normal. Construction of the four major South Florida canal systems diverted waters from Lake Okeechobee in the 40s, 50s, and 60s to the ocean. Comparison of temporal patterns in coral extension with environmental variables reveals a positive correlation between extension rate and salinity (represented by sea water density). The direct cause may be linked to influences from freshwater discharge such as high turbidity and decreased light penetration, salinity, or deleterious water quality. Further analysis of skeletal chemistry will help to identify specific limitations on the growth potential of these corals. Since the early 1970's, growth rates have generally increased relative to the historical average; however, the frequency of single-year stress bands has also risen. Increased growth rates coincide with warmer temperatures and stress bands likely resulting from partial bleaching when temperature thresholds are exceeded. This research has applications to better understanding coral stress and recovery with particular regard to watershed management.

## 4-12

**The Significance Of Geochemical Proxies in Corals, Does Size (Age) Matter?**

**Tim OURBAK*[1,2]**, Kristine DELONG[1], Thierry CORRÈGE[3], Bruno MALAIZÉ[3], Halimeda KILBOURNE[4,5], Sandrine CAQUINEAU[2], David HOLLANDER[6]

[1]College of Marine Science, St Peterbsurg, FL, [2]Institut de Recherche pour le Developpement, Bondy, France, [3]UMR 5805 EPOC, Universite Bordeaux 1, Talence cedex, France, [4]Earth Systems Research Laboratory Physical Sciences Division, NOAA, Boulder, CO, [5]College of Marine Science, St Peterbsurg, [6]College of Marine Science, St Petersburg, FL

Massive corals contain a myriad of geochemical tracers that have lead to numerous paleoenvironmental studies (sea surface temperature reconstructions for example). Most of the time, coring is achieved on a coral head, which is then sampled to produce geochemical analyses, used as proxies to estimate paleoclimate variability.

The present work deals with the impact of the age (and the size) of the coral head on geochemical results.

We analyzed three pristine coral heads using a multiproxy approach (Sr/Ca, Mg/Ca, $\delta^{18}O$ , $\delta^{13}C$). The first one is a 7m high core from New Caledonia where the modern period (top of the core) is compared to the settlement period (bottom of the core, when the coral was still at a juvenile stage).

The geochemical signatures of two coral heads (small vs. large) that have grown in a similar environment (Vanuatu) are also compared.

Large geochemical differences observed (between juvenile vs. mature and, to a less extent, between small vs. large coral heads) could not be explained only because of environmental variability.

We will develop the potential causes of such differences in term of variability of the tracers (kinetic effects, reproductive patterns etc).

The implications of this work are that paleonvironmental work based on coral archives should clearly state the length of the core retrieved. For example, if the SST range is well captured by Sr/Ca ratio, independently of the size/stage of growth of the coral head, applying directly calibration equation to reconstruct absolute SST bias the result and only relative SST values should be compared and interpreted.

## 4-13

**Coral Records Of Late 20th Century Warming And Freshening in The Central Tropical Pacific**

**Intan NURHATI*[1]**, Kim COBB[1], Chris CHARLES[2]

[1]Georgia Tech, Atlanta, GA, [2]Scripps Inst. of Oceanography, UCSD, La Jolla, CA

Corals have been widely used to reconstruct past climate due to high fidelity in capturing climate variability. Modern corals from the central tropical Pacific (CTP) have provided monthly climate records that show trends toward depleted coral d18O values in the late 20th century. These trends might infer warming and/or seawater freshening in the region. It is important to understand the mechanism behind these trends, to better predict low-frequency changes in tropical Pacific climate that may be associated with anthropogenic warming. One mechanism involves weakened tropical Pacific zonal SST gradient that would warm the CTP by reducing upwelling and enhance precipitation. Alternatively, warming might have occurred without changes in upwelling, and the lower salinities may signal changes in the location and/or strength of the ITCZ. Here we reconstruct late 20th century SST and salinity using coral d18O and Sr/Ca from Palmyra, Fanning and Christmas Islands (2-6ºN,157-162ºW). Palmyra at the northern end, is heavily influenced by the North Equatorial Counter Current (NECC) and the ITCZ; while Christmas at the southern end, is heavily influenced by the South Equatorial Current and equatorial upwelling. We measure Sr/Ca (SST proxy) and coral d18O values with analytical errors of ±0.3% or ±0.4ºC(1s), and ±0.05‰(1s), respectively. We derive d18O of seawater (salinity proxy) by removing the Sr/Ca-derived SST contribution from coral d18O values. Sr/Ca-based SST reconstructions show warming of 0.22, 0.25 and 0.5ºC/decade from Palmyra to Christmas, which may suggest a decrease in equatorial upwelling. d18Osw-based salinity reconstructions show seawater freshening of 0.31, 0.1 and 0.12psu/decade from Palmyra to Christmas, which may suggest an enhanced and/or southward migration of the ITCZ as well as changes in the salinity of waters advected by the NECC. Simultaneous warming and freshening in CTP corals may indicate a weakening of the tropical Pacific zonal SST gradient in the late 20th century.

## 4-14

**Reconstructing Sea Surface Temperature Variability in The Southwest Pacific: A Replication Study Using Multiple Coral Sr/ca Records From New Caledonia**

**Kristine DELONG*[1]**, Terrence QUINN[2,3], Frederick TAYLOR[2]

[1]College of Marine Science, University of South Florida, St. Petersburg, FL, [2]Institute for Geophysics, Jackson School of Geosciences, University of Texas at Austin, Austin, TX, [3]Dept. of Geological Sciences, Jackson School of Geosciences, University of Texas at Austin, Austin

Coral Sr/Ca reproducibility was investigated using three intracolony and three intercolony coral records from the reefs offshore of Amédée Island, New Caledonia. By convention, coral colonies are sampled along the vertical growth axis. This convention was tested by comparing vertical and horizontal paths on a small *Porites* colony from Vanuatu and a larger colony from New Caledonia. No significant difference in Sr/Ca variations was observed when the corallite growth direction was parallel to the sampling path and the sampling path followed the top of the lobe. Different sampling resolutions were examined in coral Sr/Ca (fortnightly and monthly) and δ18O (fortnightly, monthly, and seasonally) as well as similar scale subsampling of the daily in situ sea surface temperature (SST) record. The mean coral Sr/Ca, δ18O, and SST values do not change as a function of sampling resolution. The coral Sr/Ca signal is highly reproducible; the average absolute offset between coeval monthly Sr/Ca determinations between any two coral time series is 0.035 ± 0.026 mmol/mol (1σ) (~0.65ºC), which is less than twice the analytical precision of the coral Sr/Ca measurements. The stack average of the monthly coral Sr/Ca variations and monthly anomalies are significantly correlated with monthly in situ SST (1967–1992; $r = –0.96$ and –0.64, respectively; $p < 0.05$; and $n = 302$) and 1º grid monthly SST data product (1900–1999; $r = –0.95$, and –0.56, respectively; $p < 0.05$, $n = 1198$). The coral Sr/Ca–SST reconstruction exhibits interannual and decadal-scale fluctuations that exceed those observed in the gridded SST record, which may reflect true differences between SST at a shallow reef site and those averaged over a 1º grid box or inadequacies in the methodology used to create the gridded SST product when few observations are available.

## 4-15

**Stable Isotope Records From Western Pacific Shallow-Water Soft Coral And Black Coral**

**Branwen WILLIAMS*[1]**, Andrea GROTTOLI[2]

[1]School of Earth Sciences, Ohio State University, Columbus, [2]School of Earth Sciences, Ohio State University, columbus, OH

In some genera of soft corals and black corals, the $\delta^{13}C$ and $\delta^{15}N$ composition of the concentrically banded organic skeleton is controlled by the $\delta^{13}C$ and $\delta^{15}N$ composition of the particulate organic matter (POM) consumed by the coral colony. To test if these organisms record differences in the geochemistry of POM across depth, a sub-surface black coral (5m) and a deeper soft coral (85m) were collected live in 2006 from Palau (western tropical Pacific). High resolution (100 micron increments) $\delta^{13}C$ and $\delta^{15}N$ values were measured across a radial transect of the base of the organic skeleton in both colonies. The sub-surface black coral record showed an overall depletion of organic skeletal $\delta^{13}C$ values at a rate comparable to that measured over the past few decades in atmospheric $CO_2$-$\delta^{13}C$ (i.e., Suess effect). The 85m soft coral record showed a depletion of $\delta^{13}C$ values consistent with the past century of the Suess effect suggesting that this specimen was over one hundred years old. Overall, these initial data suggest the 85m colony had a slower growth rate typical of deep-water taxa, and that POM is the main source of carbon for skeletogenesis in these organisms. The ages of the two colonies will be more accurately constrained using radiocarbon measurements. A statistical comparison of the skeletal records with a seven year in-situ temperature record will be run to test for correlations between temperature (i.e., a proxy for water mass such that colder temperatures represents water below the mixed layer), and stable isotopes in the skeletal records. Together, soft corals and black corals in the western Pacific may provide paleoceanographic information on decadal to centennial timescales across the entire ocean depth range.

## 4-16

**523 Years Of Interannual (Enso-Like) To Multidecadal (Pdo-Like) Climatic Signals Continuously Recorded in New Caledonia By Sr/ca And $\delta^{18}o$ in A Giant Massive Porites**

**Tim OURBAK*[1,2]**, Thierry CORRÈGE[2], Bruno MALAIZÉ[2], Florence LE CORNEC[3], Boris DEWITTE[4]

[1]College of Marine Science, St Peterbsurg, FL, [2]UMR 5805 EPOC, Universite Bordeaux 1, Talence cedex, France, [3]Institut de Recherche pour le Developpement, Bondy, France, [4]Observatoire Midi Pyrénées., Toulouse, France

The southwest Pacific is a critical region concerning interannual to interdecadal climatic phenomena, such as El Niño Southern Oscillation (ENSO) or the Pacific Decadal Oscillation (PDO). Unfortunately, the length of meteorological data critically limits the understanding and analyses of such climatic variability. Trace elements and stable isotopes have been investigated in a 7m long coral core which records more than 500 years of environmental variability from Ile des Pins, south of New Caledonia (22°S, 167°E). This multiproxy approach allows reconstruction of sea surface temperature (SST) and sea surface salinity (SSS). SST variations, estimated from Sr/Ca, reveal a long-term warming over the period 1475 to 1998, modulated by interdecadal cycles. By removing SST component from the $\delta^{18}O$ signal, we have estimated the paleosalinity variability. The SSS reconstruction presents mean saltier conditions at the beginning of the record, and a slow decrease in SSS throughout the whole record punctuated with freshening events, such as the one coinciding with a strong warming trend observed since ~1890. We argue that changes in wind intensity (via evaporation/precipitation), together with advection processes, have changed over the last centuries in New Caledonia. Moreover, this very long core has recorded very intense ENSO phenomena during the end of the 16th century and the beginning of the 17th century consistent with numerous proxies circum-Pacific.

## 4-17

**Water Quality in Nearshore Areas Of The Great Barrier Reef: A Large Scale Monitoring Program And An Assessment Of The Use Of Benthic Foarminifera As Water Quality Indicators**

**Sven UTHICKE*[1]**, Schaffelke BRITTA[1], Angus THOMPSON[1], Damian THOMSON[1]

[1]Water Quality, Australian Institute of Marine Science, Townsville MC, Australia

As for most Coral Reefs, a potential decline in water quality (WQ) is a concern for reef health of Great Barrier Reef (GBR) inshore reefs. A large scale (32 reefs, 4 regions) GBR inshore monitoring program was initiated in 2005, encompassing annual coral community analysis, and half-yearly WQ measurements. We additionally investigated the benthic foraminifera at these monitoring sites to evaluate their utility as WQ indicators in the GBR. WQ measurements confirmed that most parameters (e.g. chlorophyll a, suspended solids) are higher in inshore areas of the GBR when compared to offshore reefs. Higher concentrations of most parameters were measured during the wet season, but regional differences in WQ were more distinct in the dry season.

Regional differences in coral cover and community composition are pronounced. A substantial proportion of the variation in coral community composition is explained by differences in the hydrodynamic conditions, with several genera resilient to sedimentation attaining consistently higher relative abundance in areas where fine sediments predominate. Coral cover estimates mostly reflect recent disturbance history rather than WQ conditions. Along a distinct WQ gradient, the FORAM index (FI), as previously developed and applied in the Caribbean, showed a high correlation with WQ. Foraminiferan communities also showed distinct regional differences. While the FI did not predict coral cover, one symbiont-bearing species (Calcarina mayori) was positively correlated with high algal/low coral cover. Because of the vulnerability of corals to other disturbances it appears that foraminifera are more specific indicators for WQ. Combined analysis of the WQ, coral- and foraminiferan community data from this monitoring program provides important insights into the value of WQ indicators based on individual species' density or a combined FORAM index. We consider the future application of this index in the GBR as beneficial, after refinements in the weighting of individual species.

## 4-18

**Linkages Between Coral Assemblages And Coral-Based Proxies Of Terrestrial Exposure Along A Cross-Shelf Gradient Of The Great Barrier Reef**

**Stacy JUPITER*[1,2]**, Guy MARION[3], George ROFF[3], Meegan HENDERSON[3], Verena SCHRAMEYER[3], Malcolm MCCULLOCH[1], Ove HOEGH-GULDBERG[3]

[1]Research School of Earth Science, ARC Centre of Excellence for Coral Reef Studies, Canberra, Australia, [2]Australian Institute of Marine Science, Townsville, Australia, [3]Centre for Marine Studies, ARC Centre of Excellence for Coral Reef Studies, Brisbane, Australia

We present a novel approach to assess cross-shelf differences in coral community structure by linking present day coral assemblages with disturbance histories from sites within varying proximity to the agricultural region of Mackay (Queensland, Australia). In March 2006, transects were scored for benthic cover composition at sites along a gradient of distance offshore from the Pioneer River mouth. We additionally measured multiple proxies from massive *Porites* corals (luminescence lines, Ba/Ca, δ15N) collected along the same transect to assess the frequency and intensity of exposure to terrestrial discharge and fertilizer-derived nitrogen. High, significant cross-shelf variability in live hard coral cover was observed. The sites closest to the mainland (Round Top, Keswick, St. Bees) were characterized by low hard coral cover (≤10%), with no significant differences among sites. Corals at Round Top Island (5 km offshore) occurred as isolated colonies or thin veneers. Distinct annual luminescence lines and elevated baseline Ba/Ca (mean = 5.0 μmol/mol) in the core records indicated chronic (sub-annual) exposure to freshwater and resuspended terrestrial sediment that may have historically prevented reef formation. By contrast, reef assemblages at Keswick and St. Bees Islands (~33 km offshore) were categorically different due to the dominance of large stands of macroalgae overgrowing dead reef matrix. Cores from Keswick Island indicated high exposure to Pioneer River discharge during extreme flood events (1974, 1991), with bright luminescent lines and significantly enriched δ15N (12-14‰) reflecting an isotopically distinct lower Pioneer catchment source (~9‰) combined with further fractionation by phytoplankton blooms. Scawfell Island (50 km offshore) had high hard coral (22%) and soft coral (35%) cover, and coral core records indicated little exposure to Pioneer catchment influence. These results suggest that nearshore reefs adjacent to highly modified catchments may be particularly vulnerable to phase shifts if they are episodically disturbed by pulses of nutrient-rich terrestrial runoff.

## 4-19

**Unable To Retrieve Title from Database**

**Tsuyoshi WATANABE*[1]**, Atsushi SUZUKI[2], Tatsunori KAWASHIMA[1], Shoshiro MINOBE[1], Yolanda AGUILAR[3], Koji KAMEO[4], Kayo MINOSHIMA[2], Ryoji WANI[5], Hodaka KAWAHATA[6], Tomoki KASE[7]

[1]Natural history Sciences, Hokkaido University, Sapporo, Japan, [2]National institution of Advanced Industrial Science and Techlology, Tsukuba, Japan, [3]Bureau of Mine and Geosciences, Philippine, Manila, Philippines, [4]Chiba Univercity, Chiba, Japan, [5]Yokohama National University, Yokohama, Japan, [6]University of Tokyo, Tokyo, Japan, [7]National Science Museum, Tokyo, Japan

Global mean temperature and atmospheric CO2 concentration during the early Pliocene warm period (PWP; 5-3 Ma) were substantially high as much as those predicted for the future climatic system in 100 years future. The oceanic and atmospheric conditions can be studied in the context of future global warmth. However, the role of El Nino-Southern Oscillation (ENSO) in this greenhouse warming remains controversial mainly because of the lack of the information about seasonal to inter-annual variability in sea surface water in low latitude regions. We found two well-preserved fossil corals in muddy sand layers of the northern part of Philippians including this warm period (3.5-3.8Ma). Here, we demonstrate two 35 years coral oxygen isotopic profiles with monthly resolution in order to investigate seasonal and interannual characteristics of Pliocene ENSO. In the present day, the anomalies of sea surface temperature and precipitation were significantly evident in Philippine during El Nino occurring. Significant attenuations of seasonal amplitude were found in 18O/16O ratios of both two PWP coral records, which were also detected in the recent corals during modern El Nino events.

## 4-20

**High-precision U-series and 14C Dating Of The Deep-Sea Coral *Enallopsammia rostrata***

**Fanny HOULBREQUE*[1,2]**, Brendan ROARK[1], Robert DUNBAR[1], Tom GUILDERSON[3], Malcolm MCCULLOCH[4], Anders MEIBOM[5]

[1]Geological & Environmental Sciences, Stanford University, Stanford, CA, [2]Marine Environment Laboratory, International Atomic Energy Agency, Monaco, Monaco, [3]Center for Accelerator Mass Spectrometry, Lawrence Livermore National Laboratory, Livermore, CA, [4]Research School of Earth Sciences, Australian National University, Canberra, Australia, [5]Laboratoire d'Etude de la Matiere Extraterrestre, Museum National d'Histoire Naturelle, Paris, France

We utilize deep-sea corals in a systematic approach to reconstruct past ocean conditions over centennial to millennial timescales. As part of this endeavor we present new results on *Enallopsammia rostrata*, a pan-oceanic scleractinian species. Here we show that *E. rostrata* collected live using the Pisces submersibles from water depths between 480-790 m at three locations in the Line Islands (~160°W, central Equatorial Pacific) has the potential to act as a recorder of changes in deep-sea environments over centennial time scales. To improve the utility of this scleractinian species as a monitor of interior ocean variability, we have applied a high-precision, low blank technique to measure 230Th and 238U-234U in small amounts (80 ± 10 mg) of modern and near modern calcareous skeletons using MC-ICPMS (Multicollector Inductively Coupled Plasma Mass Spectrometry). Absolute dated specimens exhibit radial growth rates from 23-114 μm/yr and vertical extension rates from 0.57 to 1.87 mm/yr. Colony life spans ranged from 108 ± 5 yrs to 607 ± 6 yrs. The growth rates reported here are similar to those of other deep-sea scleractinian corals, but with a 2 to 3-fold greater life span for the oldest samples. Slow growth rates and great longevity make this species especially vulnerable to disturbances and impacts from climate change and anthropogenic activities. Paired U-series and 14C dating measurements along radial sampling tracks of different colonies of *E. rostrata*, allow us to estimate 14C-ventilation rates of the water masses that the corals experienced on centennial timescales. Our initial results document a centennial periodicity in the 14C ventilation ages in this region of the Pacific Basin.

## 4-21

**The P/ca, Ba/ca, And B/ca Proxies in The Solitary Deep Sea Coral *d.dianthus*: Mapping And Sources Of Contamination**

**Eleni ANAGNOSTOU*[1]**, Robert SHERRELL[2], Michele LAVIGNE[1], Jess ADKINS[3], Alex GAGNON[4]

[1]Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, [2]Institute of Marine and Coastal Sciences/ Department of Earth and Planetary Sciences, Rutgers University, New Brunswick, NJ, [3]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, [4]Division of Chemistry, California Institute of Technology, Pasadena, CA

We present skeletal proxies for nutrient and carbonate system seawater properties by measuring elemental ratios in globally distributed modern samples of *D. Dianthus*. Mean P/Ca, Ba/Ca, and B/Ca ratios for each coral, integrating multiple years of growth, are obtained for lines along the exterior surfaces of septa using 193nm laser ablation HR-ICP-MS, and are regressed against hydrographic data from nearby stations. P/Ca is strongly correlated with seawater phosphate ($D_{PO4}$~0.7, where D=element/Ca in coral divided by element/Ca in seawater; $R^2$~0.85), and Ba/Ca with seawater dissolved barium ($D_{Ba}$~1.8, $R^2$~0.96), while B/Ca is positively correlated with seawater pH. Additionally, we present 2-D maps of P/Ca, Ba/Ca, and B/Ca across different skeletal features including centers of calcification and surrounding aragonite, to identify possible non-environmental factors influencing skeletal elemental ratios. We also examine patterns of appearance of contaminant iron/manganese phases enriched in phosphorus that are incorporated into the skeletal structure. Finally, we summarize the above results to present possible mechanisms of incorporation of phosphorus, barium, and into the coral aragonite to explore the potential and feasibility of applying these deep sea coral proxies for reconstruction of past nutrient and carbonate system distributions.

## 4-22

**Stable Isotopes And Sr/ca Ratios Indicate Records Of Groundwater Influence On Florida Reefs**

**Peter SWART*[1]**, Sarah BELLMUND[2], Richard DODGE[3], Kevin HELMLE[4], Rene PRICE[5], Jeremy STALKER[5]

[1]MGG, University of Miami, Miami, FL, [2]NPS, Miami, FL, [3]Oceanographic Center, Nova Southeastern University, Dania, FL, [4]Oceanographic Center, Nova Southeastern University, Dania, FL, [5]Geology, Florida International University, Miami, FL

The waters off Elliot Key, within Biscayne National Park (BNP) in the United States, contain some of the longest lived specimens of *Montastraea faveolata* in the Caribbean. Previously we have noticed an inconsistency between measured water temperatures and temperatures estimated using the Sr/Ca and the □18O of the coral skeletons. This inconsistency is a result of the fact that the reefs are influenced by evaporated water emanating from Biscayne Bay as well as groundwater from the adjacent mainland. The water from Biscayne Bay is elevated in 18O, which influences the reefs to a greater extent during the summer thereby depressing the □18O amplitude of the skeleton. At the same time the ground and surface waters are highly elevated in calcium, resulting in lower than expected Sr/Ca ratios. This enhances the range of Sr/Ca in the corals. By combining these two proxies with measured SST data, it is possible to use the corals as proxies of the amount of freshwater discharge from the adjacent mainland. It is possible to distinguish surface water from ground water using the Ba/Ca ratio. Surface waters have elevated Ba/Ca ratios compared to ground water, and therefore distinctions between surface discharge and groundwater discharge can be assessed using this ratio in the coral skeletons. In this presentation we present (i) high resolution reconstructions (>40 samples per year) over the past 50 years from three sites in Biscayne National Park, and (ii) a lower resolution record extending back to ~1750.

## 4-23

**Historical Land Use Patterns Recorded By Coral Chemistry From Moloka'i, Hawaii**

**Nancy GRUMET PROUTY*[1]**, Michael FIELD[1]

[1]Coastal and Marine Geology, U.S.G.S., Santa Cruz, CA

Land-use practices, such as clearing and agriculture, can degrade river catchments and increase the amount of sediment flowing in rivers to the coastal ocean. An increase in erosion on the island of Moloka'i, Hawaii has been linked to intensification of farming, clearing of native vegetation, and introduction of both feral and domesticated grazing animals. The fringing reef of Moloka'i's southern coast has been the focus of several studies to understand the dynamics of sediment transport and its impact on coral reef health. These results have documented chronic turbidity in coastal waters that results from both flood discharge following heavy rains from a Kona storm and daily suspension of terrigenous sediment by trade-wind waves. The belt of suspended sediment extends across the reef flat and beyond.

It is difficult, however, to decisively demonstrate a clear link between land use patterns and changes in coral condition based on surveys alone. Geochemical proxy records from corals offer a technique for recording environmental changes. Because suspended sediment in river water contains minor levels of barium, as the river water enters the ocean, barium is carried to the ocean where corals incorporate it into their skeletons. Thus, coral Ba/Ca records provide in-situ baselines of past seawater quality. We collected a suite of coral cores from *P. lobata* heads from the fringing reef off south Moloka'i to investigate the link between sedimentation and coral reef ecosystem health due to chronic exposure to sedimentation; we also investigated the effects of infrequent, large scale events and perturbations due to modification of the coastline. Our results were compared to historical information from adjacent watersheds to compare present day conditions with those of the past several decades.

## 4-24

**Geochemical Analyses From Florida's 'Monster Coral': Reconstructing Environmental Changes From The Port Everglades Area Over The Last 100 Years**

**Amanda WAITE*[1]**, Kevin HELMLE[2], Richard DODGE[2], Peter SWART[1], J. Harold HUDSON[3]

[1]Marine Geology and Geophysics, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [2]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Dania, FL, [3]FKNMS (retired), NOAA, Miami, FL

In 2005, a 300+ year old colony of the star coral, *Montastraea faveolata*, was cored in 20 feet of water approximately 2 miles south of Port Everglades, Florida USA. Given the coral's latitude and proximity to the activity and impact of a large urban population and a large shipping and cruise port, it is considered exceptional for both its age and size. The specimen therefore may provide insight into the effects of South Florida's development on corals over time. Stable isotopic analysis of this coral's skeleton reveals δ18O values between -4.1 and -2.6‰, and δ13C values between -3.5 and +0.4‰. Both the oxygen and carbon isotopes demonstrate regular seasonal cyclicity. Minor element concentrations were also measured. Ratios of Sr/Ca, Mg/Ca, and Ba/Ca vary between ~9.1 and 9.6 mM/M, 5 and 13 mM/M, and 4.5 to 6.5 mM/M respectively, and depict annual fluctuations in concentration. X-radiography of slabs from this coral's skeleton reveals a 300 year chronology of seasonal density banding along with a period of anomalously high density from 1940 to 1970 which suggests that some sort of stress was acting on the coral. Re-evaluating the geochemical data in light of this density anomaly reveals, with few exceptions, little difference between the typical modern growth and the relatively high density period between 1940 and 1970. The exception to this is in the amplitude of stable isotopic variation, which does appear to be slightly suppressed where density was anomalously high in the coral with δ18O from -3.8 and -2.6 ‰ and δ13C between -2.5 and +0.4‰.

## 4-26

**Biologic Influence On Proxies Of Scleractinian Coral Skeleton**

**Anne JUILLET-LECLERC*[1]**, Stéphanie REYNAUD[2]

[1]LSCE, CNRS, Gif sur Yvette, France, [2]CSM, Monaco, France

The coral skeleton d18O is the most commonly used SST proxy essentially depending on external factors such as SST and water d18O.

Acropora cultured under variable light (equivalent to seasonal light variation) show systematic d18O fractionation. But, temperature and light lead to opposite responses with a lower effect due to light. This effect is associated to metabolic processes underlining the strong relationship between metabolism of symbiotic algae and skeleton formation. However, isotopic fractionation obeys to physical rules. Weber and Woodhead (1972) provided annual mean isotope values, statistically significant, partly rejecting vital effect. By using these data and introducing seawater d18O, we derived from these data Acropora calibration similar to ones of Epstein.

The question arises if this effect is specific to cultured Acropora? In order to estimate the influence of seasonality, we compared data measured on Porites colonies that developed close to each other in a well-constrained environment. Although deposited under identical conditions we obtain highly variable SST calibrations for different species, different colonies and even different sampling on a single head. This can be only explained by additional seasonal biologic effects. Light and temperature being the main seasonal changes, we conclude that both temperature and light, in addition to the physical SST influence, affect d18O through metabolism.

Based on these evidences we developed a new method using multi-proxies, which revealed that corals are likely a better archive than a simple isotopic thermometer.

## 4-27

**High-Resolution Acropora Cervicornis $\delta^{18}$o: Implications For Early Holocene Caribbean Temperatures And Position Of The Intertropical Convergence Zone**

**Lida TENEVA*[1]**, Lisa GREER[2], William PATTERSON[3]

[1]Earth and Environmental Sciences, Columbia University, Palisades, NY, [2]Geology, Washington and Lee University, Lexington, VA, [3]Geological Sciences, University of Saskachewan, Saskatoon, SK, Canada

High-resolution coral □18O data, coupled with precise dating techniques, have the potential to provide critical information on paleoclimate variability and tropical ocean-atmosphere interactions through time. Here we present paleotemperature data from well-dated pristine early Holocene (~9360-8900 years BP) *Acropora cervicornis* of the Enriquillo Valley, Dominican Republic. A new paleotemperature reconstruction equation based on previous *Acropora* coral culture studies (Reynaud et al. 2007) was used to calculate Holocene temperature variability. Taking into account deglacial changes in seawater □18O (Δ□18O) in the early Holocene, our data reveal lower temperatures than previously estimated using equations based on molluskan calcite (Epstein et al. 1953, O'Neil et al. 1969) and molluskan aragonite (Grossman and Ku 1986). Our calculations show the early Holocene in the Dominican Republic was ~4oC cooler than today's average (26.5-29.5oC). We consider this temperature difference unrealistic, and propose Dominican Holocene coral □18O data can be attributed to combined temperature and salinity effects. The latter refers to a precipitation effect associated with a northward incursion of the Intertropical Convergence Zone (ITCZ) in the early Holocene. Using the culture-based temperature equation, the modern annual temperature range of 3oC for the Dominican Republic would correspond to half the □18O amplitude observed in our study. Thus, precipitation changes likely played an important role in □18O signal variability since the deglacial Δ□18O contribution peaked at ~0.46‰. On first order, oxygen isotope records from this study show covariability in time with tropical ice cap $\square^{18}$O data from Huascaran, Peru and Sajama, Bolivia. This may imply that at least in the early Holocene, the northern Caribbean and northern South America may have derived their moisture from the same source at the same time (i.e. enhanced ITCZ precipitation).

## 4-28

**Eighty Years Long Oxygen And Carbon Isotopic Data Series From A Southwestern Atlantic Coral**

**Ruy KIKUCHI*[1]**, Henning KUHNERT[2], Jürgen PÄTZOLD[3], Zelinda LEAO[1], Alexandre COSTA[4], Ricardo DOMINGUES[5], Marília OLIVEIRA[1], Carlos LENTINI[4]

[1]Geophysics and Geology Research Center, Universidade Federal da Bahia, Salvador, Brazil, [2]RCOM Research Centre for Ocean Margins, Universitaet Bremen, Bremen, Germany, [3]Universitaet Bremen, Bremen, Germany, [4]Institute of Physics, Universidade Federal da Bahia, Salvador, Brazil, [5]Institute of Geosciences, Universidade Federal da Bahia, Salvador, Brazil

The oldest sea surface temperature instrumental records available in Brazilian Navy records date from 1973, and climate proxy indicators in the Southwestern Atlantic are scarce, if not absent. Our project aim to evaluate the quality and reconstruct the longer possible time series of temperature record based on isotopic proxies in the endemic coral Mussismilia braziliensis skeleton. This species is the main reef builder in Abrolhos Reef Complex. Seasonal temperature amplitude in the region is about 4-5oC varying from about 23.5oC to 28.5oC. Turbidity and cloudiness are greater during winter when southern polar fronts tend to reach Brazilian Eastern Coast as far as 12oS. Among 15 cores taken in the region, one 70 cm long coral core (from 17o47,173'S, 39o02,935'W) was cut as a slab of 1,5 cm thick, X-rayed and sampled along a growth axis from top to bottom every 0,5 mm with a 0,8 mm wide drill. The analyses were made in a Finnigan MAT mass spectrometer coupled with an automated sampler. Both d18O and d13C exhibited a cyclical pattern that, in general, conforms to the density banding. Oxygen and carbon curves have inverse behavior relative do each other. d18O varies from -3.42 to -3.70‰ (VPDB) and d13C from 2.04 to -2.46‰ (VPDB). The seasonality in d18O, in the order of 0.4‰ is low compared to the expected seasonality 0.8‰-1.0‰, but is explained by the depletion in 16O that occurs during the summer in seawater (ca. 0.5‰). The 80 years represented by the isotopic data exhibit a decadal (ca. 12 years) variability and milder temperatures before the 70's. Highest temperature signal occur in the end of the 70's and beginning of the 80's and in 2001-2003.

## 4-29

**Corals As Recorders Of Land-Ocean Carbon Transport in Puerto Rico Using $\delta^{13}$c And Ba/ca**

**Ryan MOYER*[1]**, Andrea GROTTOLI[1]

[1]School of Earth Science, The Ohio State University, Columbus, OH

Rivers link terrestrial and marine ecosystems and influence the abundance, composition, and timing of carbon delivered to the coastal ocean. During periods of sustained high river discharge, the stable carbon isotope (δ13C) signature of coastal seawater DIC is likely influenced by the δ13C of the organic and inorganic carbon of the adjacent catchment. In coastal areas where coral reefs occur in close proximity to the mouths of rivers, coral skeletal δ13C should record deviations in seawater DI- δ13C during periods of high river discharge. Additionally, Ba in coral skeletons acts as a conservative tracer of freshwater pulses in coastal marine systems, and can be used to identify past flood events in coral cores. To further establish this connection and extend the record of river discharge, coral skeletal δ13C and Ba/Ca were measured in a *Montastraea faveolata* coral core collected approximately 400 m from the mouth of the Fajardo River (Puerto Rico). Cross-spectral analysis of coral skeletal Ba/Ca and river discharge yields significant bi-weekly coherence for the portion of the record where instrumental river discharge records are available (1979 - 2004). Coral $\delta^{13}$C and river discharge are annually coherent over this same time interval, with $\delta^{13}$C decreasing as discharge increases. Coral Ba/Ca and $\delta^{13}$C are also annually coherent over the entire 56-year record. These data suggest that such a multi-proxy approach is extremely valuable in elucidating periods of heavy river discharge where coral $\delta^{13}$C is likely affected by terrestrial carbon transport. In combination with previous work, the data also suggest that skeletal $\delta^{13}$C in corals growing near the mouths of small tropical rivers provide a record of terrestrial carbon delivery to the coastal ocean and coral reefs, as well as the land-use history of the river catchment.

## 4-30

**Corals At The Flower Garden Banks: Monitors Of Environmental Change And North American Climate Variability**

**Amy WAGNER*[1]**, Niall SLOWEY[1,2]

[1]Oceanography, Texas A&M University, College Station, TX, [2]Oceanography, Texas A&M University, College Station

The Pacific/North American (PNA) pattern is a dominant atmospheric pattern of climate variability in the extratropical Northern Hemisphere and strongly influences the winter climate of the southeast United States. The instrumental record used to characterize the PNA pattern does not exist prior to the mid-1940s. However, information about past variability in the PNA pattern is preserved in the skeletons of long-lived corals at the reefs of the Flower Garden Banks National Marine Sanctuary (NMS). The Flower Garden Banks NMS is located approximately 180 km south of the Texas/Louisiana border in the Gulf of Mexico and is the northernmost hermatypic reef on the United States continental shelf. It has previously been shown that linear coral extension rates at the Flower Garden Banks are highly correlated with winter air and sea surface temperatures. In addition, average winter temperatures in the southeastern United States are negatively correlated with the phase of the PNA pattern. During a positive phase of the PNA pattern, the southeast US experiences stronger and more frequent winter storms while a negative phase of the PNA pattern brings milder winters to the region. Thus, past coral extension rates at the Flower Garden Banks provide a means to reconstruct the history of temporal variations in the PNA pattern. We have collected several long cores of skeletal material from long-lived Montastrea faveolata and Siderastrea siderea coral heads from the Flower Garden Banks NMS. Annual extension rates have been determined based on X- radiographic analysis of high/low density growth bands and are used to characterize interdecadal variability associated with changes in the PNA pattern. In addition, the presence of winter stress bands due to below average water temperatures indicate winters with more severe and/or frequent storms. Analysis of these results will contribute directly to our understanding of the temporal character of interannual and interdecadal variations of North American winter climate.

## 5-2

**The Transition From Autotrophy To Heterotrophy in The Coral Montastraea Cavernosa Over A Depth Range Of 3 M To 91 M**

**Michael LESSER*[1]**

[1]Department of Microbiology, University of New Hampshire, Durham, NH

Most studies on coral reefs have focused on shallow reef (<30 m) systems. This is not surprising given the technical limitations of conducting scientific diving deeper than 30 m. Recently the technical limitations of deep reef research have been overcome by the introduction of mixed gas technical diving (both open circuit SCUBA and closed circuit rebreathers) to the scientific diving community. Our lack of knowledge about deep reef environments, and in particular coral populations, has slowed our broader understanding of the ecology, connectivity, and biodiversity of coral reef communities. We know that the light environment is an important component of the productivity, physiology, and ecology of corals and restricts the distribution of most species of coral to depths of 60 m or less. In the Bahamas one of the deepest occurring corals is Montastraea cavernosa and it is found at depths exceeding 90 m. Using a range of optical, physiological, and biochemical approaches the relative dependence on autotrophy versus heterotrophy was assed for this coral from 3 m to 91 m. It was observed that the quantum yield of PSII fluorescence for this species increases significantly with depth while gross primary productivity decreases with depth. While morphological and physiological photoacclimatization is evident down to 91 m, stable isotope data of the tissues, symbionts, and skeleton show a marked decrease in overall metabolism and a sharp transition to heterotrophy between 45 and 61 m that is consistent with previous studies and models despite the fact that the 1% light level in this system occurs at 80 m. Food and light limitation below these depths appear to induce severe energy conservation in these corals, and the deep "Twilight Zone" appears to support significantly fewer, slower growing, individuals of M. cavernosa.

## 5-3

**Effect Of Light And Feeding On The Fatty Acid And Sterol Composition in *Turbinaria Reniformis***

Treignier CLAIRE[1], Grover RENAUD[1], Tolosa IMMA[2], **Ferrier-Pagès CHRISTINE*[1]**

[1]CSM, Monaco, Monaco, [2]IAEA, Monaco, Monaco

We investigated the effect of light and feeding on the composition and □13C signature of the fatty acids (FA) and sterols of the scleractinian coral *Turbinaria reniformis*. Other parameters (calcification, photosynthesis, chlorophyll concentrations) were also measured. Nubbins were maintained during six weeks under two light (100 and 300 µmoles photons m-2 s-1) and feeding (starved and fed) levels in a factorial experiment. In all conditions, polyunsaturated fatty acids (PUFA) such as C18:4 n-3, C20:5 n-3, C22:6 n-3 were in higher concentrations in the zooxanthellae than in the host, suggesting that they were synthesized by the algae and transferred to the host. This lipid transfer was confirmed by a similarity in the □13C-lipid signatures between the host and the symbiont. High light increased rates of photosynthesis and growth in fed corals. Total concentrations of FA and sterols were also increased for corals maintained under high light, with significantly higher □13C values, compared to those exposed to low light. This supports the widespread theory of enhanced 13C fixation with increasing irradiance and photosynthesis. Feeding affected differently the coral metabolism depending on the light level. Under low light, feeding enabled corals to slightly increase their growth rates and accumulate greater concentrations of storage lipids (SAFA) and membrane constituents (PUFA and sterols). Conversely, under high light, energy provided by feeding increased calcification, chlorophyll and protein contents whereas. no change was noticed in lipid concentrations. Feeding enriched some FA (C14, C16, C18 and C22:4n-6) of the host tissue and of the zooxanthellae (composite C18:3n-6+C18:4n-3 and C22:6n-3) in 13C. Isotopic results also indicated that the animal did not assimilate directly the zooplankton FA, but he likely synthesised them from the selective assimilation of carbohydrates or amino acids contained in the food.

## 5-4

**Impacts Of Nitrogen On Great Barrier Reef Coral**

**Annamieke VAN DEN HEUVEL*[1]**, William LEGGAT[2], David YELLOWLEES[2], Sophie DOVE[1]

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia, [2]School of Pharmacy and Molecular Sciences, James Cook University, Townsville, Australia

Elevated levels of inorganic nitrogen can have severe impacts on coral health. Key to understanding why corals respond detrimentally to elevated inorganic nitrogen is to fully comprehend the pathways involved in nitrogen uptake and assimilation for both the symbiont and host. This study examined the effects of elevated nitrogen on the coral-algae symbiosis. Coral fragments of Acropora aspera were collected from the reef flat of Heron Island, Australia and exposed to high concentrations of ammonium and nitrate in separate treatments. Fragments were sampled throughout the day for changes in the expression profile of ammonium transporters, nitrate transporters and glutamate synthase. Real Time PCR revealed that changes in the concentration of both ammonium and nitrate affected the expression profile of these genes. In addition, characterization of ammonium transporters from Symbiodinium sp. symbiotic with A. aspera, show high sequence conservation. Sequence analysis shows Symbiodinium transporters come from two distinct ammonium transporter families, the eukaryotic like AMT1 family and the prokaryotic like AMT2 family. This is the first time that ammonium transporters have been characterised in dinoflagellates and that members of the AMT2 family have been identified outside of bacteria and higher plants.

## 5-5

**Symbiotic Intertidal Temperate Sea Anemones (Anthopleura Spp.): Their Contribution To Our Understanding Of Cnidarian-Algal Symbioses.**

**Gisele MULLER-PARKER*[1]**

[1]Biology, Western Washington University, Anacortes, WA

The first evidence for direct transfer of photosynthetic carbon from zooxanthellae to the host was obtained for the temperate anemone *Anthopleura elegantissima* by L. Muscatine in 1958. Since then, researchers have concentrated on the relationship between zooxanthellae and tropical corals and anemones, major contributors to coral reef primary productivity. This effort has assumed increased urgency with the need to understand the mechanisms of coral bleaching and to predict how symbioses will continue to respond to climate change. Symbiotic associations in temperate regions offer relevant comparisons in both environmental conditions and the physiological responses of zooxanthellae. Anemones in the temperate intertidal zone are of particular interest, as they are exposed to pronounced fluctuations in air and seawater temperature on time scales ranging from hourly to decadal, and they host multiple symbionts with different tolerances to temperature. Our work with *Anthopleura elegantissima* has revealed exceptionally broad thermal tolerance (~15oC) for growth and photosynthesis of zooxanthellae. The distribution patterns of two zooxanthellae and a green algal symbiont within the host are strongly correlated with physiological tolerances of the algae to temperature, suggesting environmental control of algal complements. However, anemones in the Pacific Northwest with mixtures of symbionts predominantly contain algae of one type; 50:50 mixtures are extremely rare and probably inherently unstable and suggestive of host control. Also in contrast with tropical cnidarians, *A. elegantissima* hosts constant population densities of algal symbionts year-round, despite 7-fold reductions in light during winter. This is probably accomplished through a reduction in growth and expulsion of algae, coupled with algal heterotrophy. These results, and future studies with temperate associations, are important in the development of general models to help predict the effects of climate change on algal-cnidarian symbioses.

## 5-6

**Acquisition And Allocation Of Carbon in Bleached Hawaiian Corals**

**Andrea GROTTOLI*[1]**, Adam HUGHES[2,3], Tamara PEASE[2]

[1]School of Earth Sciences, The Ohio State University, Columbus, OH, [2]Department of Marine Science, The University of Texas at Austin, Port Aransas, TX, [3]School of Earth Sciences, The Ohio State University, Columbus

Photosynthesis and growth are dramatically reduced in bleached corals. *Montipora capitata* corals compensate by dramatically increasing heterotrophy, while *Porites compressa* corals sustain themselves by utilizing their stored energy reserves when bleached. Here, we further assessed how photosynthetically and heterotrophically acquired carbon is acquired, allocated, and utilized among the host tissue, zooxanthellae, and skeleton in bleached and non-bleached *P. compressa* and *M. capitata* corals using 13C-labeled bicarbonate in seawater and 13C-labeled rotifer pulse chase labeling techniques. Photosynthetically acquired carbon was taken up from bicarbonate by the zooxanthellae, transferred to the host tissue, respired, and taken up by the skeleton at dramatically lower rates in bleached corals relative to controls. In both bleached and non-bleached corals, the photosynthetically derived carbon appeared to be the primary source of carbon for calcification but was not incorporated into either the zooxanthellae or host tissue for long-term storage. In contrast, heterotrophically-derived carbon (i.e., rotifers) was rapidly translocated between the zooxanthellae and host tissues in bleached and non-bleached *M. capitata* and non-bleached *P. compressa* (but not bleached *P. compressa*), was not a source of carbon for calcification, and appears to be the primary source of carbon for long-term tissue growth and carbon storage. Thus, long-term recovery from bleaching will depend on a coral's ability to acquire fixed carbon via heterotrophy to support its tissues while bleached, and to regain photosynthesis in order to stimulate calcification.

## 5-7

**When Is Not Bleaching "Unhealthy" For Corals And/Or Coral Reefs?**

**Sophie DOVE*[1]**, George ROFF[1], Simon DUNN[1]

[1]Centre for Marine Studies, University of Queensland, St Lucia, Australia

"Thermal tolerance" and "bleaching tolerance" are used interchangeably in the coral literature. Furthermore the subject who is "tolerant" is often very vague with unexplained transitions from symbiont to host and/or coral reef ecosystems. Any of these levels are viewed as "healthy", as long as they are not bleached. Mass coral bleaching events where entire coral reef ecosystems turn white, accompanied by the sulfurous smells of death are obviously unhealthy; but how universally applicable is this label to colonial corals that tend to reduced symbiont densities in actively growing regions and on a seasonal basis, or to symbionts that have the ability to increase or maintain productivity by reducing the chlorophyll concentration of their light harvesting antennae? Conversely, as observed by Len Muscatine, symbiont densities are linked to quantity of carbon-skeletons leaked to the host. A more parasitic symbiont may fail to bleach simply because it passes on any losses in productivity to the host by reducing the quantity of fixed carbon translocated. In this way, a greater pool of energy is retained by the symbiont to repair photosystems and maintain symbiont populations at the expense of host metabolic activity or health. Data will be presented demonstrating that (i) corals can be 80% bleached, supporting remnant symbionts with 3 fold greater Pnet max cell-1 than adjacent non-bleached corals; (ii) that symbiont cultures can be at least 60% bleached yet growing at 2.5 times the rate of unbleached cultures. The results from 14C experiments on whole colonies from a variety of host-symbiont associations exposed to temperature x CO2 treatments, and starved at tips or bases will also be presented to monitor effect of treatment on carbon translocation not only between symbiont and host, but also between polyps.

## 5-8

**The Importance Of Zooplankton To The Total Energy Budget Of Healthy And Bleached Corals At Two Depths**

**James PALARDY*[1]**, Lisa RODRIGUES[2], Andrea GROTTOLI[3]

[1]Department of Ecology & Evolutionary Biology, Brown University, Providence, RI, [2]Department of Geography and the Environment, Villanova University, Villanova, PA, [3]School of Earth Sciences, Ohio State University, Columbus, OH

Bleached and non-bleached fragments of three species of Hawaiian corals were exposed to enhanced and ambient concentrations of zooplankton at 1 and 6 m depth to determine the contribution of zooplankton to the coral's total energy budget. The size and taxonomic grouping were recorded for every zooplankton captured and the relative input of zooplankton of different size classes determined. The contribution of heterotrophic carbon to animal respiration (CHAR) was calculated using an improved calculation method that included the proportionate contribution of zooplankton from all size classes. The results show that feeding rates followed the same pattern in both ambient and enhanced zooplankton concentrations. Corals captured the same size and assemblage of zooplankton under all evaluated conditions, and preferentially captured plankters smaller than 400μm. Feeding rates increased with depth in non-bleached corals, but not in bleached corals. Relative to non-bleached fragments at the same depth, feeding rates of bleached Montipora capitata increased, Porites compressa decreased and Porites lobata remained unchanged at both 1 and 6 m depth. Therefore, the response of corals to the same disturbance may vary considerably. The calculated CHAR values show that heterotrophic carbon from zooplankton plays a much larger role in the total energy budget of corals than was previously estimated, and may account for over 65% of some coral species' daily metabolic energy requirements when healthy and over 200% when bleached. Our results show that heterotrophically acquired carbon makes a significant contribution to the total carbon budget of corals under all conditions and depths, and suggests that nutrient acquisition via zooplankton feeding may play a significant role in coral-algal symbiosis balance.

## 5-9

**Unravelling Coral Photoacclimation: *symbiodinium* Strategy And Host Modification**

**Sebastian HENNIGE*[1]**, David SMITH[1], Kathleen MCDOUGALL[2], Mark WARNER[3], David SUGGETT[1]

[1]Coral Reef Research Unit, University of Essex, Colchester, United Kingdom, [2]Environmental Research Institute, North Highland College, Caithness, United Kingdom, [3]College of Marine Studies, University of Delaware, Lewes, DE

Light is often the most abundant resource within the nutrient poor waters surrounding coral reefs. Consequently, zooxanthellae (*Symbiodinium spp.*) must continually photoacclimate to optimise productivity and ensure coral success. To accurately assess *Symbiodinium* photoacclimation *in situ*, differences in acclimation strategies and bio-optical signatures need to be characterised between genetic types of *Symbiodinium.* Using a systematic series of laboratory experiments, eight types of *Symbiodinium* were cultured and examined using techniques such as active (FIRe) fluorescence, Photosystem I (PSI) and II counts, spectrophotometry and high performance liquid chromatography. Two key 'strategies' of photoacclimation are known to exist amongst microalgae: a preferential modification of the light harvesting antennae (□-based) or of the reaction centre bed (n-based) for PSII and/or PSI. Our measurements demonstrated that acclimation strategies employed by *Symbiodinium* were highly varied between algal type but despite this variability, many optical signatures were conserved. Also, when absorption was considered per photosystem, a 1:1 balance was observed between PSI and PSII. Acclimation strategies of intact *Acropora formosa* and *Seriatopora caliendrum* at two light levels were further examined using fluorescence and optical signatures to determine host contribution to acclimation. Overall, our results demonstrated that (1) biophysical (active fluorescence, photosystem-specific) but not bio-optical signatures were highly variable between algal types; consequently, bio-physical signatures that are altered by an adaptation of the algal community structure may be misinterpreted as photoacclimation and (2) host acclimation and modification of the light environment plays a key role in *Symbiodinium* photoacclimation.

## 5-10

**Combining O2 Microsensors And Fiber-Optic Technology To Measure Photo-Physiological Responses Of Symbiodinium**

**Karin ULSTRUP*[1,2]**, Michael KÜHL[1], Peter RALPH[2], Madeleine VAN OPPEN[3], David BOURNE[3]

[1]Department of Biology, Marinbiological Laboratory, University of Copenhagen, Helsingør, Denmark, [2]Department of Environmental Science, University of Technology, Sydney, Sydney, Australia, [3]Australian Institute of Marine Science, Townsville, Australia

Corals associate with a diverse microbial assemblage of which endosymbiotic and phototrophic microalgae, i.e. dinoflagellates belonging to the genetically diverse genus Symbiodinium, are best known. Traditional techniques to estimate photosynthesis activity such as oxygen exchange and 14C-incorporation of Symbiodinium are confounded by processes due to the coral host. In three case studies we employed a novel approach using two technologies that enable differentiation of the photosynthesis activity of Symbiodinium, pulse-amplitude-modulation (PAM) and O2 microsensors. The case studies included i) monotypic Symbiodinium associating with a coral (Pocillopora damicornis), ii) a ciliate forming a brown band on the coral Acropora muricata, and iii) a genotypically diverse Symbiodinium association with Acropora valida. In all instances, the combination of fibre-optic technology and an O2 microelectrode enabled parallel measurements of gross photosynthesis rate and photosystem II quantum yield at the coral surface under steady-state conditions as a function of increasing irradiances. The studies showed large plasticity in photo-physiological acclimation of Symbiodinium linked to light microclimate as well as motility (in the case of the ciliate) and Symbiodinium genotype (in the case of A. valida). In case i) and iii) there was non-linearity between relative electron transport rate (rETR) and gross photosynthesis measurements at moderate to high irradiances possibly due to vertical heterogeneity of the symbionts in the tissue and/or the operation of an alternative electron pathway such as cyclic electron flow around PSII. Case ii) demonstrated that Symbiodinium ingested by ciliates are photosynthetically competent and do not become compromised during the progression of the brown band zone. In contrast to case i) and iii) the symbionts produced relatively high gross photosynthesis rate and rETR at moderate to high irradiance due to greater efficiency of light absorption caused by a higher density of symbionts in the ciliate.

## 5-11

**Coral Holobionts Over Large Depth Ranges: Investigating The Roles Of Host Species, Colour Morphs And Functional Diversity Of Algal Symbionts**

**Pedro R FRADE*[1,2]**, Rolf PM BAK[1,2]

[1]Marine Ecology and Evolution, Netherlands Institute for Sea Research, Den Burg, Netherlands, [2]Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Amsterdam, Netherlands

We investigate the roles of host and symbiont on the *in situ* physiological response of coral genus *Madracis* holobionts towards light. Across a large depth gradient (5-40 m) and for four *Madracis* species, we studied the *Symbiodinium* identity as defined by rDNA ITS2 sequence variation and assessed a large set of functional variables by measuring chlorophyll *a* fluorescence, photosynthetic pigment composition and symbiont population descriptors. The same approach was applied on three colour morphs of the species *Madracis pharensis*. Overall, three symbiont types were identified, whose distributions are strong evidence for niche partitioning by depth, host species and colour morphs, as shown by logistic regression models. Multivariate analyses on the functional variables indicated most of the holobiont variation to be explained by few main photobiological components, which are ranging from environmentally flexible to more genetically constrained. Thus, photochemical or photosynthetic efficiencies are highly variable with external environment; symbiont cell densities and sizes strongly depend on genetic identity; and xanthophyll-cycle photoprotective pigments are regulated by both host and environment. This interaction between host and environment highlights the role of host properties in adjusting the internal environment available for the endosymbionts. The functioning of symbiont types plays a significant role in coral adaptation along reef slopes. Furthermore, different holobiont strategies are recognized, which vary in their optimization of light harvesting or protective mechanisms and which relate to host species or colour morph distribution and dominance over the reef slope.

## 5-12

**Phototropic growth and molecular basis for axial polyp differentiation in the branching coral Acropora aspera**

**Paulina KANIEWSKA*[1]**, Paul CAMPBELL[2], Maoz FINE[3], Ove HOEGH-GULDBERG[1]

[1]University of Queensland, Brisbane, Australia, [2]Department of Primary Industries and Fisheries, Brisbane, Australia, [3]Bar-Ilan University, Eilat, Israel

Reef building corals have high morphological variation across coral families, with many species also displaying phenotypic plasticity across environmental gradients. In particular, the colony geometry of branching corals is altered by the frequency, location and direction of branch initiation and growth. The environmental cues and molecular signaling pathways involved in axial polyp differentiation, the basis for new branch formation, are currently unknown. This study demonstrates that for the branching species *Acropora aspera*, light plays a key role in axial polyp differentiation. *A. aspera* branches exhibited a directional growth response, where axial polyp structures only developed when light was available, and towards the incident light. Field experimentation revealed that there was a light intensity threshold of 45 µmol photon m-2 s-1, below which axial polyp structures would not develop and this response was blue light (400 nm to 500 nm) dependent. There was a fourfold increase in axial polyp structure growth above this light intensity threshold. These features of coral branch growth are highly reminiscent of phototropic branch growth in terrestrial plants, which is directed by the blue light component of sunlight. To understand molecular signals involved in axial polyp differentiation, experiments investigating differential expression of genes in axial and radial polyps were conducted. This study is the first to present genes involved in axial polyp differentiation and therefore branch initiation. Here we indicate that a negative feedback may be involved. These results present a new avenue for discovering molecular processes involved in colony integration, an area which should become increasingly more important if we are to understand the complex responses of corals at a colony level to environmental change.

## 5-13

**The Role Of Photorespiration in The Symbiotic Association Between Dinoflagellates And Scleractinian Corals**

**Alicia CRAWLEY*[1]**, Ken ANTHONY[1], Sophie DOVE[1]

[1]Centre for Marine Studies, University of Queensland, St Lucia, Australia

Rising $CO_2$ levels in the sea threaten to break-down the important relationship between reef-building corals and their symbiotic dinoflagellates. Photorespiration plays a significant role in maintaining dinoflagellate well-being by offering an alternative photochemical-quenching pathway and potentially triggering the Carbon-Concentrating Mechanism. As photorespiration is dependant on the ratio of $CO_2$ to $O_2$, rising $CO_2$ may ultimately lead to reduced capacity for photoprotection and increased occurrence of coral bleaching. Here we present data from a microcosm experiment with controlled levels of $CO_2$ and $O_2$. Physiological data has been derived from classical respiration measurements to produce Photosynthesis-Irradiance (P-E) curves. The P-E curves showed a decline in symbiont production at the highest $CO_2$ level (1100 ppm, pH 7.6). Excitation pressure, measured with a pulse amplitude modulation fluorometer, increased significantly with increasing $CO_2$ and decreasing $O_2$. However, these relationships were dependant on the proximity of growth light to saturating light intensities. We observed calcification at pH 7.8 but decalcification at pH 7.6 using the total alkalinity technique. These findings were closely linked to the gene expression of a key enzyme in the photorespiratory pathway, phosphoglycolate phosphatase (PGPase). mRNA of PGPase declined significantly by 54% at 560 ppm $CO_2$ (pH 7.8) and by 70% at 1100 ppm $CO_2$ (pH 7.6). This decline in photorespiration at high $CO_2$ provides a key insight towards the mechanism of $CO_2$-induced bleaching.

## 5-14

**Directed Pocilloporin Expression And Amino Acid Translocation in Response To Physical Injury in Scleractinian Coral Colonies**

**Jeffry DECKENBACK*[1]**, Sophie DOVE[1]

[1]Centre for Marine Studies, University of Queensland, St Lucia, Australia

This research focused upon the potential for coral colonies to collect dissolved organic materials from external sources in response to physical injury and to translocate these materials in a specific manner in order to aide in regrowth and/or increased pocilloporin production. Within healthy coral tissues, myriad biochemical pathways exist both to harvest solar energy and prevent photo-inhibition by blocking or channelling excess energy that would otherwise damage the photosystems. Calcium carbonate skeleton exposed by injury may increase the path length of incident visible wavelength photons, reflecting them into the already disturbed tissues that border the sites of injury. By pooling and reallocating biochemical resources as appropriate, Scleractinian coral colonies can decrease the cost of regrowth to polyps at the site of injury by spreading this cost throughout the whole colony. Observations identified bands of bright pigment, likely a pocilloporin variant, surround sites of injury within 48 hours of initial injury. 14C-labelled amino acids were injected into selected artificially injured colonies of tan morph *Montipora sp.* and allowed to incubate. Upon appearance of pigment bands at injury sites, samples were collected to quantify host pigment content, mRNA signal expression, amino acid content, and total radioactivity. Injured corals expressed a strong response to physical injury, collecting available amino acids and allocating these within the colony as required to start the regrowth processes while also up-regulating pocilloporin mRNA signal expression within polyps closest to the site of injury. At the site of injury, regrowth was observed within two days, creating a region distinct from both the healthy tissue and exposed skeleton. Within this region, chlorophyll-specific absorbance was significantly lower than within healthy tissues, but pocilloporin-specific absorbance was unchanged relative to healthy tissues. In all, the coral colonies demonstrated very active and directed healing and recovery responses in response to physical injuries.

## 5-15

**The Effect Of Fluctuating Light On *symbiodinium* Photosynthetic Gene Expression**

**Lynda BOLDT*[1]**, David YELLOWLEES[2], Sophie DOVE[3], Bill LEGGAT[2]

[1]School of Pharmacy and Molecular Sciences, James Cook University, Townsville, QLD, Australia, [2]School of Pharmacy and Molecular Sciences, James Cook University, Townsville, Australia, [3]Centre for Marine Studies, University of Queensland, Brisbane, Australia

This study examined the membrane bound light harvesting proteins of *Symbiodinium*, an endosymbiotic dinoflagellate of reef building corals as well as other marine invertebrates. We investigated whether genes involved in photosynthesis are differentially expressed on a diurnal basis and if known physiological responses can be linked with differential gene expression. Putative membrane bound light harvesting proteins of *Symbiodinium* isolated from *Acropora aspera* collected from the reef flat surrounding Heron Island were characterized with several indicating homology with red algae while the major homology was with other dinoflagellate light harvesting proteins. To further elucidate the relationship between light and *Symbiodinium* photosynthesis, *Symbiodinium* isolated from *Acropora formosa* collected from Orpheus Island, part of the Palm Island group on The Great Barrier Reef, were analysed and photosynthetic gene expression compared with samples exposed to no light over a 24 hour period. While there were no significant physiological differences or variation in photosystem II functionality between coral branches exposed to no light and those exposed to diurnal light fluctuations, the response of various genes involved in photosynthetic processes did vary diurnally. This work is the first to examine the putative membrane bound light harvesting proteins of *Symbiodinium* and confirm that photosynthetic genes of *Symbiodinium* isolated from a reef building coral are differentially expressed on a diurnal basis and that the removal of light results in the down regulation of key light dependent photosynthetic genes.

## 5-16

**Light Energy Transformation Processes By Fluorescent Pigments Of Corals**

**Anya SALIH*[1]**, Yuri ZAVOROTNY[2]

[1]Confocal Bio-Imaging Facility, University of Western Sydney, Penrith, Australia, [2]Advanced Laser Technologies Department, Institute of Laser and Information Technologies RAS, Moscow, Russian Federation

Tissues of reef building corals are pigmented by multi-colored and fluorescent proteins belonging to a family of GFPs (Green Fluorescent Proteins). Experimental evidence indicates that one of the major biological functions of these pigments is in light regulation and photoprotection by light absorption, scattering and energy transformation via fluorescence. Here we examine the different modes of energy transformation by GFP-type proteins in tissues of shaded, light-acclimated and bleached Great Barrier Reef (Australia) corals using steady state fluorescence spectroscopy and Fluorescence Life-Time Imaging (FLIM) confocal microscopy. We show that corals can dynamically regulate energy transformation properties of their tissues in response to light as it passes through pigments. In low light corals, Förster resonance energy transfer (FRET) capacity of tissues was reduced compared to high light corals and both non-radiative FRET and radiative energy channelling capacity were increased in the latter. Cellular fluorescence lifetimes were highest in several acroporiid bleached species examined, indicating that GFP-type proteins increased cellular capacity to dissipate excessive incident light. Since light energy transfer processes among chlorophyll molecules determine the photosynthetic efficiency of coral's symbiotic microalgae, FLIM of symbionts in live tissues was also used to provide a rapid and efficient means to access their health. At high irradiances, chlorophyll lifetimes of GFP-pigmented tissues were shorter than of less pigmented ones, indicative of less photo-stressed microalgae. Our study showed that confocal micro-spectral imaging in combination with FLIM provides a rapid and an accurate method to visualise and analyse cellular and optical properties of the coral host and to quantitatively determine the photosynthetic capacity of the symbionts. The study provides important information about the physiological responses of the host to light, the cellular mechanisms it uses to counteract photo-stress and to reduce the susceptibility to bleaching.

## 5-17

**Roles And Origins Of Superoxide Dismutases in A Symbiotic Cnidarian**

**Paola FURLA*[1]**, Sophie RICHIER[2], Pierre-Laurent MERLE[1], Ginette GARELLO[1], Amandine PLANTIVAUX[3], Didier FORCIOLI[1], Denis ALLEMAND[4]

[1]EA ECOMERS, Nice-Sophia Antipolis University, Nice cedex 02, France, [2]UMR 7093, Villefranche-sur-mer oceanological observatory, Villefranche-sur-Mer Cedex, France, [3]NUI Galway, Galway, Ireland, [4]Scientific Center of Monaco, Monaco, Monaco

Cnidarians living in symbiosis with photosynthetic dinoflagellates daily experience hyperoxia state due to the photosynthetic activity of the symbiont. Studies on the symbiotic sea anemone, Anemonia viridis, showed an increase of three-fold normoxic value within the coelenteric cavity after 20 minutes of light exposure. However, no accompanying oxidative damage was observed suggesting the presence of efficient antioxidant defenses. Among them, superoxide dismutases (SOD) constitute the first line of antioxidant defense. A detailed analysis of this enzyme family in both host tissues and symbionts showed several particularities in 'symbiotic cnidarians' such as high isoform diversity and presence of extracellular SOD and common isoforms between the two partners. Eight SOD isoforms have been identified belonging to four SOD classes : 4 Manganese SOD (MnSOD), 1 intracellular copper-zinc SOD (CuZnSOD), 1 extracellular copper-zinc SOD (ECSOD) and 2 iron SOD (FeSOD). Although both intracellular and extracellular CuZnSOD were localized exclusively to the cnidarian host tissues MnSOD and FeSOD isoforms are shared between the two partners. Investigation of the genetic origin of these shared SODs unveiled high degree of co-evolution between the two organisms inferring mechanism of protein translocation and events of horizontal gene transfert.

## 5-18

**Morphological Dependence Of The Variation in The Light Amplification Capacity Of Coral Skeleton**

**Susana ENRÍQUEZ*[1]**, Eugenio MÉNDEZ[2], Ove HOEGH-GULDBERG[3], Roberto IGLESIAS-PRIETO[1]

[1]Unidad Académica Puerto Morelos, Universidad Nacional Autonoma de Mexico, Cancun, Mexico, [2]Departamento de Óptica, CICESE, Ensenada, Mexico, [3]Center for Marine Studies, University of Queensland, Brisbane, Australia

Multiple scattering produced by the highly reflective aragonite coral skeleton, has been associated with a strong increment in the light absorption capacity of the symbiotic algae. For a Caribbean scleractinian coral used as a model organism, it has been quantified that algal pigments in the intact tissues are between 2 and 5 times more efficient for absorbing light than freshly isolated cell suspension containing similar amount of pigments. Theoretical calculations based on a flat lambertian surface indicate amplification factor up to three. More complex structures or concave surfaces are expected to have much higher values, although are theoretically intractable. Here, we analyzed the variability in the light amplification capacity of naked coral skeletons associated with the variation in skeleton morphology. We quantified the capacity of light amplification of 76 Indo-Pacific coral species belonging to 9 different families. Among them, 49 species belonged to the Faviide family. We found large variation among coral skeleton morphologies, in their light amplification capacity, from a minimum of 3 shown by the species *Caulastrea curvata* to a maximum of 10 shown by *Echinopora lamellose*. These results confirm the importance of coral skeleton morphology for understanding algal light environment and the magnitude of pigment packaging within coral tissue. We will discuss the patterns found in this comparison and their evolutionary implications.

## 5-19

**Characterization Of Optical Properties Of Reef-Building Coral Skeletons**

Vadim BACKMAN[1], Margaret SIPLE[2,3], Erin DALY[2], Andrew FANG[2], Mark WESTNEAT[4], Vladimir TURZHITSKY[1], Jeremy ROGERS[1], **Luisa MARCELINO*[2,3]**

[1]Biomedical Engineering Department, Northwestern University, Evanston, IL, [2]Civil and Environmental Engineering, Northwestern University, Evanston, IL, [3]Zoology, Field Museum of Natural History, Chicago, [4]Zoology, Field Museum of Natural History, Chicago, IL

A successful symbiotic algae-coral partnership is largely determined by the efficiency with which reef-building corals absorb light. This is achieved in two major ways: by controlling symbionts/pigment concentration and by multiple light-scattering in the skeleton resulting in homogenization of the light available to the coral tissue. Here we propose that light redistribution needs vary among corals with different growth forms. We characterized the optical properties of coral skeletons using a novel technique, low-coherence enhanced-backscattering (LEBS). We measured light mean free-path length (ls) in coral skeletons grouped into three growth forms: Branching, Massive and Laminar. We found that ls is significantly longer in Branching compared with Massive and Laminar corals. Longer ls results in a better redistribution and delivery of light to the shaded parts of a coral colony and increases the amplification of light availability to the entire colony. We tested if skeleton density determines these observed optical properties. Branching and Laminar corals had significantly higher densities then Massive corals. This agrees with previous studies: greater density is required by Branching and Laminar corals to support their mechanical stability. However, increased skeletal density typically results in shorter ls. To reconcile these observations, we measured the micro-architecture of coral skeletons using LEBS. We found that the length-scale of nanoscale density variation (i.e. granularity) is lower in Branching corals than in Massive or Laminar. According to light-scattering theory, this finer granularity results in longer ls. Thus, the nanoarchitecture of Branching corals ensures long distances of light transport necessary for light delivery to coral tissue without sacrificing their mechanical stability. Because light transport in coral is responsible for the amplification of light availability to coral tissue and Branching corals show higher bleaching-related mortality, this finding may have implications for differential bleaching resistance in different corals.

## 5-20

**In Hospite Operation Of The Photosystem Ii Repair Cycle in Symbiotic Dinoflagellates**

**Xavier HERNANDEZ-PECH*[1]**, Roberto IGLESIAS-PRIETO[1]

[1]Unidad Academica Puerto Morelos ICMyL UNAM, Puerto Morelos, Mexico

Photosynthesis by symbiotic microalgae is a fundamental process in coral reefs. Algal photosynthesis can provide more than 100% of the metabolic requirements of the intact symbiotic association. The maintenance of optimal photosynthetic rates in nature is achieved by balancing the rates of light-induced damage of photosystem II (PSII) with the *de novo* synthesis of PSII. The intracellular environment in which symbiotic dinoflagellates flourish experiences dramatic diurnal oscillations in O2 concentrations. During the daylight hours, *p*O2 can be as high as 300% saturation, whereas during the nighttime, *p*O2 may reach values as low as 5%. These conditions may modify the rates of damage and repair of PSII in hospite. To understand the factors that control the regulation of photosynthesis in hospite, we inhibited protein synthesis with chloramphenicol (50mg/L) and Licomycine (50 µg/L) on *Porites astreoides* nubbins exposed to half of the surface irradiance in external aquariums. Synthesis was inhibited during one hour at different times of the day. A continuous inhibition treatment from 6 am to 2 pm, and a control treatment without inhibition were maintained. PSII charge separation efficiency (ΔF/Fm`) was monitored every hour during the experiment. Our data showed significant reduction on ΔF/Fm` proportional to the time of exposure and light intensity at which synthesis was inhibited. In the experimental treatments, ΔF/Fm` fail to recover at dusk. These losses were proportional to the light intensity and time of inhibition. Our analyses revealed average lifetimes for PSII of 3.1 hours, suggesting that this process consume large amounts of energy that could not be translocated to the coral host.

## 5-21

**Asymbiotic Coral Larvae Preferentially Acquire Free-Living Symbiodinium From The Sediment Rather Than From The Water Column**

**Lisa ADAMS*[1]**, Vivian CUMBO[2], Misaki TAKABAYASHI[1]

[1]Marine Science Department, University of Hawaii at Hilo, Hilo, HI, [2]James Cook University, Townsville, Australia

Primary or secondary acquisition of free-living Symbiodinium could influence recovery, resilience, and long-term adaptation of many species of symbiotic marine invertebrates. Previous studies have identified environmental populations of free-living Symbiodinium in the water column and sediments of coral reefs. The diversity, abundance, and distribution patterns of these free-living Symbiodinium that are acquired by animal hosts are not well characterized to date. We conducted tank experiments to test whether asymbiotic coral larvae of Acropora monticulosa acquired free-living Symbiodinium from the water column or sediment. Treatments included natural sediment and filtered (0.22um) seawater (FSW), natural sediment with unfiltered seawater (SW), no sediment with FSW, and no sediment with SW. In treatments containing natural sediment, 40 +/- 8.2 % of larvae had acquired Symbiodinium after 3 days of exposure, and 80-90 +/- 7.85 % by 6 days of exposure. The Symbiodinium densities within the larvae were highly variable at all time points. In treatments without natural sediment, acquisition of Symbiodinium was not evident until day 6, and only up to 20 +/- 10 % of the larvae were infected throughout the 12-day experiment. Furthermore, Symbiodinium densities in larvae of seawater treatments were consistently low, averaging 1-2 cells per larva. Results from this experiment indicate that infaunal population of Symbiodinium is more accessible for asymbiotic larvae of A. moticulosa either because the infaunal population of Symbiodinium is higher than in water column, the infaunal Symbiodinium is more viable than their counterpart in water column, due to larval behavior that puts them more in contact with sediment than water column, or a combination of these factors. Moreover, preliminary DNA analysis suggests that larvae are acquiring different strains Symbiodinium from sediment to those from the water column.

## 5-22

**Dynamic Establishment Of Coral-Dinoflagellate Symbioses in Heat Stressed Coral Juveniles**

**David ABREGO*[1]**, Bette WILLIS[1], Madeleine VANOPPEN[2]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

Very little is known about how environmental conditions affect the capacity of newly settled coral juveniles to acquire symbionts and establish the initial symbiosis. Here we examine the uptake of *Symbiodinium* dinoflagellates by newly settled *Acropora* corals kept at three different temperatures and two light levels including treatments typically considered environmentally stressful. Visual scoring and cell counts of the corals revealed a significant delay in the uptake and establishment of symbionts in high temperatures (31 °C) and/or high light, even though the relative survival of juveniles in these treatments was similar to those in the control temperature (28 °C) and low light. Using real-time quantitative PCR we measured the proportion of symbionts taken up from a pool of two phylotypes offered. In *A. millepora* juveniles type D *Symbiodinium* was detected in higher proportions than type C1 in juveniles at high temperatures and high light. These results suggest that type D is more competitive under environmentally stressful conditions. By comparing the uptake patterns in *A. tenuis* juveniles we will discuss the role of the host in regulating the initial establishment of the symbioses and the generality of type D as a stress-tolerant symbiont.

## 5-23

**Initiation Of Coral/algal Symbioses: The Role Of Cell Surface Lectin/glycan Interactions in Recognition And Specificity**

**Elisha WOOD-CHARLSON*[1]**, Virginia WEIS[1,2]

[1]Zoology, Oregon State University, Corvallis, OR, [2]Zoology, Oregon State University, Corvallis

The majority of corals rely on horizontal transmission of the dinoflagellate symbionts *Symbiodinium* spp. to perpetuate their symbiotic condition from one generation to the next, and most coral hosts are only found in association with a specific clade of symbiont. How do larval corals and their symbiotic algae discriminate between their preferred partner and other hosts or microbes during the onset of symbiosis? We hypothesized that cell surface lectin/glycan interactions act as one mechanism of recognition and specificity during initial contact between the partners. To determine the role of these interactions during infection, we modified the glycans on the cell surface of algal symbionts (C1f and C31, found in nature in adult *Fungia scutaria* and *Montipora capitata*, respectively), introduced the modified symbionts to *F. scutaria* larvae, and then looked for changes in infection success. After cell surface modification, infection rates of native C1f algae decreased. In contrast, cell surface modification of non-native C31 algae resulted in higher infection rates compared to unmodified, control algae. These data suggest that the symbiont cell surface plays a role in specificity between *F. scutaria* larvae and C1f symbionts. To explore the source of this specificity, we investigated the variability of glycans present on the cell surface of several clade C symbionts. We found that cell surface glycan profiles were different for each symbiont, and we hypothesize that a specific glycan profile serves to identify the symbiont to its host coral. Finally, we described a complex array of C-type lectins, a type of glycan receptor, in the anemone *Nematostella vectensis* genome. The diversity of glycan profiles on symbiont cell surfaces and C-type lectins in cnidarians suggests that these interactions serve as a signal for recognition and specificity between symbiotic partners.

## 5-24

**Variability In Cell Surface Glycan Profiles Across A Range Of *Symbiodinium* Dinoflagellate Types.**

**Daniel LOGAN*[1]**, Anne LAFLAMME[1], Virginia WEIS[2], Simon DAVY[1]

[1]Victoria University of Wellington, Wellington, New Zealand, [2]Oregon State University, Corvallis, OR

*Symbiodinium* sp. dinoflagellates are the symbiotic partner in many cnidarian hosted mutualistic relationships. These *Symbiodinium* show a degree of specificity for particular hosts with a limited range of symbiont types being found in association with a given host. This specificity may be partially determined through cell surface glycan-lectin interactions during the initiation of the symbiosis. The diversity of glycans present on the *Symbiodinium* cell surface was investigated through the use of sugar-specific fluorescently labeled lectin probes and flow cytometry. The four lectin probes utilized exhibited differential levels of binding to the cell surfaces of the initial four *Symbiodinium* types examined, suggesting variation in cell surface glycan diversity and concentration between *Symbiodinium* types. It appears that variation in glycan profiles may be lowest between *Symbiodinium* types originally isolated from similar hosts. This work is ongoing with an expanded range of *Symbiodinium* types and lectin probes. Once a wider range of glycan profiles have been compiled, these data will be analyzed to elucidate whether any correlations between glycan variation, phylogenetic distance and host-symbiont specificity exist.

## 5-25

**Identification and Expression Analysis of Symbiotically Enhanced Coral mRNAs**

**Ikuko YUYAMA*[1]**, Toshiki WATANABE[1]

[1]Department of Marine Bioscience, Ocean Rsearch Institute, The University of Tokyo, Tokyo, Japan

Hermatypic corals live in obligatory mutualistic symbiosis with the dinoflagellates Symbiodinium spp. The molecular mechanisms by which corals establish and maintain symbiosis, however, remain unknown. With the purpose of identifying coral mRNAs that play pivotal roles in symbiosis, the mRNA expression profiles were compared between juvenile polyps of Acropora tenuis in the following two states: (i) aposymbiotic, and (ii) inhabited by Symbiodinium cells strain PL-TS-1 (clade A3) or CCMP2467 (A1). Using suppression subtractive hybridization and HiCEP (a cDNA AFLP-based expression profiling technique), eight cDNA fragments were isolated including those which encode sulfate transporter, syndecan, lipase, and protein kinase. Sequence analysis of the sulfate transporter cDNA suggested that the encoded protein, an integral membrane protein with eleven trans-membrane domains, is a cnidarian member of the SLC26A11 sulfate/anion exchanger family. The expression level of the mRNA was increased by the presence of both Symbiodinium strains PL-TS-1 and CCMP2467. An immunohistochemical study showed that the sulfate transporter protein is expressed in a cell-specific manner. Notable expression of the protein was observed in the following cells: (i) endodermal cells in the tissue between the coelenteron and skeleton in the peritheca, (ii) mucus cells, and (iii) cells of unidenfied types in the mesenterial filament. These results may suggest that in the above cells the uptake of SO42- is augmented and synthesis of sulfated macromolecules (such as glycosaminoglycans) is thereby enhanced by the presence of Symbiodinium cells. Such sulfated molecules are presumably used for the formation of the mucus and organic matrix of the calcified skeleton.

## 5-26

**Suicide Is Painless, It Brings On Many Changes: Apoptosis And Autophagy in Cnidarian-Dinoflagellate Symbiosis.**

**Simon DUNN*[1]**, Sophie DOVE[1]

[1]Center for Marine Studies, University of Queensland, St Lucia, Brisbane, Australia

The underlying cellular pathways that control the onset, maintenance and breakdown of cnidarian–dinoflagellate symbiosis are just beginning to be described. The pathways that have been shown to operate during these processes are highly conserved from yeast to complex metazoans, including higher vertebrates. Two examples of these pathways are apoptosis and autophagy, which are crucial to development, tissue homeostasis and immunity. Apoptosis and autophagy leading to the suicide of specific cells has been shown to be active when the cnidarian-dinoflagellate symbiosis is under stress. Key molecular components of these signal transduction pathways have been identified in cnidarians. However, the triggers activating the initiation of these pathways in this symbiosis remain unresolved and are now under investigation. This study focuses on the role of mitochondria in these cellular processes.

## 5-27

**Potential Parental Effects On Establishment And Maintenance Of Cnidarian-Algal Symbioses**

**Daniel POLAND*[1]**, Andrew HANNES[1], Mary Alice COFFROTH[2]

[1]Department of Biological Sciences, SUNY at Buffalo, Buffalo, NY, [2]Department of Geology, SUNY at Buffalo, Buffalo, NY

During early stages of cnidarian-algal symbioses coral recruits acquire a diverse array of symbiotic dinoflagellate algae (genus *Symbiodinium*). Yet over time *Symbiodinium* diversity within the host is reduced as the adult host-*Symbiodinium* specificity is established. The factors controlling this are unclear. Here, we investigated the establishment of symbioses between a Caribbean octocoral, *Briareum asbestinum*, and its *Symbiodinium* partners. Adult *B. asbestinum* harbor *Symbiodinium* of two lineages within clade B (B178 and B184), which are distinguished by sequence variability in the chloroplast large subunit (23S) ribosomal DNA. *B. asbestinum* harbored *Symbiodinium* B178 in most Caribbean and Florida Keys populations sampled. However, in the Florida Keys, a few *B. asbestinum* populations harbored mostly B184 or B178+B184 *Symbiodinium*. To investigate the progression of the symbiosis from newly settled polyps (recruits) to established colonies, asymbiotic larvae were collected from parents with B184 or B178 *Symbiodinium*. Larvae from B178 adults were placed in several habitats and larvae from B184 adults were raised at a site where only B178 adults were found. Regardless of the *Symbiodinium* populations in adults, recruits initially harbored *Symbiodinium* assemblages dominated by B184, although other algal symbionts were also present. After 24 months, 98% of recruits originating from parents with B184 *Symbiodinium* harbored only B184, despite the predominance of B178 in the local host population. Recruits originating from parents with B178 *Symbiodinium* showed an increased frequency of B178 with 10% and 40% of the recruits harboring B178 and B178+184, respectively, and 50% maintaining only B184 *Symbiodinium*. These results suggest that establishment of symbiotic relationships in cnidarians may remain dynamic for many years following settlement and initial *Symbiodinium* acquisition.

## 5-28

**Cell-Cycle Regulation in The Dinoflagellate-Cnidarian Symbiosis**

**Santiago PEREZ*[1]**, John PRINGLE[1], Carlo CARUSO[1]

[1]Genetics, Stanford, Stanford, CA

Studies of cnidarian-algal symbiosis have described many aspects of their anatomy and physiology. However, to date, the molecular and cellular underpinnings of these ecologically important symbioses remain grossly understudied. For example, several studies of the hydrozoan species *Hydra viridis* concluded that its symbiotic green-algal cells coordinate their cell cycles with those of the host cells and that light, inorganic nutrients, and host feeding are important regulators of this process. Yet, we do not know the mechanisms either of host-symbiont coordination or of the environmental influences on the process, nor is it clear whether the controls that appear to operate in *Hydra* are also found in other systems such as coral-dinoflagellate symbioses. We are one of several laboratories attempting to develop the small tropical sea anemone *Aiptasia* spp. as a tractable laboratory model system for study of the molecular and cell biology of cnidarian-dinoflagellate symbioses. *Aiptasia,* like the scleractinian corals, is symbiotic with dinoflagellates of the genus *Symbiodinium,* so it is likely that our results will be widely applicable. We will describe our progress in developing methods for the study of and in elucidating the coordination between the host and symbiont cellular reproduction during the initial establishment of the symbiosis, its steady-state maintenance, and the stress conditions that lead to the breakdown of the symbiois.

## 5-29

**Functional Diversity in The Symbiotic Interactions Between Coral And *symbiodinium***

**Michael STAT*[1]**, Emily MORRIS[1], Ruth GATES[1]

[1]HIMB, University of Hawaii, Kaneohe, HI

The symbiotic continuum ranges between mutualism and parasitism. In coral-dinoflagellate symbiosis, the interaction has been defined as mutualistic via the exchange of organic and inorganic nutrients that in turn allows for the growth and formation of coral reefs. The symbiotic dinoflagellate genus *Symbiodinium* is genetically diverse containing eight broad lineages (clades A-H). Corals predominantly associate with clade C *Symbiodinium*, and less commonly with clades A, B, D, F, and G. Variation in the function and interactive physiology of different coral-dinoflagellate assemblages is virtually unexplored but important to our understanding of factors that contribute to coral reef resilience. In this study, we evaluated the symbiotic interaction between coral and *Symbiodinium* belonging to two clades, A and C. We approached this using ecological, phylogenetic, and biochemical analyses. Our data shows 1) that there is a significant correlation between the presence of *Symbiodinium* clade A and health compromised corals; 2) that phylogenetic and genetic distance analyses place clade A as more closely related to free-living dinoflagellates than the other *Symbiodinium* lineages; and 3) that *Symbiodinium* clade A fixes and releases significantly lower amounts of carbon in the presence of a coral synthetic host factor than clade C. Collectively these data demonstrate that the interaction between coral and *Symbiodinium* clade A is not the same as the relationship between clade C and coral and that along the symbiotic continuum the interaction between clade A and coral is closer to parasitic than mutualistic in nature.

## 5-30

**Introduction Of Foreign Genes in *symbiodinium*: A Strategy To Study The Function Of The Cytoskeleton And Other Proteins**

**Marco VILLANUEVA*[1]**, Tania ISLAS-FLORES[2], Claudia MORERA[1], Roberto IGLESIAS-PRIETO[1], Patricia THOMÉ-ORTIZ[1], Frantisek BALUSKA[3], Diedrik MENZEL[3], Boris VOIGT[3]

[1]Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología-UNAM, Puerto Morelos, Mexico, [2]Plant Molecular Biology, Instituto de Biotecnología-UNAM, Cuernavaca, Mexico, [3]Institute of Cellular and Molecular Botany, University of Bonn, Bonn, Germany

Two proteins were visualized through the use of their corresponding fusions to the reporter green fluorescent protein (GFP). First, the actin microfilaments in *Symbiodinium* cells in culture were visualized through the introduction of an actin-binding domain of fimbrin (ABD2) fused to GFP. In addition, the constitutively expressed distribution of a receptor for activated protein kinase C (RACK1) from the plant *Arabidopsis thaliana* also fused to GFP was assessed in *Symbiodinium kawagutii* cells. In both cases, the plasmid vectors containing the 35S constitutive promoter and the corresponding fusions, also contained resistance genes for selection of the transformed cells. The ABD2-GFP construct was located in a pCAMBIA 1390 vector with a resistance gene to hygromycin, and the GFP-RACK1 construct was in pCB302 with a resistance gene to the herbicide Basta™. The plasmid constructs were introduced by a brief treatment of the cells with a bead beater in the presence of polyethylene glycol and glass beads. The cells were grown in ASP-8A with the corresponding selection agent. The selected cells were analyzed at the initial stages and after prolonged cell culture with normal light and epifluorescence under a Zeiss Axiostar Plus FL microscope and a Zeiss confocal microscope. In the case of the GFP-RACK1 expression, the fluorescence of the GFP was evident and reflected the expression of the protein introduced in the construction, which was throughout the cell in the cytoplasmic matrix. In the case of ABD2-GFP, the fluorescence was evident in the cytoskeletal matrix. This strategy will be useful for the study of the cytoskeleton and other proteins relevant in various biological processes in *Symbiodinium*.

## 5-31

**Redistribution Of Endosymbiotic Dinoflagellates Between Different Tissue Layers in Coral Larvae**

**Hui-Ju HUANG*[1]**, Li-Hsueh WANG[1,2], Hui-Jun KANG[1], Lee-Shing FANG[3], Chii-Shiarng CHEN[1,2]

[1]Coral Research Center, National Museum of Marine Biology and Aquarium, Pingtung, Taiwan, [2]Institute of Marine Biotechnology, National Dong Hwa University, Pingtung, Taiwan, [3]Cheng Shiu University, Kaohsiung, Taiwan

In adult cnidarians, symbiotic dinoflagellate *Symbiodinium* is usually located in the gastrodermis. However, during early development, they have also been observed in oocytes or the epidermis of the planula larva. It indicates that the cellular site of the cnidaria-dinoflagellate endosymbiosis may be regulated developmentally, highlighting a dynamic and complicated interaction between the host cell differentiation and the symbiont. This study first examined the distribution of the *Symbiodinium* population in tissue layers of planula larvae in the stony coral *Euphyllia glabrescens*. Here, *Symbiodinium* were redistributed from the epidermis to the gastrodermis, at a rate that was fastest during early planulation and then decreased prior to metamorphosis. Based on the whole embryo analysis and the transmission electron microscopic examination, the redistribution of symbionts is attributed to a direct translocation of the *Symbiodinium* sp. from the epidermis to the gastrodermis. The translocation can be inhibited by treatments with nocodazole and DCMU (3-(3, 4-Dichlorophenyl)-1, 1-dimethylurea), leading to the retardation of larval settlement and metamorphosis. This suggested the involvement of host cytoskeleton and photosynthesis of the symbiont in regulating the translocation. Finally, using MALDI imaging mass spectrometry and synchrotron radiation-based infrared microspectroscopy, the timing of *Symbiodinium* translocation was shown to be correlated with changes of spatial distribution and composition of lipid bodies (LB) in the host cell. The result indicates that the *Symbiodinium* translocation is regulated by the host tissue.

## 5-32

**Juvenile Corals Acquire More Carbon From High-Performance Algal Symbionts**

**Neal CANTIN*[1,2]**, Madeleine VAN OPPEN[2], Bette WILLIS[1], Jos MIEOG[3], Andrew NEGRI[2]

[1]James Cook University, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville, Australia, [3]University of Groningen, Haren, Netherlands

Algal endosymbionts of the genus *Symbiodinium* play a key role in the nutrition of reef building corals and strongly affect the thermal tolerance and growth rate of the animal host. We used 9 month old *Acropora millepora* juveniles that had a common parentage and had been experimentally infected with either *Symbiodinium* C1 or D immediately following metamorphosis to test the influence of genetically distinct symbionts on the physiological performance of reef-building corals. Here we report that the capacity of photosystem II (rETRMAX) is 87% greater in *Symbiodinium* C1 than in *Symbiodinium* D *in hospite*, and that 14C photosynthate incorporation (carbon based energy) into juvenile tissues of the coral, *A. millepora*, is doubled in C1 corals. Greater carbon delivery from *Symbiodinium* C1 provides juveniles with a competitive advantage since rapid early development typically limits mortality. *Symbiodinium* C1 corals, however, lose this competitive advantage under stressful conditions that limit electron transport. These findings significantly advance our current understanding of symbiotic relationships between plants and animals and describe a photophysiological mechanism that may enhance the growth and resilience of corals facing an uncertain future climate.

## 5-33

**Determinant Of Histoincompatibility Reactions in Corals**

**Michio HIDAKA*[1]**, Diah PERMATA[2]

[1]Department of Chemistry, Biology and Marine Science, University of the Ryukyus, Nishihara, Okinawa, 903-0213, Japan, [2]Diponegoro Univeristy, Semarang, Indonesia

In colonial corals, two allogeneic colonies display various contact reactions such as rejection, non-fusion, overgrowth, and fusion, while clonemates invariably fuse with each other. It has been suggested that historecognition system is not fully developed in early stages of development in some corals. The objective of this study was to investigate whether outcomes of allogeneic contact are determined by the genetic relatedness of the pairs or influenced by developmental stages. We observed the interface of allogeneic pairs of primary polyps and adult colonies of *Pocillopora damicornis* under light and electron microscopes. We found that pairs of primary polyps derived from different colonies of *P. damicornis* showed either fusion, non-fusion, or incompatible fusion response. In incompatible fusion, tissues were continuous but a white zone with few zooxanthellae was formed at the interface and polyps at the interface zone were sometimes absorbed. The skeleton at the interface was also continuous but irregular in shape. Shrunk nuclei and large extracellular spaces suggest that cell death via apoptosis occurred at the interface region. Incompatibly fused pairs transformed to non-fusion after several months, though the speed of this shift differed among pairs. Shrunk nuclei and extracellular spaces were also observed in non-fused pairs of adult branches. Even in non-fused pairs, tissues of the paired branches touched each other at the growing edge and competition occurred at a cellular level. When two allogeneic tissues contact with each other, some pairs show stable fusion resulting in chimeric colonies, while others transform from temporary fusion to incompatible fusion response, which later transform into non-fusion response. The speed of this shift of contact reaction might be determined by the genetic relatedness of the pairs rather than developmental stages of the pairs.

## 5-34

**Developmental Mechanisms And The Onset Of Symbiosis in Scleractinian Coral Embryos**

**Heather Q. MARLOW*[1]**, Mark Q. MARTINDALE[1]

[1]Kewalo Marine Laboratory, University of Hawaii, Honolulu, HI

Advances in understanding symbiosis, bleaching, eco-toxicology and mineralization are being made in adult corals, but fewer studies into the early embryonic and larval stages of the coral life cycle have been conducted. Events critical to the survival of the coral polyp occur in these early stages such as the development of tissue layers, acquisition of symbionts, and formation of the nervous system. Embryonic coral development provides the opportunity to examine ecologically relevant questions such as the onset of symbiosis as well as questions surrounding the evolution of developmental mechanisms in corals. Practically, embryonic material from scleractinian corals provides an excellent opportunity to study the cell biology of the onset of symbiosis without the difficulties associated with adult skeleton and contaminating commensal organisms. To examine the onset of symbiosis, we have utilized cell lineage tracing experiments as well as high resolution microscopy to examine symbiodinium uptake and localization in *Fungia scutaria* and *Pocillopora meandrina*. Our findings suggest that an ancient anthozoan mechanism that allows early embryos to localize yolk stores has been co-opted to facilitate symbiodinium localization in the embryo. As a next step in more carefully examining these events as well as those surrounding developmental mechanisms such as neurogenesis and body axis specification we are utilizing genomic and molecular techniques developed for the model anthozoan *Nematostella vectensis*. We have cloned genes necessary for axis specification, gut formation, and neurogenesis and have performed in situ hybridization experiments to localize these transcripts in embryonic corals. These studies allow us to understand common themes in anthozoan development and determine how these mechanisms affect the early life history and survival of coral embryos.

## 5-35

**A Computational Model For Gene Regulation Of Early Development in The Sea Anemone *nematostella Vectensis* And The Coral *acropora Millepora***

**Jaap KAANDORP*[1]**, Konstantin KOZLOV[2], Vitaly GURSKY[3], Yves FOMEKONG NANFACK[1], Maksat ASHYRALIYEV[4], Marten POSTMA[1], Maria SAMSONOVA[2], Alexander SAMSONOV[3], David MILLER[5], Joke BLOM[4]

[1]Section Computational Science, University of Amsterdam, Amsterdam, Netherlands, [2]St. Petersburg State Polytechnical University, St Petersburg, Russian Federation, [3]Theoretical Department, The Ioffe Institute of the Russian Academy of Sciences, St Petersburg, Russian Federation, [4]Center for Mathematics and Computer Science (CWI), Amsterdam, Netherlands, [5]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Queensland, Australia

Recently significant progress has been made towards understanding the genetic regulation of early development of the cnidarians *Nematostella vectensis* and *Acropora millepora*. Both organisms are members of the basal cnidarian Class Anthozoa, with relatively simple body plans. Whereas in many organisms early embryogenesis involves complex sequences of unequal cell divisions, the fact that cell division up to gastrulation occurs equally and the expectation of relatively simple gene regulation, make *Nematostella vectensis* and *Acropora millepora* excellent case studies for developing a cell-based computational model of gene regulation of early development. Despite some major morphological differences, the body of molecular data indicates that the underlying developmental biology of both organisms is similar in many ways, The most obvious physiological difference is that *N. vectensis* is a non-calcifying sea anemone, while *A. millepora* secretes an extensive aragonite skeleton after settlement. Based on in situ hybridizations available for different developmental stages of both organisms we have developed a spatio-temporal model of gene regulation of early embryogenesis which can be applied to both organisms (the ``AcroNema'' model). The model is based on a set of coupled partial differential equations. The AcroNema model is generic for the early development of both organisms and can produce an 8-folded radial symmetry which is characteristic for the bodyplan of *Nematostella vectensis* and a 6-folded symmetry which is found in the body plan in *Acropora millepora*. In this generic model we propose that the gene *dpp* (*decapentaplegic*), which is responsible for bilateral symmetrical body plans in animals, plays a fundamental role in setting up the basic radial symmetric pattern in the developing polyp and where the initial expression pattern of *dpp* determines the number of mesenteries in a developing polyp.

## 5-36

**Circadian Clock Genes in The Coral Stylophora Pistillata, Red Sea**

**Eli SHEMESH*[1]**, Oren LEVY[1]

[1]Bar Ilan University, Ramat Gan, Israel

Life on Earth has evolved under rhythmic day to night cycles of light and temperature, which are caused by our planet's rotation. Most organisms, including prokaryotes and eukaryotes, have evolved endogenous clocks in response to these predictable changes, allowing them to anticipate daily and seasonal environmental cycles, and to adjust their biochemical, physiological, and behavioral processes accordingly. The molecular mechanism of the circadian clock contains autoregulatory feedback loops comprised of positive and negative elements that generate 24-hour circuits. This work will present for the first time the presence of two circadian core genes known as Clock (Clk) and Bmal, found in the coral host Stylophora pistillata, by using degenerate primers homolog to Clock and Bmal form higher organisms. The expression patterns of both genes was investigated under ambient light dark cycles, continuous darkness and continuous light intensity, in order to test whether the S. pistillata clock genes act as circadian clock genes or not. Nubbins from four mother colonies were sampled at intervals of four hours and served for RNA extractions. The pattern of expression was tested by using QPCR and in situ hybridizations. The results show clearly that both genes oscillate as circadian clock genes found in higher organisms. The results presented here add important aspects into the origin of clock genes found in the base of animalia, the cnidarians.

## 5-37

**Physiology of Calcification and Light-Enhanced Calcification : the Scleractinian Coral Stylophora pistillata as a Model**

**Sylvie TAMBUTTÉ*[1]**, Eric TAMBUTTÉ[1], Didier ZOCCOLA[1], Aurélie MOYA[1,2], Denis ALLEMAND[1]

[1]Centre Scientifique de Monaco, Monaco, Monaco, [2]UMR 1112 INRA-UNSA, University of Nice-Sophia-Antipolis, Nice, France

The mechanism of calcification in corals still remains enigmatic but increasing data are available especially for the hermatypic scleractinian coral Stylophora pistillata which can be cultivated in laboratory under controlled conditions and is thus considered as a good model to study calcification. Since coral calcification is a case of biomineralization it involves several components: the interface between the tissue and the skeleton, the synthesis of an organic matrix, the transport of ions and the nucleation/growth and inhibition of crystal formation. I will pass under review what we actually know/don't know on the control of the organism on these components. As an introduction, I will present an up-to-date review of the anatomy, histology and characteristics of the interface tissue-skeleton to understand how the animal and its skeleton are linked. I will then summarize the data obtained by physiogical and molecular approaches on the transport of ions in Stylophora pistillata. Then I will present the current status of knowledge on the organic fraction, from its synthesis by the tissues to its incorporation in the skeleton. I will also highlight what are the consequences of a biological control of calcification on the effect of environmental parameters. I will end with a presentation of the numerous interconnected hypotheses proposed to explain light-enhanced calcification, and I will discuss some of them in the light of the last data that we have obtained both at the physiological, biochemical, cellular and molecular levels. I will insist on the available data but also on the missing data necessary for a better understanding of coral calcification.

## 5-38

**Differential Expression Of Genes Between Light And Dark Calcification**

**Aurélie MOYA*[1,2]**, Sylvie TAMBUTTÉ[1], Guillaume BÉRANGER[3,4], Béatrice GAUME[1], Jean-Claude SCIMECA[3], Séverine LOTTO[1], Denis ALLEMAND[1], Didier ZOCCOLA[1]

[1]Centre Scientifique de Monaco, Monaco, Monaco, [2], University of Nice-Sophia Antipolis, UMR 1112 INRA-UNSA, NICE Cedex 2, France, [3]Faculté de Médecine, GéPITOS, K 2943, CNRS, NICE Cedex 02, France, [4]- Research Institute of Molecular Pathology, Vienna, Austria

Most scleractinian corals establish a symbiotic relationship with phototrophic dinoflagellates. This symbiosis is responsible for the "light-enhanced calcification" (LEC) phenomenon in corals. Despite numerous researches on this phenomenon, the mechanisms by which photosynthetic symbionts enhance calcification still remain enigmatic. In order to characterize the LEC in corals we tested the hypothesis that coral genes are differentially expressed between light and dark calcification. As a preliminary approach, the differential expression of three genes involved in calcium and bicarbonate supply for calcification (Ca channel, Ca ATPase, and carbonic anhydrase) was tested between light and dark conditions in the coral Stylophora pistillata, using the real-time Polymerase Chain Reaction as a technique.

For this purpose, we first cloned and sequenced a housekeeping gene, 36B4 gene from the coral Stylophora pistillata. We then validated 36B4 and ß-actin as housekeeping genes and two photosynthetic genes (Rubisco and D1 protein of the photosystem II) as positive control genes between light and dark conditions.

Finally, we determined that the two genes encoding proteins involved in calcium transport for coral calcification (a calcium ATPase and a calcium channel) do not show differential expression between light and dark conditions, while the gene encoding a carbonic anhydrase is two-fold more expressed in the dark than in the light. We suggest that up-regulation of the gene encoding a carbonic anhydrase in the dark allows to cope with night acidosis of tissues.

## 5-39

**Photoacclimation, Photoadaptation And Coral Bleaching**

**Roberto IGLESIAS-PRIETO*[1]**

[1]Instituto de Ciencias del Mar y Limnología, Unidad Académica Puerto Morelos, Universidad Nacional Autónoma de México, Cancún, Mexico

During the last 200 million years scleractinian corals in symbioses with photosynthetic dinoflagellates have been responsible for the formation and maintenance of coral reefs. In these organisms, algal photosynthesis can provide more that a 100% of the basal metabolic requirements. The nutritional advantages that symbiotic invertebrates obtain from the translocation and consumption of algal photosynthates can explain why symbiotic corals possess significantly larger calcification rates relative to non-symbiotic invertebrates. In this context, algal photosynthesis is a key element in the formation of modern coral reefs. Considering the importance of algal photosynthesis for the well being of symbiotic corals, the study of the photobiology of these organisms has attracted significant attention. Symbiotic corals inhabit the entire photic zone and are subject to extraordinary variations in light intensity. I will review the physiological mechanisms employed by corals and their symbiotic algae to successfully harvest and utilize the available solar radiation. Based on comparative analyses of the differential responses of individual algal species to variations in growth irradiance in culture, or intact associations in nature, it has been postulated that the differential utilization of solar radiation is an important axis for niche diversification among reef-building corals. Recent analyses of the optical properties of intact coral surfaces using transmittance determinations indicate that due to the multiple scattering on the highly reflective aragonite skeleton, the specific absorption coefficients of the symbiotic algae are much higher that those obtained from freshly isolated algae, making symbiotic scleractinians one of the most efficient solar collector in nature. The role of the animal skeleton in modulating the absorption properties of the symbiotic algae has profound implications for our understanding of the evolution of these organisms. Finally, I will discuss the role of multiple scattering of coral skeletons in the propagation of thermal stress, leading to coral bleaching.

## 5-40

**Thermal Stress Stimulates The Production Of Nitric Oxide in *symbiodinium Microadriaticum* : Is Nitric Oxide A Key Molecule in The Coral Bleaching Phenomenon?**

**Josée Nina BOUCHARD*[1]**, Hideo YAMASAKI[1]

[1]University of the Ryukyus, Nishihara, Japan

In a recent study, nitric oxide (NO) has been suggested to be implicated in the mechanism leading to the expulsion of symbiotic algae from the coral host during a thermal stress event. In this previous study, the production of NO was attributed exclusively to the coral host and not to its algal symbionts. Recently, the production of NO has been shown to occur in diverse species of marine microalgae and to act as a signal molecule of stress response and/or as an indicator of growth status. These findings prompted us to determine whether coral symbiotic microalgae also produce NO both under normal growth and thermal stress conditions. Our results showed that *Symbiodinium microadriaticum* grown under laboratory conditions can produce NO when supplemented with either sodium nitrite or L-arginine as a substrate. The production of NO was confirmed by electrochemical and fluorimetric techniques. Microscopic observations of cells marked with the NO fluorescent dye DAF-2 DA also confirmed that NO was truly produced inside the microalgal cells. Ultimately, when *S. microadriaticum* were exposed to an acute heat stress (from 27 to 41 °C) the production of NO increased along with the increasing temperature. This increase in temperature was also associated with a decline in the physiological state of the cells as observed by a decline in the $F_v/F_m$ values. Results from the present study are the first to unambiguously report that zooxanthellae can synthesize NO even when they are not in a symbiotic association with a coral host. The increase in NO production upon heat stress suggests that NO can be synthesized upon exposure of the microalgae to stressful environmental conditions. The possible implications of such findings are discussed in the light of the coral bleaching phenomenon which is associated with global warming.

## 5-41

**Induced Bleaching Of Stylophora Pistillata By Darkness Stress And Its Subsequent Recovery**

**Zvy DUBINSKY*[1]**, Shachar KOREN[1], Osnat CHOMSKY[2]

[1]Life Sciences, Bar Ilan University, Ramat Gan, Israel, [2]Biology, National Institute of Oceanography IOLR, Haifa, Israel

Bleaching, the visible effect of losing zooxanthellae by corals, has been observed with increasing frequency in most of the world's reefs. Since it usually leads to coral colony death and whole reef destruction, it has been the subject of several studies in recent years. In the present article we describe a method to causing complete, but reversible, bleaching in the common Red Sea coral, *Stylophora pistillata* by darkness stress. That treatment affects the coral by reducing the density of the zooxanthellae, the endosymbiotic algae living within the coral's cells, causing the animal tissue to lose pigmentation. After 8 days in the dark the coral begins to show visible bleaching, which a week later progressed to 70%, and by the 44th day we obtained complete bleaching. At that time no zooxanthellae or chlorophyll were detected in the coral tissue. Following the transferal of the corals to darkness, at first the algal cells exhibit a photoacclimative response, accumulating chlorophyll up to 10 fold of the initial values. Fragments that were 70% bleached showed full recovery 30 days after having been returned to light. In the course of recovery, cellular chlorophyll gradually decreased to control – and initial concentrations

## 5-42

**Cellular Defense in Corals: Characterisation And Functional Analysis Of A Multi-Xenobiotic Resistance (P-Glycoprotein) Gene Homolog in The Reef-Building Coral *montastraea Franksi***

**Alexander VENN*[1]**, Jennifer QUINN[1], Ross JONES[1], Andrea BODNAR[1]

[1]Bermuda Institute of Ocean Sciences, St Georges, Bermuda

Multi-xenobiotic resistance (MXR) in marine organisms is on the front line of cellular defense against natural toxins and anthropogenic contaminants, and is a phenomenon analogous to multidrug resistance in mammalian tumour cells tolerant of anti-cancer drugs. Transmembrane P-glycoproteins (P-gp) play a key role in multidrug resistance mechanisms by actively transporting a wide variety of structurally and functionally diverse compounds out of cells. The purpose of this study was to identify the presence of a P-gp encoding gene in a reef building coral and investigate its function. Consensus-degenerate hybrid oligonucleotide primers (CODEHOPs) were designed in conserved regions of P-gp sequences from other organisms, and used to isolate a fragment of P-gp from *Montastraea franksi* mRNA by reverse transcription PCR. Rapid amplification of cDNA ends (RACE) PCR and sequencing revealed that the deduced amino acid sequence has strong structural similarities to known P-glycoproteins in well characterised vertebrate systems including humans. Expression analysis of this gene by Taqman real-time PCR confirmed that it was responsive to the classic inducer of P-gp, the chemotherapeutic drug vinblastine. Further experiments were conducted on coral fragments in specially constructed all-Teflon dosing chambers to test the response of this gene to environmentally important contaminants such as copper and oil-dispersant. These findings provide important insight into how corals defend themselves against pollution and will be integrated into initiatives to develop molecular biomarkers of stress in reef-building corals.

## 5-43

**Comparative Analysis Of The Gastrodermal Proteome Of Scleractinian Coral (Euphyllia Glabrescens) in Heat Stressed And Subsequently Bleached State**

**Shao-En PENG*[1,2]**, I-Te LEE[1], L.H. WANG[1,2], H.J. HUANG[2], Lee-Shing FANG[3], Chii-Shiarng CHEN[1,2]

[1]Institute of Marine Biotechnology, National Dong-Hwa University, Pingtung, Taiwan, [2]Department of Planning and Research, National Museum of Marine Biology and Aquarium, Pingtung, Taiwan, [3]Department of Kinesiology, Health and Leisure Studies, Cheng Shiu University, Kaohsiung, Taiwan

Endosymbiosis between coral and its photosynthetic dinoflagellate symbiont Symbiodinium spp, (also called zooxanthellae) is a crucial relationship to sustain the coral reef ecosystem. This endosymbiosis occurs inside specifc host gastrodermal cells, and its molecular mechanism still remains unclear notwithstanding decades of research. In this study, we developed a new method to isolate and extract the gastrodermal and epidermal protein of scleractinian coral (Euphyllia glabrescens) and then subjected to proteomic analysis. It revealed that the stress response related proteins were up-regulated in the gastrodermal tissue of stressed coral and the proteins that involved in nitrogen metabolism, cytoskeleton, de novo purine synthesis, protein degradation and protein folding were subsequently down-regulated in bleached (aposymbiotic) state. The comparative analysis of epidermal and gastrodermal proteome demonstrated that the endosymbiosis related proteins (e.g. the key protein involved in nutrition metabolism) were differently regulated in epidermal and gastrodermal tissue of coral during the high temperature stress and bleaching event. This is also the first report to demonstrate the protein expression profiles in the gastrodermal tissue of coral that endosymbiosis occurs inside.

## 5-44

**The Effect Of Temperature On Integrin-Mediated Adhesion in The Sea Anemone, *Aiptasia Pulchella***

**Sara SAWYER*[1]**, Gina PAULAUSKIS[2]

[1]Biological Sciences, Southern Illinois University Edwardsville, Edwardsville, IL, [2]Southern Illinois University Edwardsville, Edwardsville, IL

Temperature-induced coral bleaching results from the loss of the symbiotic dinoflagellate algae from the coral host. One potential mechanism underlying temperature-induced coral bleaching is loss of the host cell containing the endosymbiotic algae. This loss of host cells could be the result of apoptosis, or could induce apoptosis. We have been investigating how temperature affects integrin mediated cell adhesion in the tropical symbiotic sea anemone, *Aiptasia pulchella*. A β-integrin has been sequenced from Cnidarians, but the function has not been investigated in these animals. Using both commercially available anti-β1-integrin antibodies and an antibody made again a conserved extracellular domain of the Cnidarian integrin (CNβ1) we have identified a protein of the correct molecular weight for an integrin (approximately 120 kDa) from tissue extracts from the sea anemone, *A. pulchella.* In addition, we have identified by immunoprecipitation a putative focal adhesion kinase (FAK) protein of approximately 125 kDa protein using an anti-FAK antibody in tissue extracts from *A. pulchella*. Using immunohistochemistry, we have investigated the tissue localization of integrins using the CNβ1 antibody. Integrin staining is the strongest where the cells of the endoderm attach to the acelllular mesoglea. To investigate how temperature affects the tissue distribution of these integrins, anemones were heat shocked for 12, 24 and 48 hours at 30°C and then processed for immunohistochemistry. Temperature shock disrupts the strong integrin staining at the base of the endodermal cells suggesting that integrin adhesion is disrupted by temperature shock. Further studies will investigate how temperature affects integrin signaling and as well as the timing of the temperature effect on integrin distribution.

## 5-45

**Long-Term Changes in The Chlorophyll Fluorescence Of Bleached And Recovering Corals From Hawaii**

**Lisa RODRIGUES*[1]**, Andrea GROTTOLI[2], Michael LESSER[3]

[1]Geography & the Environment, Villanova University, Villanova, PA, [2]Ohio State University, Columbus, OH, [3]University of New Hampshire, Durham, NH

Chlorophyll fluorescence has been used to predict and monitor coral bleaching over short timescales (hours to days), while long-term changes during recovery remain largely unknown. To evaluate changes in fluorescence during long-term bleaching and recovery, *Porites compressa* and *Montipora capitata* corals were experimentally bleached in tanks at 30°C for one month, while control fragments were maintained at 27°C. A pulse amplitude modulated (PAM) fluorometer measured the quantum yield of photosystem II fluorescence (Fv/Fm) of the zooxanthellae each week during bleaching, and after 0, 1.5, 4, and 8 months recovery. *M. capitata* appeared bleached 6 days sooner than *P. compressa*, yet their fluorescence profiles during bleaching did not significantly differ. Changes in minimum (Fo), maximum (Fm), and variable (Fv) fluorescence throughout bleaching and recovery indicated periods of initial photoprotection followed by mostly photodamage in *P. compressa* and chronic photoinhibition in *M. capitata*. Fv/Fm fully recovered 6.5 months earlier in *P. compressa* than *M. capitata*, suggesting that the zooxanthellae type of *P. compressa* was more resilient to bleaching stress. Other host-related physiological (energy reserves, photosynthesis and respiration) and biogeochemical (stable carbon isotopes) evidence indicates that the host of *M. capitata* recovers faster than that of *P. compressa.* Altogether then, these two corals utilized different strategies for recovery from coral bleaching.

## 5-46

**Mechanisms Of Coral Bleaching And Cell Death Under Thermal Stress**

**Badrun NESA*[1]**, Michio HIDAKA[2]

[1]Department of Marine and Environmental Science, Graduate School of Engeneering and Science, University of The Ryukyus, Nishihara, Okinawa 903-0213, Japan, Nishihara, Japan, [2]Chemistry, Biology and Marine Science, Faculty of Science, University of the Ryukyus, Nishihara, Okinawa 903-0213, Japan, Nishihara, Japan

We have established an experimental system to study the response of coral cells to stress treatment using coral cell aggregates (tissue balls). Dissociated coral cells aggregate to form spherical bodies, which rotate by ciliary movement. These spherical bodies (tissue balls) stop their rotation and become disintegrated when exposed to stress. The objective of this study was to test the hypothesis that zooxanthellae become a burden for coral hosts under stressful conditions and to study cell death mechanisms using tissue balls as experimental system. Tissue balls prepared from dissociated cells of *Pavona divaricata* and *Fungia* sp. were exposed to elevated ($31^0$C) and control temperature ($25^0$C) under normal light (35 µmol $m^{-2}s^{-1}$). The relationship between the survival time and zooxanthella density of tissue balls were recorded. Cell death mechanisms were investigated using a Comet Assay (single cell gel electrophoresis), which can detect DNA damage in individual target cells. There was a negative correlation between the survival time and zooxanthella density of tissue balls at $31^o$C, while no significant correlation between these parameters was found at $25^o$C. The present results support the hypothesis that zooxanthellae become a burden for host corals under high temperature stress and suggest that zooxanthellae produce harmful substances under stress condition. Antioxidants extended the survival time of tissue balls at high temperature in some cases. This suggests that zooxanthellae produced active oxygen species under the stress condition. Apoptotic death of coral cells was detected in tissue balls exposed to high temperature stress using comet assay. This study also showed that tissue balls provide us a good experimental system to study the effect of stress and various chemical reagents on corals cells.

Key words: Coral, apoptosis, comet assay, bleaching

## 5-47

**Characterizing Bleaching Responses in Corals Exposed To Dcmu, Copper, And Elevated Temperature Using Pam Fluorimetry And Gene Expression Profiling.**

**Amy ANDERSON*[1]**, Alexander VENN[2], Ross JONES[2], Michael MORGAN[1]

[1]Berry College, Mount Berry, GA, [2]Bermuda Institute of Ocean Sciences, Ferry Reach, St George's, Bermuda

The photosynthetic inhibitor DCMU, the heavy metal copper, and heat stress, are all individually capable of inducing bleaching (the dissociation of the coral-algal symbiosis) in hard corals. Whether this is by the same or different cellular or physiological mechanism is presently unknown. In this study, small branches of the hard coral *Madracis mirabilis* were exposed to various concentrations (0, 10, 30, 100, 300 ppb) of DCMU, or copper, or to different temperatures (28°C or 32°C) for 72 h. Pulse Amplitude Modulated (PAM) chlorophyll fluorimetry was used to characterize effect of these treatments on the photosynthetic capacity of the symbiotic dinoflaglleates in the tissues (*in hospite*). These analyses were combined with Representational Difference Analysis (RDA) to amplify differentially expressed genes associated with each treatment. Sixty-six genes were isolated from corals exposed to 300 ppb DCMU and a subset of these genes appears to differentially expressed. Genomic and Proteomic database searches reveal many of the RDA products have significant homology to proteins of functional relevance. Expression profiles for each putatively differentially expressed gene were established by probing for targeted transcripts within RNA samples from each stressor treatment. A number of genes showed up-regulation at different concentration of DCMU. Copper exposures also produced varied expression profiles for the genes investigated. In contrast, most of the genes exhibited decreased expression as temperature increased. The specificity of responses varied between genes as well as between concentrations used for an individual stressor exposure. The expression profiles generated in this study represent a new and informative way to characterize of how corals respond to different environmentally relevant stressors as well as being a useful tool for examining the molecular mechanism associated with coral bleaching.

## 5-48

**Differential Stability Of The Photosynthetic Membrane Of Symbiotic Dinoflagellates in Response To Elevated Temperature**

Erika M. DÍAZ-ALMEYDA[1], Roberto IGLESIAS-PRIETO[2], **Patricia E. THOMÉ*[2]**

[1]Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Cancún, Quintana Roo, Mexico, [2]Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Puerto Morelos, Quintana Roo, Mexico

Coral bleaching has been correlated with small increments of sea surface temperature of local summer averages. This phenomenon is initiated with the uncoupling of light harvesting and photosynthesis and may result in expulsion or death of the symbiont and eventually death of the host. Not all coral species are equally susceptible to elevated temperature. Using charge separation efficiency of photosystem II (Fv/Fm) after brief exposures (5 minutes) to high temperatures, we assessed the fluidity of the photosynthetic membrane of cultured and freshly isolated symbiotic dinoflagellates. The melting temperatures of the thylakoid membrane in 5 cultures grown at 24°C, show differences of 4.5°C between the most temperature-sensitive *Symbiodinium microadriaticum* and the temperature resistant *Symbiodinium sp.* (clade D1a) suggesting a strong genetic component. To explore temperature acclimation responses, these two symbionts were grown at 31°C. Results indicate changes in melting temperatures as well as changes in lipid composition of the photosynthetic membrane, suggesting limited acclimation to high temperature.

The photosynthetic membrane from freshly isolated dinoflagellates of the *Madracis auretenra* were found to be more temperature resistant than those isolated from *Montastrea faveolata*, suggesting that the stability of the photosynthetic membrane is an important component in determining susceptibility to coral bleaching.

**The Role of Oxidative DNA Damage and Repair in Cnidarian-Dinoflagellate Symbiosis Breakdown**

**Joshua MEISEL*[1]**, Ruth REEF[2], Mauricio RODRIGUEZ-LANETTY[2], Sophie DOVE[2], Ove HOEGH-GULDBERG[2]

[1]Centre for Marine Studies, University of Queensland, Highgate Hill, Australia, [2]Centre for Marine Studies, University of Queensland, St. Lucia, Australia

In an effort to further understand the cellular and molecular processes underlying cnidarian-dinoflagellate symbiosis breakdown, this study investigates the role of oxidative DNA damage and repair in coral bleaching. In the presence of high light and heat, compromised dinoflagellate photosystems can generate reactive oxygen species (ROS) that damage both host and symbiont cellular components and may ultimately initiate a bleaching response. This study focuses on the oxidative damage ROS inflict on the genomes of the Scleractinian coral *Acropora aspera* and its endosymbiont *Symbiodinum sp.* and what mechanisms exist to combat this damage. *Acropora* branches collected from the Heron Island reef flat were mounted into racks and subjected to a gradual 20-day heating regime, peaking at 32 degrees, and symbiosis breakdown was quantified through dinoflagellate counts and dark-adapted photosynthetic yields. DNA was extracted from both host and symbiont at 8 time points throughout the bleaching course and probed for the oxidative DNA base lesion 8-hydroxyguanine using a competitive ELISA assay. To further understand the role of oxidative stress in this process, experiments were repeated in the presence of DCMU (a photosynthesis-inhibitor that generates ROS), catalase (an anti-oxidant enzyme that neutralizes hydrogen peroxide), 3-amino-1,2,4-triazole (a catalase-inhibitor), and hydrogen peroxide. To investigate pathways that may operate in repairing this damage, the OGG1 protein (which excises 8-hydroxyguanine lesions) was cloned from *Acropora* and will be used in qPCR studies to monitor oxidative DNA repair. This is the first study to quantify oxidative DNA damage in the cnidarian-dinoflagellate system and may provide insight into how oxidative stress, DNA damage, and genomic instability initiate symbiosis breakdown and coral bleaching.

## 5-50

**Cell-Death Pathways Associated With Vibrio Infection And Inhibition Of Heat Shock Proteins And Apoptosis "Cell Death Signals"in Clade Subtypes A,b,c,d**

**James CERVINO*[1,2]**, Nancy KRUCHER[1], Konrad HUGHEN[3]

[1]Biological Sciences, Pace University, NY, NY, [2]Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, [3]Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, MA

The biochemical impairment mechanisms associated with infection of *Symbiodinium spp.* results in a reduction of protein synthesis within 4 hr of treatment *in vitro*. Heat shock proteins (HSPs) are a family of highly conserved proteins found in cells that are induced due to cell stress. We have found an HSP70-related protein in *Symbiodinium* (sub-type C1) with an apparent molecular weight of 120-140kd using HSP70 specific antibodies. This putative HSP70-related protein is expressed highly in CLADE C, at low levels in CLADE A, but was not found in CLADES B and D, which is consistent with the observed patterns of CLADE D and A sub-type thermal tolerance. Interestingly, inoculation of *Vibrio* pathogens reverse the induction of the HSP70-related protein in heat stressed (33oC) *Symbiodinium* CLADE C1. These data are also consistent with cell-cycle mitotic index impairment analysis. All *Symbiodinium* CLADE subtypes show a decline in cell division following 48 hr treatment with *Vibrio* pathogens together with thermal stress. HSP and cell-cycle inhibition are also consistant with Apoptosis markers using Annexin *V* flouresence staining. Improperly regulated apoptosis is implicated during the *Vibrio* induced disease states at higher temperatures. Thermally stressed cells are detected by annexin *V* binding to externalized phosphatidylserine, however with thermal stress together with *Vibrio* infection, the presence of phosphatidylserine is not evident. These data support the recent findings and hypothesis that coral disease cell death mechanisms follow a different cell-death process compared to thermal bleaching mechanisms. Using *Symbiodinium* CLADE subtypes as in vitro models can also give researchers and better understanding into cancer cell research that are associated with bacterial infections.

## 6-2

**The Coral Transcriptome – A Beginner's Guide**

**David MILLER*[1,2]**, Eldon BALL[2]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]ARC Centre for the Molecular Genetics of Development, Australian National University, Canberra, Australia

Although corals are amongst the simplest true animals at the morphological level, in terms of the total number and types of genes they are comparable with the most complex of animals – the vertebrates. The coral genome contains a large number of genes once thought of as vertebrate-specific, including clear homologs of many key components of the vertebrate innate immune repertoire; considerable effort is presently being directed into exploring the roles of these in combating coral disease. The genomes of anthozoan cnidarians such as corals also contain a significant number of "non-metazoan" genes – genes only previously known from members of the other kingdoms of life. These are not the products of recent lateral gene transfers, but long-term residents of cnidarian genomes that potentially increase the biochemical complexity of the organism. The unexpected complexity and heterogeneity of the coral transcriptome represents a major challenge in understanding the functional biology of corals; essentially, one cannot predict how corals will respond based on what is known about other animals.

Whole genome sequences are now available for two cnidarians – the sea anemone Nematostella vectensis and the freshwater Hydra magnipapillata – and comparisons between the coral Acropora and these organisms have the potential to provide insights into nominally coral-specific processes such as calcification and symbiosis. Moreover, comparisons between the Indo-Pacific coral Acropora millepora and the Caribbean species Acropora palmata permit the identification of genes under positive selection that are candidates for roles in allorecognition, gamete interactions and other coral-specific traits. Future progress in coral functional biology will increasingly rely on microarray and genomic approaches based on high-throughput DNA sequencing, coupled with use of biological 'models' for coral traits.

## 6-3

**Gene Expression in Symbiodinium Under Stress**

Bill LEGGAT[1,2], David YELLOWLEES[2], Sophie DOVE[3,4], **Ove HOEGH-GULDBERG*[3,4]**

[1]Biochemistry and Molecular Science, James Cook University, Townsville, Australia, [2]ARC CoE for Coral Reef Studies, James Cook University, Townsville, Australia, [3]Centre for Marine Studies, University of Queensland, Brisbane, Australia, [4]ARC CoE for Coral Reef Studies, Brisbane, Australia

It is now well documented that the dinoflagellate Symbiodinium (zooxanthellae) are a weak link in the coral symbiosis. An obvious example of this is the fact that small increases in temperature lead to damage to the Symbiodinium photosynthetic apparatus and their eventual expulsion from their coral host (coral bleaching). However we know very little about how Symbiodinium copes with stress. Characterisation of a Symbiodinium stress transcriptome, which is made up of over 5000 contigs, has found that a large number of genes that are expressed when under temperature, nutrient or CO2 stress are novel and do not match any sequences in the available databases (approximately 55%). In fact the function of the most highly expressed gene, which makes up to 3% of the transcriptome, is also unknown. In addition to these unknown genes Symbiodinium contains a variety of typical "stress" response genes (e.g. heat shock proteins, catalase, super-oxide dismutase etc). However even these are sometimes often not what would be expected a typical alga; for example the Symbiodinium catalase is most closely related to that found in bacteria and fungi rather than a traditional eukaryote catalase. This unique genetic make up means that how the genes that are up- or down-regulated in response to stress in Symbiodinium may differ from what is seen in other photoautrophs. The use of a newly developed Symbiodinium microaray is now allowing us to examine how these ecologically key dinoflagellates respond to stress at the gene expression level. We are examining how changes in temperature, CO2 and nutrients affect the Symbiodinium transcriptome and the phenotype of the alga.

## 6-4

**Integrating Genomics With Coral Reef Biology And Management**

**Cheryl WOODLEY*[1]**, Craig DOWNS[2]

[1]NOAA National Ocean Service, Charleston, SC, [2]Haereticus Environmental Laboratory, Clifford, VA

Genomics is a methodology for studying genomes (the chromosomes and their genes). The original purpose was to sequence the genomes of organisms, identify and map genes to the genome, categorizing (annotate) new genes based on similarities with previously identified genes of known function, and document which genes are activated under various conditions. The initial focus for these efforts was aimed at improving human health. One of the most successful outcomes of genomic efforts has been identifying genes responsible for heritable diseases involving only a few genes. Diagnostic tests were quickly developed and drug development began targeting specific steps in disease pathways. Genomics uncovered disease variations that allow more discriminating diagnosis such as subtyping tumors (e.g., breast cancers) and individualized treatments. Sequencing genomes quickly spread to model organisms, domestic animals and crops, and more recently to commercially valuable marine organisms (e.g., salmon, shrimp, oysters). The rationale varied for each genome but included understanding development, comparative studies for altered physiological or environmental conditions, pathology, population genetics, breeding, crop improvement or drug development. Coral reef biologists have recently turned to genomics in hopes of answering questions in toxicology, symbiosis, pathology, development, evolutionary and ecological processes and environmental monitoring. Genomics alone, however, will fail in trying to address these questions. It is a tool that can provide unprecedented amounts of data, but more data does not mean more knowledge. Not until we view genomics as a tool to be used in the context of a scientific research plan or resource management strategy with other methods and disciplines (e.g., genetics, physiology, biochemistry and cell biology) for conducting hypothesis driven experiments, will our understanding coral reef biology and health move forward.

## 6-5

**Differential Gene Expression During The Initial Onset Of Coral/algal Symbiosis Using A Cdna Microarray**

**Christine SCHNITZLER*[1]**, Virginia WEIS[1]

[1]Department of Zoology, Oregon State University, Corvallis, OR

Very little is known about the molecular and cellular mechanisms controlling the successful establishment of a stable relationship in the early stages of coral/algal symbiosis. The planula larva of the solitary Hawaiian scleractinian coral *Fungia scutaria* and its dinoflagellate symbiont *Symbiodinium* sp. type C1f represents an ideal model for studying the onset of coral/algal symbiosis due to the predictable availability of gametes, and the ability to raise non-symbiotic larvae and establish the symbiosis experimentally. The goal of this study was to identify genes differentially expressed in *F. scutaria* larvae during the initiation of symbiosis with its algal symbiont using a high-throughput technique. We predicted that our discovery-based approach would identify expression differences in host genes involved in cellular processes critical to the establishment of coral/algal symbiosis, such as cell signaling, proliferation, metabolism and immunity. Symbiotic larvae were compared to non-symbiotic larvae using a custom cDNA microarray. The 5,184-feature array was constructed with cDNA libraries from newly symbiotic and non-symbiotic larvae, including 3,072 features (60%) that were enriched for either state by subtracted hybridization. The array was hybridized with cDNA from newly symbiotic and non-symbiotic *F. scutaria* larvae using a multiple dye swap design and six biological replicates. Following normalization to control features, transcripts differentially expressed (up- or down-regulated) as a function of the symbiotic state were sequenced and used to identify homologs, and differential expression was quantified using real time PCR. Specific primers were constructed for use in PCR with host-only and algae-only genomic DNA to confirm the source of genes expressed from the symbiotic larval cDNA library. Future studies will focus on functional and biochemical assays in an attempt to further characterize individual target genes.

## 6-6

**Coral Reef Genomics: A Genome Wide Approach To Study Establishment And Maintenance Of Coral-Zooxanthellae Symbioses**

**Christian VOOLSTRA*[1]**, Jodi SCHWARZ[2], Mary Alice COFFROTH[3], Alina M. SZMANT[4], Mónica MEDINA[5]

[1]School of Natural Sciences, University of California, Merced, Merced, CA, [2]Vassar College, Poughkeepsie, NY, [3]State University of New York at Buffalo, Buffalo, NY, [4]UNCW-Center for Marine Science, Wilmington, NC, [5]University of California, Merced, Merced, CA

Symbioses between scleractinian corals and their photosynthetic unicellular symbionts (dinoflagellates or zooxanthellae) form the basis of coral reef ecosystems. While the importance of this mutualistic relationship is well documented, surprisingly little is known about the cellular processes involved in the establishment and maintenance of this partnership.

We use large scale gene expression profiling (microarrays) to study the transcriptomic changes in two Caribbean reef building coral species (*Montastraea faveolata* and *Acropora palmata*) in response to infection with different strains of zooxanthellae. A high number of genes change expression upon infection; and genes involved in signal transduction, cytoskeletal activity, metabolism and energy production, and stress are modified. In contrast, only a few differences exist upon infection with different zooxanthella strains.

These data indicate that although there is a profound change in coral physiology upon establishment of symbiosis, an evolutionarily conserved mechanism of establishment of symbiosis exists.

## 6-7

**Differential Gene Expression During Thermal Stress And Bleaching in The Caribbean Coral *montastraea Faveolata***

**Michael DESALVO*[1]**, Christian VOOLSTRA[1], Shinichi SUNAGAWA[1], Jodi SCHWARZ[2], Mary Alice COFFROTH[3], Alina SZMANT[4], Mónica MEDINA[1]

[1]School of Natural Sciences, University of California, Merced, Merced, CA, [2]Department of Biology, Vassar College, Poughkeepsie, NY, [3]Graduate Program in Evolution, Ecology, and Behavior, State University of New York at Buffalo, Buffalo, NY, [4]Center for Marine Science, University of North Carolina, Wilmington, Wilmington, NC

The declining health of coral reefs worldwide is likely to intensify in response to continued anthropogenic disturbance from coastal development, pollution, and climate change. Reef-building corals respond to stress by bleaching, in which their symbiosis with zooxanthellae collapses. Mass coral bleaching in response to elevated water temperature can devastate coral reefs on a huge geographic scale. In order to understand the molecular and cellular basis of thermal bleaching in corals, we have taken a transcriptomic approach. cDNA microarrays, containing features representing 1,310 genes of the Caribbean coral *Montastraea faveolata*, were utilized to measure gene expression changes associated with thermal stress and bleaching. Thermal stress experiments were conducted in temperature-controlled aquaria, and bleaching was elicited by increasing the temperature by 3oC above normal. Differentially expressed genes were identified in two separate experiments: the first experiment compared gene expression between control fragments and partially bleached fragments; and the second experiment compared control fragments to heat stressed fragments along a time course ending at partial bleaching. Our findings suggest that thermal stress and bleaching in *M. faveolata* results in: heat shock protein expression, oxidative stress, re-organization of the cytoskeleton, disruption of Ca2+ homeostasis, decreased calcification, metabolism, and protein synthesis, increased activity of transposons and defensin-like peptides, and the initiation of cell death. We believe that oxidative stress in heat-stressed corals results in a disruption of cellular Ca2+ homeostasis, which leads to cytoskeletal and cell adhesion changes, decreased calcification, and the initiation of cell death via apoptosis and necrosis.

## 6-8

**An Ecological Microarray Study Of Coral Bleaching**

Francois SENECA[1,2], **Francois SENECA*[1,2]**, Sylvain FORET[3], Nicolas GOFFARD[4], Carolyn SMITH[2], Lauretta GRASSO[3], David HAYWARD[3], Robert SAINT[3], Madeleine VAN OPPEN[2], Eldon BALL[3], David MILLER[1,3]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville 4811, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville 4810, Townsville, Australia, [3]ARC Centre for the Molecular Genetics of Development, Australian National University, Canberra 2601, Canberra, Australia, [4]Louis Malardé Institute, Papeete 98713, Papeete, French Polynesia

Reef building corals live close to their upper thermal tolerance limit and prolonged exposure to temperatures exceeding 31°C induces coral bleaching – the expulsion of *Symbiodinium sp.* which is often the first step toward mass mortality. Current projections suggest that average tropical ocean temperatures could warm by 1-3°C by the end of this century, so unless corals have the capacity for adaptation to anthropogenically induced climate change, those species that survive are likely to undergo dramatic shifts in distribution patterns. To investigate coral stress responses at a fundamental level we used microarrays of approximately 17,000 expressed sequence tags (ESTs) from the hermatypic coral *Acropora millepora* to attempt to identify genes responsible for individual fitness and the capacity to survive.

Bleaching responses have traditionally been investigated largely by subjecting corals to acute thermal stress in vitro. Our approach has focussed on several coral colonies growing in a single bay that have been sampled in situ through a natural bleaching episode and the subsequent recovery period. During the sampling period, water temperature was continuously monitored (at 15 min intervals) and symbiont density recorded at monthly intervals as a measure of bleaching status.

Individual colonies differed dramatically in their overall responses to similar environmental conditions – the extent of reduction of symbiont density varied considerably and, whereas some colonies recovered after the summer period, others died. Microarray experiments on a subset of colonies, which showed similar patterns of symbiont loss, identified a large number of genes with expression significantly correlated to decreases in symbiont density. The implications of these experiments in terms of understanding the mechanisms by which corals respond during bleaching episodes will be discussed.

## 6-9

**Bacterial Community And Gene Expression Profiling Using 16srrna Gene And Cdna Microarrays: Introduction Of A Dual High-Throughput Approach To The Study Of Coral Disease And Bleaching**

**Shinichi SUNAGAWA*[1]**, Paul FISHER[2], Michael DESALVO[1], Christian VOOLSTRA[1], Ernesto WEIL[3], Gary ANDERSEN[4], Roberto IGLESIAS-PRIETO[2], Mónica MEDINA[1]

[1]School of Natural Sciences, University of California Merced, Merced, CA, [2]Unidad Académica de Sistemas Arrecifales ICML-UNAM, Universidad Nacional Autónoma de México, Puerto Morelos, Mexico, [3]Department of Marine Science, University of Puerto Rico, Mayagüez, Puerto Rico, [4]Center for Environmental Biotechnology, Lawrence Berkeley National Laboratory, Berkeley, CA

Increasing evidence highlights the fact that bacteria play a crucial role within coral holobiont, i.e. the coral host and its associated microbial communities. Current approaches to describe the bacterial diversity in corals involve the universal amplification of bacterial 16SrRNA gene via the polymerase chain reaction (PCR) with subsequent analysis by terminal-restriction fragment length polymorphism (t-RLFP), temperature/denaturing gradient gel electrophoresis (T/DGGE), or sequencing of recombinant 16SrDNA clone libraries. Analyzing the expression of one or a few genes in coral samples may be accomplished through quantitative PCR. However, large-scale comparative studies with the aim to discover statistical differences in bacterial species composition as well as global changes in the coral transcriptome would require the application of more efficient high-throughput technologies. In light of increasing frequencies of coral disease and bleaching events, it is imperative to gain a better understanding of (a) concomitant changes in coral-associated bacterial communities and (b) the molecular responses of coral hosts to such stress events. Here, we introduce the application of 16SrRNA gene microarrays in combination with coral host cDNA microarrays to simultaneously profile both changes in microbial community composition and coral gene expression. Specifically, we are comparing healthy versus both diseased and bleached corals using the Caribbean coral species *Montastraea faveolatea* as a model system. This approach applies statistical tools to identify differentially abundant bacteria in diseased or bleached coral samples and aims to identify genes or gene pathways that are involved in the immune as well as thermal stress response of corals. The expected results may validate the application of these high-throughput tools as a versatile platform for monitoring and assessing the health status of corals, and thus could guide their implementation for effective management strategies to preserve coral reefs.

## 6-10

**Thermal Regulation in Coral Larvae: A Microarray Screening**

**Mauricio RODRIGUEZ-LANETTY*[1,2]**, Saki HARII[3], Ove HOEGH-GULDBERG[1]

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia, [2]Department of Biology, University of Louisiana at lafayette, Lafayette, [3]Graduate School of Engineering and Science, University of Ryukyus, Naha, Japan

Coral reefs around the world are in decline with much of the mortality attributed to coral bleaching – the loss of photosynthetic algal symbionts – resulting from global warming. To understand how corals may respond to the current global warming threat, we need to understand how the coral/algal symbiont responds to the increase of sea water temperature not only on an organismic and physiological level but also on a molecular and cellular level. Microarrays are currently being shown to be an adequate tool to explore and screen for molecular pathways that are affected and change in response to increases in temperature. In this study, we have conducted a microarray experiment to document the changes of gene expression that occur in the coral host cell during the first hours of thermal stress. This study focuses on determining the direct effect of temperature on the host cell and not those secondary effects arising from physiological impaired algal symbionts after being exposed to high temperature. In order to dissect these two effects with different origins, we conducted our thermal stress experiments on aposymbiotic (lacking of symbiont) coral larvae from the scleractinian coral Acropora millepora. Results from this study show the cellular dynamics of coral larvae gene expression in the first hours after being challenged in a thermal stress experiment.

## 6-11

**The Genomic Bases Of Stress Tolerance And Temperature Adaptation in Corals**

**Eli MEYER*[1]**, Shi WANG[1], Galina AGLYAMOVA[1], Mikhail MATZ[1]

[1]Biological Sciences, University of Texas, Austin, Austin, TX

Reef building corals are extremely sensitive to thermal stress, but the potential for these ecologically important animals to adapt to increasing ocean temperatures remains uncertain. We are characterizing the genetically determined natural variation in responses to thermal stress and settlement cues to better understand the traits under selection during climate change. We used reciprocal crosses between colonies of the coral *Acropora millepora* to produce larvae that we maintained in culture at standard (28°C) and constant elevated temperatures (32°C). Direct measures of thermal tolerance were obtained from measurement of survival during short (2 d) periods of temperature stress (34°C). These different stress phenotypes were further characterized by measuring changes in protein content and RNA:DNA ratios during development and growth under these conditions. Physiological measurements of metabolic activity and temperature response were simultaneously obtained for large numbers of individual larvae, allowing estimation of individual, genetically determined, and environmentally induced variation within a single experiment. To understand the genomic bases of these responses, we are sequencing the larval transcriptome and measuring global gene expression profiles. These profiles, in combination with the whole-genome genotyping methods currently being developed in our lab, will allow us to establish links between genetic markers, gene expression, and thermal tolerance. These data will help to build a framework for understanding the long-term impacts of climate change on coral reefs.

## 6-12

**Using A Stressed-Focused Microarray To Characterize Coral Responses To Copper**

**Michael MORGAN*[1]**, Sara EDGE[2], Alexander VENN[3], Ross JONES[3]

[1]Berry College, Mount Berry, GA, [2]Harbor Branch Oceanographic Institute, Ft. Pierce, FL, [3]Bermuda Institute of Ocean Sciences, Ferry Reach, St George's, Bermuda

Copper is a well recognized marine pollutant, having been used extensively in antifouling paints of boats. In corals it is known to induce bleaching at very low concentrations, but the mechanism associated with this response, and how it differs from warm-water induced bleaching of corals is presently unknown. A stress-focused microarray composed of 153 genes was used to investigate which coral genes are most responsive to copper. In this study, small fragments of *Montastraea franksi* were exposed to different concentrations of copper (0, 0.3, 3.0, and 30 ppb) for various exposure periods (2 h, 24 h, and 7 d). Exposure treatments were conducted under natural light in temperature controlled, Teflon®, dosing chambers developed at the Bermuda Institute of Ocean Sciences (BIOS). Some coral stress genes on this microarray have previously demonstrated responses to elevated copper concentrations. Results presented will illustrate how this study represents a first attempt to characterize the expression profiles of various genes (a) under different concentrations of copper (b) on different temporal scales and (c) within and between colonies.

## 6-13

**Microarray Characterization Of Gene Expression in *montastraea Cavernosa* Through Space And Time**

**Sara EDGE*[1]**, Michael MORGAN[2], Joshua VOSS[1], Terry SNELL[3]

[1]Robertson Coral Reef Program, Harbor Branch Oceanographic Institute at Florida Atlantic University, Fort Pierce, FL, [2]Department of Biology, Berry College, Mount Berry, GA, [3]School of Biology, Georgia Institute of Technology, Atlanta, GA

Coral communities are increasingly impacted by a variety of natural and anthropogenic stressors acting on local or global scales. Based on the nature of stress and scale of impact, corals exhibit variable responses. Through the application of microarray technology, gene expression profiles can be used to diagnose stressors impacting coral populations in the field. Changes in gene expression are key elements of the stress response, often occurring before physiological damage is evident. Furthermore, responses such as bleaching or tissue loss may result from a multitude of factors, whereas the regulation of gene expression can be directly related to the causative agent of stress. In this study, a stress-focused microarray was used to detect gene expression patterns of *Montastraea cavernosa* on South Florida reefs at different sites over a fifteen month period. The array consisted of 148 genes involved in a variety of cellular functions, ranging from metabolism and development to the regulation of apoptosis and the stress response. Gene expression patterns revealed a strongly significant, episodic stress response at three of the five sites investigated. In addition, a significant correlation between the expression of symbiont genes and the expression of coral stress response genes was evident across all dates and sites. To our knowledge, this is the first study to use a Cnidarian microarray to detect changes in the physiological condition of coral in the field associated with seasonal events as well as point source stress.

## 6-14

**Preliminary Characterization Of The Genomic "Defensome"in A Model Cnidarian, Nematostella Vectensis, And Predicted Stress Response Genes in Reef-Associated Corals**

**Nikki TRAYLOR-KNOWLES*[1]**, Adam REITZEL[2], James SULLIVAN[1], Les KAUFMAN[1], John FINNERTY[1]

[1]Department of Biology, Boston University, Boston, MA, [2]Wood Hole Oceanographic Institution, Woods Hole, MA

There is a pressing need for quantitative stress and resilience indicators in globally embattled coral reefs to be used to track the efficacy of conservation efforts. One way to start addressing this issue is to use genomics and bioinformatics. *Nematostella vectensis* is a burrowing anemone common to estuarine habitats along the east coast of North America, from Nova Scotia to Louisiana. It's a superb model for studying the evolution and ecology of cnidarian stress response because (1) it is easy to cultivate in the laboratory and collect in the field, (2) it inhabits hyper-variable habitats across a wide geographic range, (3) it is known to exhibit pronounced genetic structure at small spatial scales, and (4) its genome has been sequenced. Comparing the genomic complement of stress-genes in *Nematostella* and Triploblastica will help illuminate the stress-response system of early animals, perhaps revealing the importance of transcriptional control. Furthermore, the stress-response genes in *Nematostella* are likely to exhibit a homologous function in other cnidarians, including tropical reef-associated corals. A bioinformatics screen of the *Nematostella* genome identified 110 predicted chemical response proteins, 384 predicted wound healing proteins, and 128 predicted innate immunity proteins. Key elements of the innate immune system were identified, including members of the Toll and interleukin signaling cascades: IRAK, TRAF, ECSIT, IKK, MKK, JNK, IKB, p38, NF-κB and AP-1. Complements of genes active during wound healing in vertebrates were also identified. The highly conserved transcription factor, *Grainy head* has been shown to be a critical component in the formation of an epithelial barrier and can be recognized by the possession of a highly conserved CP2 domain. A search for this domain identified a single significant match. Identification and structural characterization of these genes will allow for functional assays to be performed. This work is a contribution of the MMAS Program.

## 6-15

**Coral Reef Metagenomics**

**Forest ROHWER*[1]**, Elizabeth DINSDALE[1], Robert EDWARDS[2], Linda WEGLEY[1], Rebecca THURBER[1], Kristen MARHAVER[3], Stuart SANDIN[3], Dana HALL[1], Florent ANGLY[4], Beltran BRITO RODRIGUEZ[4], Nancy KNOWLTON[3]

[1]Biology Department, San Diego State University, San Diego, CA, [2]Computer Science, San Diego State University, San Diego, CA, [3]Marine Biology, Scripps Intitution of Oceanography, San Diego, CA, [4]Computational Sciences, San Diego State University, San Diego, CA

An increasing body of evidence suggests that microbes are key players in both healthy and degraded coral reefs. We have been using metagenomics (i.e., shotgun sequencing of community DNA) to characterize the microbial communities within the coral holobiont, as well as in the surrounding water column. In the Northern Line Islands, the water column metagenomes showed that the microbial and viral communities changed from an even mix of autotrophs and heterotrophs to predominantly heterotrophs along a gradient of human disturbance and oceanographic conditions. In metagenomic studies of coral-associated microbial communities, we have found that the endolithic fungi are important to nitrogen recycling within the holobiont. Finally, metagenomic analyses of viral communities from corals showed that herpes-like viruses are induced by natural and anthropogenic stressors. Together, these studies demonstrate the power of metagenomics to deconvolute the complex interactions of corals and microbes.

## 6-16

**Settling On The Right Genes: Functional Genomics Of Variation in Marine Invertebrate Larval Settlement**

**Sandie DEGNAN*[1]**

[1]School of Integrative Biology, University of Queensland, Brisbane, Australia

The capacity of marine animals to cope with the rapid environmental challenges they now are facing is likely to be encoded in their genomes. Responses on the generational time scale will rely on natural genetic variation already existing within species and populations, especially where this is manifested as variable gene expression during crucial developmental stages. In the pelagobenthic life cycle shared by most marine invertebrates, a particularly crucial stage is when the dispersing larva settles out of the plankton onto the benthos, and metamorphoses into a reproductive adult. Settlement and metamorphosis cannot proceed without the larva first reaching developmental competency, and then encountering an appropriate inductive cue. The timing and success of these steps directly determine the structure, stability and evolution of natural populations. Variation around this transition is thus likely to be an important source of response to environmental change. We have used microarray gene profiling in two coral reef invertebrates - a haliotid mollusc and a pyurid ascidian - to identify candidate genes underpinning this critical developmental and ecological transition. We have found large numbers of genes that show differential expression associated with the onset of competency and settlement. Of particular interest are genes putatively involved in the innate immune pathway, which appear to be involved in responding to benthic cues, and coping with new challenges presented by the plankton – benthos transition. Importantly, we have documented extensive variation in the expression of these and other settlement genes both within and between populations, much of it correlated with specific environmental conditions. This inherent variation in gene expression is cause for hope that natural populations carry within themselves the capacity to cope with the inevitable changes in coral reef environments.

## 6-17

**Coral Population Genomics: Genome Evolution In Action**

**Mikhail MATZ*[1]**

[1]Integrative Biology, University of Texas at Austin, Austin, TX

Population genomics is a novel integrative approach to study the evolutionary process in natural populations on a whole-genome level. Population genomics integrates information about genes involved in the biological process of interest, variation of their expression in natural populations, genomic determinants of this variation and evolution of the corresponding loci as revealed through population genetic analysis. One of the technical foundations of this workflow is the microarray-based whole-genome genotyping methodology called iDART, developed in my lab. Currently our main focus is evolution of stress resilience and dispersal potential in Acropora millepora in response to climate change. The project takes advantage of the possibility to perform controlled crosses and assess physiological parameters, genotype and profile gene expression in individual A. millepora larvae.

## 6-18

**Examining The Genetic Basis Of Coral Morphospecies: Testing The Core Genome Hypothesis With Microarrays**

**Jason LADNER*[1]**, Madeleine VAN OPPEN[2], Stephen PALUMBI[1]

[1]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [2]Marine Microbiology and Symbiosis, Australian Institute of Marine Science, Townsville, Australia

With extensive cross-specific fertility and multi-species synchronized mass spawning events, reef corals represent an animal taxon unparalleled for its potential for interspecific hybridization. Yet, in the face of potentially homogenizing gene flow between species, high species diversity with extensive sympatry is maintained. One possible explanation is that the morphospecies we recognize are each defined by a core set of genes that must remain together while other regions of the genome can be freely exchanged between species. High-density oligonucleotide microarrays provide a powerful tool to test the core genome hypothesis by allowing rapid, fine-scale genome-wide interrogation of sequence similarity between coral species. We designed an array using the publicly available *Acropora millepora* expressed sequence tag (EST) library to investigate the genomic similarity of two highly cross-fertile coral species: *Acropora millepora* and *A. pulchra*. The arrays consisted of 21,576 unique 60 base pair probes. Twelve individuals from each species were hybridized separately to the array along with a common reference. Results show that 46% of the array probes (9945 of 21,576), speckled across 75% of the ESTs included on the array (4635 of 6156), show significant hybridization differences between *A. millepora* and *A. pulchra*. These probes identify regions that likely exhibit little to no introgression between these species, and therefore, may be responsible for the morphological and physiological differences between them. If confirmed, these results would suggest the core genome for these species is quite large. Additionally, this technique produces a hybridization intensity 'barcode' for each individual that has proven to be reliable for species identification, a task single gene techniques have often failed at in corals.

## 6-19

**Variation in Gene Expression Within And Among Acropora Millepora Populations On The Great Barrier Reef.**

**Line K BAY*[1]**, Karin E ULSTRUP[2], H Bjorn NIELSEN[3], Bette WILLIS[1,4], David J MILLER[1,5], Madeleine VAN OPPEN[6]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]Marine Biological Laboratory, University of Copenhagen, Helsingor, Denmark, [3]Centre for Biological Sequence Analysis, Danish Technical University, Lyngby, Denmark, [4]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [5]Biochemistry and Molecular Sciences, James Cook University, Townsville, Australia, [6]Australian Institute of Marine Science, Townsville, Australia

Gene expression is a fundamental link between the genetic make-up of an organism (genotype) and how it functions in its environment (phenotype) and, when correlated with biological and environmental variables, can provide novel insights into the ecology, evolution and health status of the target organism. Here we used a specific cDNA microarray to investigate natural variation in global gene expression within and among populations of *A. millepora,* a common reef-building coral on the GBR. We examined the roles of acclimatization and adaptation by comparing patterns of gene expression of field sampled coral colonies from two populations with different thermal environments and bleaching histories, with that following a ten-day acclimation in a common environment. ANOVA analyses revealed that four genes were differentially expressed between Populations ($p < 3.86 \times 10\text{-}6$; median absolute fold change (MAFC) = 0.99), 114 between sampling Locations (field vs lab) ($p < 2.48 \times 10\text{-}5$; MAFC = 1.04) and six in the Population by Location interaction ($p < 8.01 \times 10\text{-}5$; MAFC = 1.42). The significant location genes represented a range of functional groups and clustered into three expression profiles. These results suggest that *A. millepora* have substantial potential to up and down-regulate genes through acclimatization when ambient environmental conditions change. We also found potential for local adaptation in gene expression under natural conditions in a few genes in the Population and Population x Location treatments. Because many additional genes displayed large MAFC (>1.5) but low statistical significance in these treatments (No. genes: Population = 14, Population x Location = 51), it is possible that inter-colony variation obscured our ability to detect local adaptation in such genes. We examine inter and intra-colony variation in gene expression in this species in a subsequent experiment.

## 6-20

**Sponge Paleogenomics And The Evolution Of Biocalcification**

**Gert WORHEIDE*[1]**, Luciana MACIS[1], Joachim REITNER[1], Bernard M. DEGNAN[2], Daniel J. JACKSON[1,2]

[1]Courant Research Center Geobiology, University of Gottingen, Gottingen, Germany, [2]School of Integrative Biology, University of Queensland, Brisbane, Australia

The ability to regulate the formation of calcified structures was a key metazoan innovation during the late Precambrian that have, for example, enabled the subsequent development of reef structures throughout the Earth's history until present. However, the evolution of the biosynthetic pathways of biocalcification remain largely enigmatic and it is unknown to what extent the last common ancestor of the Metazoa (LCAM) provided the genetic tools to enable biomineralisation. Sponges, the most ancestral-like metazoans, were prolific calcifying and reef-building organisms during the Paleozoic and Mesozoic, and some of those taxa survive today. We have studied one such 'living fossil', the demosponge *Astrosclera willeyana* which possesses a calcareous basal skeleton, and applied a paleogenomics approach to show that a key molecular component of this biomineralisation-toolkit was the precursor to the diverse α-carbonic anhydrase (α-CA) gene family, one of the most physiologically important and catalytic enzymes known. We show that α-CAs expanded through several independent gene duplication events in sponges and eumetazoans, and that these coralline sponges inherited key components of the first multicellular skeletogenic toolkit from the LCAM. Furthermore, with recent whole genome sequencing efforts of various metazoans, EST collections and targeted gene studies, examples of conserved and lineage specific biocalcification genes are gradually being identified. In some cases we are now able to infer what skeletogenic genes may have been present in the LCAM and discuss this in the context of the evolution of metazoan biocalcification mechanisms and their resilience to ocean acidification.

## 6-21

**Coral Kin Aggregations Exhibit Mixed Allogeneic Reactions And Enhanced Fitness During Early Ontogeny**

**Keren-Or AMAR*[1,2]**, Nanette CHADWICK[3], Baruch RINKEVICH[1]

[1]Biology, Israel Oceanographic and Limnological Research (IOLR), Haifa, Israel, [2]The Mina and Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Ramat Gan, Israel, [3]Biological Sciences, Auburn University, Auburn, AL

Only sparse information exists on the selective forces and ecological consequences of aggregated settlement and chimera formation by kin larvae in marine invertebrates. Kin larvae of the reef-building coral *Stylophora pistillata* settle in aggregations. Upon contact, recruits either fuse, establishing a chimera, or reject one another. Our one-year study on growth and survival of 544 genotypes revealed six types of biological entities: single genotypes, bi-chimeras, bi-rejecting genotypes, tri-chimeras, tri-rejecting genotypes, and multi-partner entities. Analysis of allorecognition responses revealed an array of effector mechanisms from true tissue fusion, transitory fusion, borderline formation, and overgrowth, to rejection and partner death; all with complex ontogeny. We found that young multi-partner entities were the largest. However, at the genotype level, single genotype entities were the largest. Survival rates did not vary significantly among entities, but multi-partner entities exhibited the highest survival rate and single genotypes the lowest. We propose that a driving force for this gregarious kin settlement stems from benefits associated with the increased total size of the entity, forming biological organizations that exhibit, simultaneously, intricate networks of rejecting and fusible interactions.

## 6-22

**Chimera Formation During The Early Life History Of Acropora Millepora And Its Persistence Through Time**

**Eneour PUILL-STEPHAN*[1,2]**, Bette WILLIS[1], Madeleine VAN OPPEN[2], Lynne VAN HERWERDEN[1]

[1]James Cook University, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

Spawning corals broadcast their gametes typically once a year in high densities with the resulting larvae often settling in aggregations. This provides opportunities for chimera formation: the fusion of genetically distinct larvae into a single colony. This study examines the extent of chimera formation under experimental conditions in juveniles of the coral, *Acropora millepora,* and the frequency of chimeras in natural populations of this species.

When larvae of *Acropora millepora* were settled in aquaria, more than 47% of juveniles (n = 2168 recruits) settled in aggregations (two or more recruits in contact). Fusion within aggregations was assumed when coral tissue was continuous within a colony and when new polyps appeared at the contact margin. In order to assess if different genotypes remained distinct within fused aggregations, 7 microsatellites were used to genotype sub-samples of potential genetic chimeras. Preliminary results highlight the occurrence of genetic chimeras, indicating that *Acropora millepora* juveniles are able to form chimeric entities in their early life history stages.

Although *Acropora millepora* juveniles form chimeras under experimental conditions, screening the extent of genetic chimeras within adult colonies will help to understand if chimerism also arises naturally within populations. Chimerism was assessed in two populations (n=30 adult colonies per population) by comparing the genotypes of branches within colonies (8 per colony) using 7 microsatellites. Chimeric colonies were found to comprise between 3 and 6 percent of each population (or 5% overall). Thus, chimerism occurs naturally at low frequencies in populations of *Acropora millepora* on the Great Barrier Reef. As chimeras represent enhanced genetic diversity within a coral colony, the presence of chimeras within natural populations of spawning corals on the Great Barrier Reef may provide a selective advantage in a heterogeneous environment.

## 6-23

**Symbiodinium – To Be An Alga Or Not, That Is The Question**

**Bill LEGGAT*[1,2]**, David YELLOWLEES[2]

[1]Biochemisry and Molecular Biology, James Cook University, Townsville, Australia, [2]ARC CoE for Coral Reef Studies, James Cook University, Townsville, Australia

Symbiodinium (also called zooxanthellae) seem to conform to our traditional idea of alga should be, they are a small single cell that photosynthesises. However the more we learn about their genetic compliment the more unique they appear. Only recently have large scale surveys of the dinoflagellate genome begun. This study characterises a recent large scale sequencing effort from Symbiodinium and describes some of the unique genetic compliment of Symbiodinium both in culture and in symbio. These unique characteristics include a large percentage of genes which are most closely related to those found in bacteria. These include genes that encode for a number of proteins involved in the transport of metabolites (such as sugars), which may play a key role in the coral symbiosis. The most abundant transcript found in the Symbiodinium transcriptome is also of bacterial origin. Sequence analysis and antibodies indicate that it is localised to the chloroplast where it function is unknown. This study also describes the variety of biochemical pathways that we have characterised from Symbiodinium and how they differ from what we might expect of a "traditional alga", with particular emphasis on those pathways that may be important for the coral-Symbiodinium symbiosis.

## 6-24

**Est Screening And Multigene Analysis Of Symbiodinium Dinoflagellates: A Phylogenomic Approach**

**Xavier POCHON*[1]**, Ruth GATES[1]

[1]Hawaiian Institute of Marine Biology, Kaneohe, HI

Symbiotic dinoflagellates in the genus Symbiodinium are essential components of coral reef ecosystems contributing to the growth, survival and success of a large array of protist and invertebrate phyla. Phylogenies based primarily on multi-copy genes and spacers of the ribosomal DNA operon have defined eight distinct groups within the genus Symbiodinium, referred to as clades A through H. Each of these groups contain multiple ribotypes (ITS types) that are often considered to represent species-level taxonomy. However, intragenomic variation (within an individual) in the rDNA ITS markers potentially results in comparisons of paralogues rather than orthologues and this creates a complex framework for taxonomic interpretation. To address this issue the current work focuses on defining new, functionally relevant and readily interpretable genes for future taxonomic studies. Interchangeable BLAST comparisons of two Symbiodinium and six dinoflagellates EST datasets have resolved 93 new Symbiodinium gene candidates. Eight of these genes (psbA, CoxI, CoxIII, Elongation Factor, Calmodulin, Actin, Alpha-tubulin, and rad24) have been sequenced from Symbiodinium DNAs representing all known clades in the genus. Five markers displayed divergence rates similar to those found in the LSU rDNA region, and three genes (Actin, Calmodulin and rad24) harbor up to four highly variable introns that can potentially resolve within clade Symbiodinium diversity. The identification and phylogenetic comparison of these markers will be presented and discussed.

## 6-25

**The Holobiont Transcriptome Of *aiptasia Pallida***

Shini SUNAGAWA[1], Monica MEDINA[1], Virginia WEIS[2], John PRINGLE[3], **Jodi SCHWARZ*[4]**

[1]School of Natural Sciences, University of California Merced, Merced, CA, [2]Department of Zoology, Oregon State University, Corvallis, CA, [3]Department of Genetics, Stanford University, Stanford, CA, [4]Biology Department, Vassar College, Poughkeepsie, NY

Aiptasia pallida has long served as a model for examining the physiology of coral symbiosis and coral bleaching. To build upon the rich history of this model system, we are examining the transcriptome of symbiotic Aiptasia, using a large insert cDNA library from which we generated a high quality dataset of approximately 8000 ESTs. We have collaborated with our undergraduate students to assemble and annotate these genes, and have characterized a rich set of stress-response, developmental, signaling, and innate immune-related proteins from both the host and the symbiont. This dataset will facilitate genomic-level examination of host-symbiont interactions and the bleaching response. Currently, using this EST dataset, we are examining both physiological and transcriptome-level pathways of the stress response under different stressors, including temperature and heavy metal contamination.

## 6-26

**Exploring Symbiotic Interactions in the Sea Anemone-Zooxanthellae Model by Large-Scale ESTs Analysis**

Philippe GANOT[1], **Aurelie MOYA*[1]**, Emeline DELEURY[2], Denis ALLEMAND[3], Paola FURLA[1], Cecile SABOURAULT[1]

[1]ECOMERS, Nice Sophia Antipolis University, Nice cedex2, France, Metropolitan, [2]UMR 1112 ROSE, INRA, Sophia Antipolis, France, Metropolitan, [3]Scientific Centre of Monaco, Monaco, Monaco

To characterize genes involved in the symbiotic association between the cnidarian sea anemone *Anemonia viridis* and its dinoflagellate symbiont (zooxanthellae) *Symbiodinium* sp., a large EST collection was generated. A cDNA library was constructed from total mRNAs (cnidarian and zooxanthellae) isolated from symbiotic, aposymbiotic (bleached) and stressed (temperature) animals. A total of 39,939 ESTs compiled in 4,614 contigs and 10,976 singletons sequences were analyzed. Comparison to the genomic *Nematostella vectensis* database and to all other annotated expressed sequences (UniProt) indicates that our *A. viridis* dataset comprises sequences related to metazoan, protists and prokaryotes, respectively 51%, 8% and 3.9%, as well as 35.1% without known homology to any sequences. Interestingly, long 3' UTR often containing a miniature non-autonomous transposon element (MITE related) are overrepresented in our Anemonia–assigned sequences. A subset of 2,000 genes, potentially involved in symbiosis (heterotrophic metabolism, transporter, cell cycle control …), were used to design a 60 mer oligonucleotides dedicated microchip. Comparative gene expression through microarrays analysis between symbiotic, aposymbiotic and stressed animals are currently underway.

## 6-27

**Genomic Insight Into Drupella Sp.: Establishment And Analysis Of An Est Database**

**Bishoy HANNA*[1]**, Felipe CHAMBERGO[2], Hamza EL DORRY[1], Moshira HASSAN[1], I CHAMBERGO[2], Amira MAHMOUD[1]

[1]American University in Cairo, Cairo, Egypt, [2]University of SÃ£o Paulo, Sao Paulo, Brazil

The corallivorous gastropod Drupella sp. has caused considerable damage to a number of coral reefs in the Red Sea over the last years. These outbreaks have been linked to other diseases, but the underlying cause is still unclear.

In this work, we establish an insight into the genome of Drupella sp. using an EST library.

Surveys were conducted on a heavily infested reef in the northern Gulf of Suez, Red Sea. The total RNA was isolated from a whole organism, which was collected from a colony of Stylophora pistillata. A cDNA library was constructed and 9408 random clones were sequenced. Computational analysis resulted in a total of 3353 sequences of which 2109 received no significant BLASTX match while the other 1244 sequences were further classified according to the Gene Ontology classification. The resulting classification covered most physiological activities carried by the organism. The sequences revealed a group of retrotransposons that were expressed at the time of collection. In addition to neurotoxins and other toxin genes that were expressed, several proteins were found that are expressed as responses to oxidative stress, hypoxia, viruses, and bacterial infections. Some of ESTs found are most likely of non-mollusk origin resembling symbionts and parasites that are part of the organism and the reef community. A website was constructed to cater for the data generated, with a BLAST search interface. The isolated genes can be investigated as potential biomarkers for water contamination and in order to understand the conditions leading to Drupella sp. outbreaks. The retrotransposons found can be compared spatially to establish population barriers. These results will also be used to find useful genes to study population genetics of this organism at different temporal and spatial scales.

## 6-28

**Do Corals Possess The Protective Mucus Encoding Muc Genes?**

**Amita JATKAR*[1]**, John BYTHELL[2], Barbara BROWN[1], Jeff PEARSON[3], Nick MORRIS[4], Reia GUPPY[1]

[1]Division of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]Division of Biology, Newcastle University, Newcastle upon tyne, United Kingdom, [3]Institute for Cell and Molecular Biosciences, Medical School, Newcastle University, Newcastle upon Tyne, United Kingdom, [4]School of Biomedical Sciences, Medical School, Newcastle University, Newcastle upon Tyne, United Kingdom

Mucus functions as first line of defence against infections, amongst other roles. The protective role of mucus depends upon gel-forming properties of mucin molecules that are encoded by the MUC genes. Although the presence of MUC genes has been detected in several vertebrate groups, mucus or a mucus-like extra cellular matrix is believed to be secreted in all groups of animals. The human MUC gene family is comparatively well studied and expanding rapidly, with 19 MUC genes discovered so far. These MUC genes have been grouped into secretory and membrane-bound mucins. Failure of this protective barrier has been associated with changes in structure, function and physical properties of mucins. These changes have been demonstrated as a possible prognostic tool for early diagnosis of diseases such as cancer, tumour and cystic fibrosis in humans. Earlier studies on coral mucus show an inconsistent chemical composition influenced by depth, aging and contamination from the environment. It is well established that coral surface mucus harbours a distinct microbial community that respond to changes in environmental factors. Study of mucus-microbial interactions is critical to understand phenomena such as bleaching and disease. Relatively little information is available regarding MUC gene structure and functions in corals. The present study examines the ways to detect coral MUC genes by tracing the evolution of MUC genes from cnidarians to mammals using bioinformatics and molecular tools. Using a range of bioinformatic techniques, six potential MUC-gene sequences have been recovered from the available coral databases. Three of these are from the hyper-variable tandem repeat (TR) domain or mucin domain and are highly likely to represent human MUC-gene homologues. This study will enhance the understanding of host responses and changes in defensive capabilities due to changing surrounding conditions.

## 6-29

**New Applications For A Proven Tool: Metabolite Profiling And Chemometrics To Characterise Effects Of Turbidity And Sedimentation On The Coral Acropora Millepora**

**Anke KLUETER*[1]**, Jonathon L. NIELSON[1]

[1]Australian Institute of Marine Science, Townsville, QLD, Australia

With constantly increasing levels of land based activities within the GBR catchment there is an increasing need to innovate and explore new methodologies of monitoring reef health and water quality. Metabolomics, a growing research discipline in systems biology, allows us to look at a metabolic response of the cell and organism as a whole. Objects of study are primary and secondary metabolites, necessary for life and the intermediates and end products of cellular regulatory processes. The state of an organisms 'metabolome' at any point in time represents the interaction of the organism's genome with its environment. By taking a 'snapshot' of the metabolic profile of an organism under various environmental stressors it is possible to identify metabolites involved in the organisms biochemical response to stress.

We examined the stress response of Acropora millepora to changing water quality. Using a tank system with controlled environmental conditions, corals from inshore and mid-shelf locations were exposed to shaded and non-shaded conditions with and without suspended particulate matter (SPM). The coral's metabolic response was investigated by preparing acetone/methanol extracts and acquiring Proton Nuclear Magnetic Resonance spectra (HNMR) and Liquid Chromatography Mass Spectrometry (LC-MS) data. Data were subjected to Principal Component Analysis. Significant clustering in relation to treatment was observed in the HNMR data sets. The first principal component was strongly correlated to presence or absence of SPM. Samples showed also a tendency to cluster according to exposure to light or shade. Analysis of LC-MS data showed the strongest correlation between the coral's geographic origin. Here we identified four different metabolites between inshore and mid-shelf colonies.

Our results demonstrate the prospective of metabolomics as a new monitoring technology to assess coral health.

## 7-1

**Patterns of Coral Diseases in the Florida Keys from 1998 – 2005**

**Deborah SANTAVY*[1]**, Susan YEE[1], Mace BARRON[1]

[1]Gulf Ecology Division, US EPA, NHEERL, Gulf Breeze, FL

Diseases have been identified as a major threat to reef-building corals causing morbidity and mortality. Increased mortality has lead to degradation, especially those reefs dominated by several susceptible species. Increased morbidity has reduced the health of reef-building corals making them more vulnerable to other environmental stressors. Reported incidence, prevalence, and distribution of coral diseases have been greatest from the tropical Western Atlantic, with emergent coral diseases, such as aspergillosis and serratiosis originating from terrestrial sources. Epizootiological studies assessed the prevalence of dominant coral diseases in the Florida Keys reef tract from 1998-2005, from the Dry Tortugas to the Upper Keys. Annual assessments were repeated at permanent sites in mid-summer throughout the area. Data were adjusted so coral community composition, specifically the absence of susceptible species, did not bias the results. Canonical correspondence analyses revealed coral diseases patterns related to spatial and temporal parameters. Reef depth was the most discriminating parameter for all coral diseases surveyed. White plague and white-band disease had the highest prevalence on deeper reefs, whereas black-band disease was most prevalent on mid-depth reefs, and red-band disease and white pox were most prevalent on shallow reefs. White-band disease had the highest prevalence in the early years, whereas dark-spots disease had increased incidence in the later years of the study. Dark-spots and yellow-blotch diseases were more common in the Dry Tortugas, whereas black-band disease had the highest prevalence in the Middle Keys. One of the first steps in identifying and managing health threats of reefs is to establish disease prevalence and incidence to understand patterns and associate them with other variables to determine causative factors. In tropical marine systems prevention or control of coral disease can assist in precluding the collapse of important ecological functions and ecosystem services.

## 7-2

**The Role Of Diseases in Coral Community Structure Shifts in Mexican Caribbean Reefs**

**Eric JORDÁN-DAHLGREN*[1]**, Rosa RODRÍGUEZ-MARTÍNEZ[2], Adan Guillermo JORDÁN-GARZA[3], David M. BAKER[4], Jason ANDRAS[5], Leonardo VAZQUEZ-VERA[6]

[1]ICMyL, UAPM, Universidad Nacional A. de México, Puerto Morelos, Mexico, [2]ICMyL, UAPM, Universidad nacional A. de México, Puerto Morelos, Mexico, [3]ICMYL, UAPM, UNiversidad Nacional A. de México, Puerto Morelos, Mexico, [4]Ecology and evolutionary Biology, Cornell University, Ithaca, NY, [5]Ecology and Evolutionary biology, Cornell University, Ithaca, NY, [6]ICMyL,UAPM, Universidad Nacional A. de México, Puerto Morelos, Mexico

Montastraea annularis, M. faveolata and M. franksi, the major local coral reef builders after the demise of Acroporids in the Mexican Caribbean, has decreased more than half in a twenty years span; presumably due to diseases. Recent data (2005-2007) from highly replicated permanent sites spread over a 200km reef tract shows relatively large rates of whole colony and partial mortality for these species, both within and between sampling sites. Yellow Blotch syndrome appears to be the major cause of the observed mortality patterns, although other disease signs also play a role. Species of Acropora, Diploria and Colpophyllia natans, the other potentially important reef builders are also being severely affected by other diseases. In contrast Agaricia agaricites, Porites astreoides and Siderastrea siderea while not being immune to coral diseases show a much higher resistance and mortality rates are comparably low; becoming the dominant components in reefs down to 15m deep. Although variable among sites, comparisons of species size structures indicates that local shifts in dominant species appears to be related to higher survival rates, rather than to increased recruitment rates. Analyzing linkages of the observed patterns with site relative degree of local development, protected and non-protected status and local thermal anomalies shows mixed trends. These findings suggest that global and regional drivers of environmental deterioration may have a stronger influence than local ones in the study area.

## 7-3

**Recent Changes To Montastraea Annularis And M. Faveolata Populations In Southwestern Puerto Rico And Associated Islands From Disease And Bleaching**

**Andrew BRUCKNER*[1]**, Ron HILL[2]

[1]NOAA Coral Reef Conservation Program, NOAA, Silver Spring, MD, [2]Fisheries, NOAA, Galveston, TX

Over the last decade, reefs off southwest Puerto Rico and the associated islands have experienced losses in live coral cover in excess of 50%, primarily due to the decline of M. annularis and M. faveolata. These species were formerly the largest and most abundant corals remaining on these reefs. Outbreaks of coral disease, especially white plague and yellow band disease, affected over 50% of the colonies in some sites during the late 1990s; disease prevalence declined between 2002-2004 and then increased immediately following a 2005 mass bleaching event. These diseases have caused unprecedented rates of mortality, with cumulative losses exacerbated by bleaching and parrotfish predation. In both species, a lack of recruitment and only limited recovery through resheeting have been observed, and exposed skeletal surfaces are being colonized by macroalgae, bioeroding sponges, hydrozoans, and other scleractinian coral recruits (primarily Porites and Agaricia). Unlike acroporids, which have the potential for rapid growth and recovery, M. annularis and M. faveolata are unlikely to recover in our lifetimes and are being replaced by shorter-lived brooding species and other massive and plating species with faster growth and higher recruitment rates. The impacts of these shifts on coral community structure and reef fisheries are unknown. Approaches undertaken to recover acroporids, such as propagation through fragmentation and grow-out of sexual recruits, are less likely to work for M. annularis (complex) - species with slow rates of growth and limited recruitment. To avoid a catastrophic and permanent shift in coral community composition, research needs to be directed towards an improved understanding of the causes and impacts of diseases and bleaching, and possible control mechanisms. Managers and policy makers must take steps to mitigate environmental and anthropogenic stressors that increase the spread and severity of disease.

## 7-4

**The Future Of Coral Reefs in The Us Virgin Islands: Why *acropora Palmata* Is More Likely To Recover Than *montastraea Annularis* Complex**

**Caroline ROGERS*[1]**, Erinn MULLER[2], Tony SPITZACK[1], Jeff MILLER[3]

[1]US Geological Survey, St John, Virgin Islands (U.S.), [2]Florida Institute of Technology, Melbourne, FL, [3]National Park Service, St John, Virgin Islands (U.S.)

The Caribbean bleaching/disease event that began in the summer of 2005 caused significant mortality of the two most important reef-building corals in the US Virgin Islands (USVI), *Acropora palmata* and *Montastraea annularis* complex (Macx). These corals characterize the shallow and mid-depth zones of the islands's reefs, and their ability to recover will define the future seascape in the USVI. Research on *A. palmata* from 2003 to 2007 around St. John documented disease prevalence ranging from 0 to 52% with high levels of white pox (and un-described diseases) and very low levels of white band disease that caused major losses 25-30 years ago. Over 94% of the white pox lesions healed at least partially. *Acropora palmata* bleached for the first time in the USVI in 2005. Forty-five percent of 460 colonies from several sites bleached, and 8% died. Bleached corals had greater disease mortality than unbleached. *Acropora palmata* had high genotypic variation, and evidence of limited, recent sexual recruitment. Survival of fragments ranged from 29 to 60%. Deeper reef zones dominated by Macx showed greater coral bleaching and mortality (primarily from white plague) following the record-high seawater temperatures in 2005. Over 98% of the Macx bleached, and ca. 90% of the disease mortality was seen on Macx. Healing of disease lesions was not observed. Over the next 50 to 100 years, *A. palmata* has a greater potential to recover than Macx because of its higher growth rate, greater ability to colonize new areas through fragmentation, and lower vulnerability to bleaching and disease. The future of these major reef-building corals and of USVI reefs will depend also on the connectivity between these reef zones and sources of coral larvae.

## 7-5

**Coral Yellow Band Disease; Current Status in The Caribbean, Outbreaks And The Links To New Indo-Pacific Lesions**

**Angela RICHARDS DONA*[1]**, J.M. CERVINO[2,3], Vicky KARACHUN[2], Elizabeth LORENCE[2], Erich BARTELS[4], Konrad HUGHEN[5], Garriet SMITH[6], Thomas GOREAU[7]

[1]Biological Sciences, Pace University, Brooklyn, NY, [2]Biological Sciences, Pace University, NY, NY, [3]Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, [4]Mote Marine Lab, Summerland Key, FL, [5]Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, MA, [6]Biological Sciences, University of South Carolina, Aiken, SC, [7]Global Coral Reef Alliance, Cambridge, MA

Yellow band disease (YBD) has had a severe impact on the major reef building corals in the Caribbean. Recent data from Lesser Antilles indicates that this disease is still in a severe epidemic phase showing similar trends compared to the late 1990s. Ten meter belt transects taken at varied depths of *Montastraea* spp. indicate high indices of yellow band lesions. At 5m depth, the largest number of live *Montastraea spp*. were found. Yellow band rings and lesions were positively identified to be affecting an average of 8.4 (79%) colonies per transect. Only an average of 2.2 (21%) colonies in this depth range appeared healthy. At 10m depth *Montastraea* colonies which could be positively identified with distinct YB lesions seem to be more numerous than at deeper depths. An average of 1.2 (16%) healthy colonies and 6.2 (84%) colonies affected by YBD per 10m transect were counted. At 15m there was an average of 1.2 (44%) healthy colonies and 1.5 (56%) colonies affected by YBD per 10m transect. These data coincide with recent severe outbreaks in the Indo Pacific where identical lesions were found on the surfaces of *Diploastrea spp*., *Herpolitha spp.*and *Fungia spp.* Cytological analysis and histological sections reveal identical cell death mechanisms as shown in Caribbean YBD coral specimens. Inoculation experiments of Indo-Pacific bacterial isolates under ambient temperatures in aquaria cause the induction of YB lesions onto *Montastraea spp. in vitro*. This recent research indicates that YBD continues to be in an infectious stage in the Caribbean and has been found to cause infection in Pacific coral genera.

## 7-6

**Coral Health And Disease Assessment In The U.S. Pacific Trerritories And Affiliated States**

**Bernardo VARGAS-ANGEL*[1]**, Benjamin WHEELER[2], Jean KENYON[1], James MARAGOS[3], Bonnie DEJOSEPH[1]

[1]Coral Reef Ecosystem Division, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [2]Department of Oceanography, University of Hawaii, Honolulu, HI, [3]Remote Islands National Wildlife Refuge Complex, USFWS, Honolulu, HI

In 2006 and 2007, quantitative coral disease assessments were conducted at 40 different coral islands, banks, and atolls (Johnston, Palmyra, and Wake Atolls, Howland, Baker, and Jarvis Islands, Kingman Reef, the Main Hawaiian Islands, the Northwestern Hawaiian Islands, Guam, and the Commonwealth of the Northern Mariana Islands), spanning over 3500 km and nearly a 20º latitudinal gradient. Distribution and prevalence were determined from 25 m belt transects at 316 sites, totaling an area of over 90,000 m2 of reef habitat. Ten broad disease categories were recognized, affecting 27 different anthozoan genera; prevalence was computed based on the estimated total number of coral colonies per survey area. The most geographically and taxonomically widespread disease was the skeletal growth anomalies, detected at nearly 60% islands/atolls and on 8 different anthozoan genera. In contrast, the most prevalent disease was the acute tissue loss, aka white syndrome, which exhibited a diverse range of host genera, including *Acropora*, *Montipora*, *Pocillopora*, *Goniastrea*, and *Platygyra*. Band diseases were rare, with only two cases enumerated for all the regions on *Porites* and *Coscinaraea*. The overall abundance of coral diseases in the US Pacific is low. However, patterns of prevalence vary among coral genera and indicate that only a few taxa are disproportionately affected by disease, namely the Acroporidae and Poritidae. Of potential concern is the white syndrome, which results in severe and rapid tissue loss, particularly on the tabular *Acropora cytherea* at Johnston Atoll and French Frigate Shoals.

## 7-7

**Guam Reefs Show A Link Between The Dominant Genus Porites And Disease Prevalence**

**Roxanna MYERS*[1]**, Laurie RAYMUNDO[1]

[1]Marine Laboratory, University of Guam, Mangilao, Guam

Coral diseases are considered to be a major cause, and often a result, of the recent worldwide decline of coral reef health and productivity. Relative to the Caribbean little is known about the impacts of coral diseases on Indo-Pacific reefs which are more widespread with greater diversity and are often more impacted by dense human coastal populations. Therefore, understanding the impact of coral diseases on Guam reefs was considered an important management issue for local scientists. Initial surveys of 12 Guam reefs conducted in 2006-07 revealed mean disease prevalence as highly variable, both within and between sites possessing a weak relationship with live hard coral cover ($R2 = 0.01$; $p>0.05$). Coral composition consisted of 13 major families and total disease prevalence ranged from a low of 2% (Pago Bay) to a high of 38% (Cocos Lagoon). Four sites were selected for long-term monitoring of disease prevalence, changes in benthic composition and temperature. Results from the first year of monitoring on Luminao Reef suggest highest disease prevalence corresponding to the period of warmest temperatures (30.1 + 1.0 ºC), with prevalence increasing from 6% to 30% in one year. Guam reefs were taxonomically diverse, but dominated by the genus *Porites*. They displayed a strong link between total disease prevalence and generic abundance per family ($R2=0.89$; $p<0.0001$). Five out of six diseases described on Guam affected various species within *Porites* (mean prevalence: 9.1% $\pm$ 4.1%). The fact that this genus is the primary reef builder on Guam reefs suggests that coral diseases which result in partial or full colony mortality have the potential to have significant long-term effects on community structure.

## 7-8

**Characterizations Of The Major Coral Diseases Of The Philippines: *porites* Ulcerative White Spot Syndrome And Novel Growth Anomalies Of *porites***

**Longin T. KACZMARSKY*[1]**, Raju SEKAR[1], DeEtta K. MILLS[2], Esther C. PETERS[3], Laurie L. RICHARDSON[1]

[1]Biological Sciences, Florida International University, Miami, FL, [2]International Forensic Research Institute, Florida International University, Miami, FL, [3]Tetra Tech, Inc., Fairfax, VA

Porites are important dominant reef-builders on Indo-Pacific reefs. Recently, Porites Ulcerative White Spots Syndrome (PUWS) and Growth Anomalies (GAs) have occurred at high prevalence on Philippine reefs. Yet, little is known about these coral-killing diseases. We applied an integrative approach to characterize environmental correlates and histological, microbiological and molecular aspects. We hypothesized that differences in coral-associated microbial communities might explain the diseases. Previous research suggested transmission of GAs between Porites colonies and thus the possible involvement of a pathogen. To manage these diseases, pathologic diagnosis and characterization are needed. In 2005, diseased and non-diseased tissues were collected. Microbial community profiling using amplicon-length heterogeneity-PCR and cloning and sequencing of 16S rRNA genes revealed differences between the diseased and non-diseased communities. Compared to healthy coral, clones from GAs included more sequences of Pseudomonas and Vibrio and an absence of Alteromonadaceae (known to have antimicrobial properties) suggesting Alteromonadaceae confer some protection. PUWS-infected tissue yielded fewer Vibrio but an abundance of Roseobacter not found in healthy corals. Cultured isolates unique to healthy coral included Bacillus and Vibrio strains. PUWS-infected tissue isolates included Roseobacter and V. harveyi. GAs yielded V. shiloi, V. harveyi, Pseudoalteromonas and distinct Bacillus strains. Antibacterial/synergism assays revealed Pseudoalteromonas from GAs inhibited Bacillus from healthy coral. One V. harveyi strain from GAs and PUWS-infected coral stimulated the growth of a different V. harveyi strain. Histologically, GAs exhibited severe vacuolation, mucocyte hyperplasia and hypertrophy, lower zooxanthellae density, altered chromophores, and calicodermal hypereosinophilia. Epidermal hypertrophy suggests hydropic changes resulting from damaged cell membranes. Analyses of water samples revealed positive correlations between high disease prevalence and high nutrient levels. Our results suggest some key factors involved in these diseases and provide direction upon which to focus future studies.

## 7-9

**Coral Disease At Palmyra Atoll in The Remote Central Pacific: Patterns Of Distribution And Histological Characterization**

**Gareth WILLIAMS*[1]**, Greta AEBY[2], Thierry WORK[3], Simon DAVY[1]

[1]Victoria University of Wellington, Wellington, New Zealand, [2]Hawaii Institute of Marine Biology, Kaneohe, HI, [3]US Geological Survey, Kaneohe, HI

Coral diseases are an ever increasing threat to coral reefs. This is clearly a concern for conservation and management of these systems and their reef associated organisms. This baseline survey was aimed at quantifying, in detail, the relationship between coral disease occurrence, environmental variables and coral community structure. Work was conducted over six weeks at the Palmyra Atoll National Wildlife Refuge, Central Pacific, during June to July 2007. Fifty-eight belt transects were haphazardly placed at 11 key sites (5 backreef and 6 forereef) established for long term monitoring around the atoll. Environmental variables measured were temperature, salinity, turbidity and chlorophyll *a* concentration. Sedimentation levels were also measured for all back reef sites. Growth anomalies were recorded on four coral genera (*Astreopora*, *Montipora*, *Fungia* and *Acropora*). In addition, tissue loss was seen on colonies of encrusting *Montipora* sp. These diseases were restricted to the backreef sites and occurred with an overall prevalence of 0.39 %, with prevalence at individual sites ranging from 0.2 – 1.0 %. This presentation will discuss how prevalence of coral disease relates to the environmental variables and coral community structure using an array of multivariate statistical techniques. Histological characterisation of the *Astreopora* growth anomalies will also be presented because this type of characterization is crucial to advancing our understanding of how diseases affect coral at a cellular level. Palmyra Atoll represents a location where the prevalence of coral disease and the impacts of environmental variables on this prevalence can be monitored in circumstances where more recent major anthropogenic impact has been greatly reduced. Moreover, knowledge of coral disease at this important wildlife refuge will aid its future monitoring and management.

## 7-10

**Effects Of Quick And Slow Diseases At Acropora Cytherea in Kerama Islands.**

**Akiyuki IRIKAWA*[1]**

[1]Department of Research, Association for Kerama coral Reef Conservation, Naha-Okinawa prefecture, Japan

In order to estimate effects of bleaching, *Acanthaster planci*, and diseases in a population of the reef-building coral *Acropora cytherea*, decadal monitoring researches have been conducted. The most severe impacts in the *A. cytherea* population are progressive diseases.

Skeletal anomalies (SAs) in *A.cytherea* develop mainly as white masses. On the surface of SAs, orderly skeletal structure and alignment of polyps became lost, and swelling SAs covered normal area like an avalanche. Negative aspects of SAs are lower potential in productivity and lack of fecundity. Although linear annual growth were 1.2～1.4cm/yr, multiple SAs became fused with neighboring ones. SA tended to start to die over 10cm diameter. If *A.cytherea* colonies keep usual growth rate, the impact by Sas are acceptable.

White syndrome (W.S.D.) arised at 2003, and became widespread at 2004. Approximately 70% colonies of *A.cytherea* have been killed by W.S.D for recent 3 years. By contrast with SAs, W.S.D have severe impact in a population of *A.cytherea*. On the lesioned part appearing white band, coral tissues are broken off. White band spread at the rate of up to 20cm centimeters per a month.

If W.S.D. does not blow over, A population of *A.cytherea* in Kerama Islands will be crushed within 10 years by interaction of bleaching, Acanthaster, and disease impacts.

## 7-11

**Prevalence And Potential Origin Of The White Pox Disease Pathogen in The Florida Keys, Usa**

**Kathryn SUTHERLAND*[1]**, James PORTER[2], Jeffrey TURNER[2,3], Brian THOMAS[1], Erin LOONEY[4], Trevor LUNA[1], Victoria WATSON[1], Erin LIPP[4]

[1]Department of Biology, Rollins College, Winter Park, FL, [2]School of Ecology, University of Georgia, Athens, GA, [3]Department of Environmental Health Science, University of Georgia, Athens, [4]Department of Environmental Health Science, University of Georgia, Athens, GA

Serratia marcescens is a causal agent of the coral disease, commonly known as white pox and etiologically known as acroporid serratiosis, that affects the Caribbean elkhorn coral Acropora palmata. The purpose of this study is to elucidate the prevalence and the source of the bacterium in the marine environment. Nearshore marine and reef environments in the Florida Keys and raw sewage were screened for the presence of the bacterium. S. marcescens were cultured and identified from environmental samples using a three-step method: culture on MacConkey Sorbitol agar followed by culture on DNase with Toluidine Blue agar followed by Serratia-specific PCR. PCR products from a sub-sample of confirmed isolates were sequenced to verify identity. Restriction endonuclease digestion (SpeI) followed by pulsed-field gel electrophoresis (PFGE) was used to determine genetic similarity among and between strains and potential source areas. A total of 383 S. marcescens were isolated from the surface mucopolysaccharide layers of the scleractinian corals Siderastrea siderea and Solenastrea bournoni, the corallivorous snail Coralliophilia abbreviata, seabird guano, beach water, canal water, and sewage. The majority of S. marcescens (72%) were obtained from sewage and contaminated nearshore sources. A total of 118 distinct PFGE patterns were identified, indicating that S. marcescens is genetically diverse in environments of the Florida Keys. Eleven groups (strains) contained two or more identical isolates, and one of these strains included isolates collected from sewage, C. abbreviata, S. siderea, and S. bournoni. This strain, isolated from both reef and sewage sources, establishes a definitive connection between human sewage and the reef ecosystem.

## 7-12

**Epizootiology Of *montipora* white Syndrome in Kaneohe Bay, Oahu, Hawaii**

**Greta AEBY*[1]**, Megan ROSS[2], Thierry WORK[3], Teresa LEWIS[1]

[1]Hawaii Institute of Marine Biology, Kaneohe, HI, [2]University of Hawaii, Honolulu, HI, [3]USGS, Natl Wildlife Health Center, Honolulu, HI

Coral disease is emerging as a problem in the Indo-Pacific yet little is known about the ecology of these diseases or factors that may be affecting disease levels. *Montipora* white syndrome (MWS) is a coral disease resulting in tissue loss that was identified in Kaneohe Bay, Oahu, Hawaii in 2004. Kaneohe Bay has a north-south gradient in anthropogenic stressors and so provided a model system to examine the relationship between proximity to potential stressors and disease prevalence. The objectives of this study were to document the distribution and abundance of *Montipora* white syndrome on reefs throughout Kaneohe Bay, examine the relationship between disease prevalence and environmental stressors and determine the ultimate damage to coral colonies from this disease. *Montipora* white syndrome was found in all regions of Kaneohe Bay but prevalence was highest in south Kaneohe Bay, the region most subject to terrestrial run-off. MWS was present on corals throughout the year with no significant difference in disease prevalence in Fall vs. Spring. Fifty-four out of 57 tagged coral colonies infected with MWS experienced progressive tissue loss ranging from 1% of the colony to complete mortality (avg. loss=36.7%) within one year. Average rate of tissue loss was 3.1% per month with one third of the colonies losing 90% or more of their tissues resulting in partial to complete colony collapse within one year. MWS was found to stop and re-start on individual colonies suggesting there are intrinsic and/or extrinsic factors controlling its progression. We also discovered differential susceptibility to MWS between two color morphs of *Montipora capitata.*

## 7-13

**Black Band Disease (BBD): A Possible Polymicrobial Disease**

Orit BARNEAH[1], Eitan BEN-DOV[1], Esti KRAMARSKY-WINTER[2], Yossi LOYA[2], **Ariel KUSHMARO*[1]**

[1]Department of Biotechnology Engineering, Ben-Gurion University, Beer-Sheva, Israel, [2]Department of Zoology, Tel-Aviv University, Ramat Aviv, Tel Aviv, Israel

Microbial communities associated with black band disease (BBD) in massive stony corals from the Northern Red Sea (Eilat) were examined for the first time using microscopy, microbiological and molecular tools. A high microbial diversity was revealed in the affected tissue in comparison with the healthy area of the same colony. Microscopy revealed the penetration of cyanobacteria into the coral mesoglea and adjacent tissues. Cyanobacterial sequences from Red Sea BBD-affected corals formed a cluster with sequences previously identified from black band and red band diseased corals from the Indo-Pacific and Caribbean. In addition, 11 sequences belonging to the genus Vibrio, a group previously documented as being pathogenic to corals were retrieved. The distribution and diversity of sulfate-reducing bacteria, a group known to be associated with BBD and produce toxic sulfide, were studied using specific primers for the amplification of the dissimilatory sulfite reductase gene (dsrA). This technique facilitated and improved the resolution of the study of diversity of this group. All the sequences obtained were closely related to sequences of the genus Desulfovibrio and 46% showed high homology to Desulfovibrio desulfuricans. The complex nature of BBD and the lack of success in isolating a single causative agent suggest that BBD may be a polymicrobial disease.

## 7-14

**Black Band Disease Dynamics And Variation in The Pathogenic Microbial Community**

**Joshua D. VOSS*[1]**, DeEtta K. MILLS[2,3], Sara E. EDGE[1], Laurie L. RICHARDSON[2]

[1]Robertson Coral Reef Program, Harbor Branch Oceanographic Institute at Florida Atlantic University, Fort Pierce, FL, [2]Biological Sciences, Florida International University, Miami, FL, [3]International Forensic Research Institute, Florida International University, Miami

Black band disease (BBD) is a pathogenic microbial assemblage that infects scleractinian corals on reefs worldwide. After more than thirty years of BBD research, involving multiple teams and approaches, the microbial composition of this assemblage, the mechanisms of pathogenicity, and the environmental conditions that promote infection remain elusive. A growing number of published studies report differences in the microorganisms that comprise BBD assemblages. While some biogeographic trends have emerged, relatively small sample sizes and differences in methodologies limit the inferences that can be made from these divergent data sets. This study utilized length heterogeneity polymerase chain reaction (LH-PCR) to provide robust, reproducible, and efficient profiling of BBD microbial communities from various sites in the Caribbean. LH-PCR differentiates organisms based on natural variation in the 16S rRNA gene and allows more rapid comparisons of community structure among multiple samples as compared to cloning and sequencing approaches, albeit with the associated limitation of discriminating taxa more broadly. The goal of this study was to assess patterns of variation in BBD microbial assemblages with respect to geographic location, host species, and time. Multivariate ordination and nonparametric analyses of the LH-PCR profiles revealed significantly distinct BBD microbial communities sampled from different geographic regions of the Caribbean. Although significant variation also exists between BBD infections on different coral species, geographic location appears to more strongly influence microbial community structure than host species. Despite minor temporal community variations within individual BBD infections, significant differences between regions persist. Together with findings of previous and ongoing molecular analyses of BBD bacterial communities, these results evidence the intrinsic complexity of this dynamic microbial assemblage.

## 7-15

**The Origin Of *Aspergillus Sydowii*, An Opportunistic Pathogen Of Caribbean Gorgonian Corals**

**Krystal RYPIEN*[1]**, Jason ANDRAS[1], Ginger GARRISON[2], C. Drew HARVELL[1]

[1]Cornell University, Ithaca, NY, [2]USGS Center for Coastal & Watershed Studies, St. Petersburg, FL

Coral reefs are increasingly suffering outbreaks of disease, causing dramatic declines in population abundance and diversity. One of the best-characterized coral diseases is aspergillosis, caused by the fungus *Aspergillus sydowii*. *A. sydowii* is a globally distributed saprophyte commonly found in soil, so its presence in marine systems raises questions about its origin. Using microsatellite markers, I analyzed the population structure of *A. sydowii* from diseased sea fans, diseased humans, and environmental sources worldwide. The results indicate that *A. sydowii* forms a single global population, with low to moderate differentiation between isolates from sea fans and those from environmental sources. Past researchers have suggested that *A. sydowii* originates from African dust blown into the Caribbean, and have identified *Aspergillus* from dust samples, although only to the genus level. To test this hypothesis, I isolated fungi from dust samples collected in Mali and St. Croix. Although a diversity of fungi were documented from African dust, including seven species of *Aspergillus*, none of the samples contained *A. sydowii*. Taken in conjunction with recent molecular evidence suggesting lack of a single point source of the fungus, these data indicate that there are likely multiple sources and introductions of this pathogen into marine systems.

## 7-16

**Fungi in Healthy And Diseased Sea Fans (Gorgonia Ventalina):**

**Carlos TOLEDO-HERNÁNDEZ*[1]**, Adelmari BONES-GONZÁLEZ[1], José RODRIGUEZ[1], Anabella ZULUAGA-MONTERO[1], Alberto SABAT[1], Paul BAYMAN[1]

[1]Biology Department, University of Puerto Rico, San Juan, Puerto Rico

The coral disease literature has mostly focused on identifying causative agents. However, lack of knowledge of microbes associated to healthy corals has undermined the ability to understand the changes in composition of microbes and their roles when colonies become diseased. This study addresses the following questions. Is the fungal community of healthy Gorgonia ventalina colonies different in diversity and composition than that of diseased ones? Within colonies with aspergillosis, does the fungal community of healthy tissue differ from that of diseased tissue? Is A. sydowii part of the resident mycoflora of healthy sea fans? Can aspergillosis also be caused by other species of Aspergillus, or by a consortium of fungi? Fungi were isolated from healthy and diseased fans found in 15 reefs around Puerto Rico, and identified morphologically and by DNA sequencing (the nuclear ribosomal ITS region) and BLAST searches in GenBank. Fungal community of healthy fans is distinct and more diverse from diseased one, and within diseased fans, fungi from diseased tissue is distinct and more diverse than from healthy tissue. Three mechanisms may explain these results: host immune depression allows pathogens to increase outcompiting other microbes; environmental factors favor some microbes over others; shift in diversity is not a cause but a consequence. An unexpected result was that A. sydowii was found in healthy sea fans and never in diseased one. A possible explanation is that the strains found in healthy fans were not pathogenic. Or others fungi may be causing the diseases since no a single fungus was consistently associated with diseased colonies. Given that it is not clear that Aspergillus is the sole pathogen, calling this disease aspergillosis is an oversimplification at best.

## 7-17

**Spatial variation in aspergillosis and the mycoflora associated to Gorgonia ventalina in Puerto Rico.**

**Anabella ZULUAGA-MONTERO*[1]**, Carlos TOLEDO-HERNÁNDEZ[1], Jose Antonio RODRÍGUEZ[1], Paul BAYMAN[1], Alberto SABAT[1]

[1]Biology, University of Puerto Rico, San Juan, Puerto Rico

Most of the coral disease literature has focused on identifying potential pathogens or environmental factors linked to disease. However, to better understand the etiology of coral diseases it is also necessary to increase our knowledge of the basic ecology of marine microorganisms. Many fungal species reported in marine organisms are common in land, but very little is known about their distribution in marine ecosystems. The objectives of this study were to determine the spatial variation in prevalence of aspergillosis, and relate it to the mycoflora associated with healthy and diseased colonies. We measured prevalence at three times during one year at six reefs sites. Colonies were tagged, photographed and categorized as healthy or diseased. The mycoflora associated to G. ventalina was identified by morphology and sequencing of the ITS region. We found significant differences in aspergillosis prevalence among sites. We also found significant spatial variation in the composition of the fungi community, and between healthy and diseased sea fans. However, sites with high or low prevalence did not have a distinctive mycoflora. Aspergillus flavus was an ubiquitous isolate at almost all sites, as well as in diseased and healthy colonies. A. sydowii was not isolated from diseased colonies. The main cause of colony death was detachment, followed by colonies that were overgrown by fouling organisms, and least by aspergillosis. The significant spatial variation in the fungi community suggests that local environmental factors are influencing the fungal composition of sea fans. The fact that A. sydowii was not isolated from diseased tissue from any reef site supports the argument that aspergillosis may be caused by a polymicrobial consortium. The data also indicates that aspergillosis is not a significant cause of mortality for sea fans in Puerto Rico.

## 7-18

**Emerging Infectious Diseases Of Coral Reef Sponges: *aplysina* Red Band Syndrome On Caribbean Reefs**

**Deborah J. GOCHFELD*[1,2]**, Robert W. THACKER[3], Julie B. OLSON[4]

[1]National Center for Natural Products Research, University of Mississippi, University, MS, [2]Environmental Toxicology Research Program, University of Mississippi, University, [3]Department of Biology, University of Alabama at Birmingham, Birmingham, AL, [4]Department of Biological Sciences, University of Alabama, Tuscaloosa, AL

A substantial and increasing number of reports have documented dramatic changes and continuing declines in the health of Caribbean coral reef communities over the past few decades. Disease is often implicated as a major factor contributing to these declines. To date, most disease reports have focused on scleractinian corals, whereas sponge diseases have been less frequently documented. Here we describe Aplysina Red Band Syndrome (ARBS), which affects Caribbean rope sponges. Visible signs of disease presence include one or more rust-colored leading edges, with a trailing area of necrotic tissue, such that the lesion forms a contiguous band around a portion or the entire sponge branch. Microscopic examination of the leading edge of the disease margin indicates that filamentous cyanobacteria are responsible for the coloration. Although the presence of this distinctive coloration is used to characterize the diseased state, it is not yet known whether this cyanobacterium is directly responsible for disease causation. Approximately 10% of the Aplysina cauliformis sponges on reefs near Lee Stocking Island, Bahamas, are affected by ARBS, and the disease has also been observed on reefs at other Caribbean sites. Transmission studies in the lab and field demonstrated that contact with an active lesion's leading edge was sufficient to spread ARBS to a healthy sponge, suggesting that the etiologic agent, currently undescribed, is contagious. Population studies indicate clumping of diseased individuals on the reef, but the presence of affected individuals in isolation suggests that waterborne transmission is also likely. Studies to elucidate the etiologic agent of ARBS are ongoing. Sponges are an essential component of coral reef communities and emerging sponge diseases have the potential to impact benthic diversity and community structure on coral reefs.

## 7-19

**The Pathological Studies Of Skeletal Anomaly in The Coral *porites Australiensis***

**Naoko YASUDA*[1]**, Yoshikatsu NAKANO[2], Hideyuki YAMASHIRO[3], Michio HIDAKA[4]

[1]Department of Marine and Environmental Science, Graduate School of Engineering and Science, University of the Ryukyus, Nishihara, Japan, [2]Sesoko Station, Tropical Biosphere Research Center, University of the Ryukyus, Motobu, Japan, [3]Department of Bioresources Engineering, Okinawa National College of Technology, Nago, Japan, [4]Department of Chemistry, Biology and Marine Science, Faculity of Science, University of the Ryukyus, Nishihara, Japan

The skeletal anomalies (SAs) of the scleractinian corals have been reported from reefs throughout the world and have been commonly referred to as 'tumors'. The SAs are characterized by swelled and abnormal skeletal structures, reduced number of polyps, and fewer zooxanthellae as compared with healthy parts. Causative agents of SAs have not been identified. In this study, the pathological characteristics of the SAs developed on a colony of *Porites australiensis* in the reef at Kayo, Okinawa, Japan were investigated. The polyp density was reduced in the SA due to enlargement of both calices and the coenosteum. Corallites in the SA region lost the skeletal architecture characteristic to *Porites australiensis*. The soft tissue in the SA region contained fewer and smaller spermaries and thinner gastrodermis containing lower density of zooxanthellae than the adjacent ordinary tissue. The gross production of SA tissues was lower than that of ordinary tissues and it decreased to almost 0 in 9 days after isolation. However, when SA fragments were brought into contact with ordinary fragments from the same colony, they fused and both SA and ordinary regions grew. The growth rate of ordinary regions was lower when they were fused with SA fragments than those fused with ordinary fragments. The present results suggest that SAs may be maintained by energy supply from the surrounding healthy tissue. The SAs of the coral may act as parasite for host corals and eventually decrease the fitness of the host coral.

## 7-20

**Is Increased Scarring Of Hard Corals From Disease Associated With Subsequent Declines in Coral Cover On Reefs Of The Great Barrier Reef.**

**Ian MILLER*[1]**, Andrew DOLMAN[1]

[1]Long Term Monitoring, Australian Institute of Marine Science, Townsville, Australia

Increased reports of disease induced hard coral mortality in recent years have highlighted the emerging threat coral disease poses to reef ecosystems. To study the effects of coral disease on the Great Barrier Reef (GBR) the Australian Institute of Marine Science monitored causes of coral mortality on a suite of 48 reefs throughout the Great Barrier Reef (GBR) annually from 1999 to 2005 and on a further 48 reefs biannually from 2006. Sampling consisted of categorising corals scars according to signs commonly associated with coral disease (white syndromes and black-band disease), crown-of-thorns starfish (COTS), *Drupella* spp. feeding activity and scars that could not be assigned directly to any of these categories. In 2005 sampling was extended to include signs of recently defined disease formerly classified as white syndromes or band diseases (brown band disease, skeletal eroding band disease and atramentous necrosis). Of those categories recorded only increases in COTS scars were independently associated with subsequent declines in coral cover on survey reefs. Between 1999 and 2005 there was no clear evidence to suggest there were any disease outbreaks that had a significant impact (above background levels) on live coral cover on survey reefs. This is despite the fact that scaring due to disease constitutes a relatively high proportion of the scars observed. This suggests that though disease plays an important role in GBR coral communities it mainly contributes to "background" levels of coral mortality. The relative proportion of scars recorded show that white syndrome and unknown scars make up the most common category of scars observed. The high proportion of scars from unknown sources suggests that the causes of many corals scars remain unexplained and highlights the difficulty classifying coral scars based on visual signs.

## 7-21

**Coral Host Processes Associated With Disease Pathology And Patterns Of Tissue Loss.**

**Tracy AINSWORTH*[1]**

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

Recent advances in sequencing cnidarian transcriptomes have revealed the unexpected genetic complexity of these morphologically simple basal organisms and have the potential to provide novel insights into the biology of these economically and ecologically important organisms. The emerging insights into cnidarian genomics provide the opportunity to develop an array of tools that can be applied to better understand the physiology, molecular biology and cellular responses of corals, and also to improve our understanding of the pathological changes that are seen on coral reefs today. Patterns of disease, tissue loss and bleaching have been described on coral reefs worldwide and appear to be increasing under increased environmental pressures. The apparent link between environmental stress and degraded coral health, and the recent information demonstrating the complexity of the cnidarians, highlights the need to understand the biology of the coral host and host responses in these patterns of change. Here we combine genome biology and pathology tools to investigate the host responses associated with coral diseases. We outline the diversity of responses that occur at the molecular and cellular level that are involved in different stages and types of disease and tissue loss. We have identified the coral homologs of many of the key molecules that are involved in the recognition of pathogen associated molecular patterns, in extrinsically and intrinsically activated apoptotic pathways, and pro- and anti-apoptotic molecules in mammals. This study demonstrates the complexity of the coral host biology associated with disease, and highlights the requirement for better understanding of the underlying physiological processes associated with coral diseases.

## 7-22

**Natural Resistance To Disease in The Endangered Staghorn Coral *acropora Cervicornis***

**Steve VOLLMER*[1]**, David KLINE[2]

[1]Marine Science Center, Northeastern University, Nahant, MA, [2]Centre for Marine Studies, University of Queensland, St. Lucia, Australia

Disease epidemics are reshaping tropical coral reefs from the reef corals on up, and yet we know very little about the abilities of the coral host to respond or resist disease infection. Understanding the potential for natural disease resistance in corals is particularly important in the Caribbean where the two ecologically dominant shallow-water corals *Acropora cervicornis* and *A. palmata* have suffered an unprecedented mass die-off due to White Band Disease and are now listed as threatened on the US Endangered Species Act. We examined the potential for natural resistance to WBD in the endangered staghorn coral *Acropora cervicornis* using *in situ* transmission assays and field monitor of WBD on tagged staghorn coral genotypes and present evidence for the occurence for WBD resistant genotypes. This WBD resistance demonstrates that staghorn corals have an innate ability to respond to the WBD epidemic, and that the propagation of WBD resistant genotypes can be used to facilitate the recovery of these endangered corals.

## 7-23

**Differential Gene Expression Displayed By *pocillopora Damicornis* in Response To Infection By *vibrio Coralliilyticus***

**Angela POOLE*[1]**, Sara EDGE[2], Amy LANE[3], Joshua VOSS[2], Michael MORGAN[1]

[1]Berry College, Mount Berry, GA, [2]Harbor Branch Oceanographic Institute, Ft. Pierce, FL, [3]School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA

Coral degradation is occurring worldwide at an alarming rate and one of the contributors is the increasing frequency and severity of disease. Previous studies have demonstrated that the coral *Pocillopora damicornis* is susceptible to a temperature-dependent infection by the bacteria *Vibrio coralliilyticus*, which induces both bleaching and lysis of the tissue. Molecular investigations can provide additional information about the coral's response to this infection. In this project, RDA (Representational Difference Analysis) was used to detect differentially expressed genes in *P. damicornis* as a result of the infection by *V. coralliilyticus*. Coral samples were collected from Fiji in August of 2006 and exposed to *V.coralliilyticus* in the laboratory. The RDA protocol successfully isolated 90 uniquely different gene fragments. Results from Northern Dot Blot analysis have confirmed differential expression for several of the isolated RDA products. Expression profiles for individual genes reveals that some of these transcripts can also be detected in other diseased conditions. These results suggest that some of these genes maybe useful biomarkers of disease pathology.

## 7-24

**Pigmentation As Part Of A General Immune Response in Scleractinians**

**Caroline PALMER*[1,2]**, John BYTHELL[1], Bette WILLIS[2]

[1]School of Biology, Newcastle University, Newcastle, United Kingdom, [2]ARC Centre of Excellence for Coral Reef Studies and School of Marine and Tropical Biology, James Cook University, Townsville, Australia

The ability of hard coral to resist infection and to recover from injury remains poorly understood, yet with the increase in coral disease and coincident global reef degradation, a greater understanding of the immune capabilities of corals is becoming increasingly important. Many invertebrates induce a basic inflammatory response to tissue invasion using the melanin producing signalling pathway and phagocytosis to encapsulate and remove the invading foreign organism. The presence of potential defence mechanisms in two different types of scleracatinian coral, *Acropora millepora* and *Porites* sp. was investigated. Compromised tissue was compared to healthy tissue using enzyme activation assays for the presence of the phenoloxidase pathway. Histological samples of compromised and healthy tissue were taken to assess differences at a cellular level using the Fontanna-Masson stain and cryo-histology. The phenoloxidase pathway was found in healthy tissue of both *A. millepora* and the *Porites* sp., with an up-regulation in compromised tissue of *A. millepora*. Histological examinations show reduced numbers of zooxanthellae in compromised tissue of both species. In addition, investigations also suggest the presence of putative ameobocytes in both corals, conclusively determined the presence and location of melanin in *Porites* sp., and the presence of a red fluorescent protein responsible for the non-normal pigmentation observed macroscopically in areas of wound healing. These results indicate that the prophenoloxidase pathway is activated in compromised tissue of scleractinian coral, and suggest the presence of fluorescent proteins as part of a generalised defence response to localised stress. This study demonstrates the presence of general immune response mechanisms in scleractinian corals and also contributes to current understanding of how differential development of innate immunity might influence ecological and life history differences among coral species.

## 7-25

**Cytotoxcity in The Innate Immune Responses Of The Sea Fan Coral To Infection By A Fungal Pathogen**

**Laura D. MYDLARZ*[1]**, Laura R. HUNT[1], C. Drew HARVELL[2]

[1]Department of Biology, University of Texas at Arlington, Arlington, TX, [2]Ecology and Evolutionary Biology, Cornell University, Ithaca, NY

The sea fan *Gorgonia ventalina* possesses effective innate immune mechanisms to fight infection by the opportunistic fungus *Aspergillus sydowii*. Some of the innate immune responses, while efficient at halting pathogen growth and invasion, can lead to cytotoxicity and self harm in the coral host. Of specific interest are immune mechanisms which produce reactive oxygen and concomitant production of anti-oxidants to mitigate the toxic effects. We have recently characterized an oxidative burst in the sea fan in reaction to fungal signals and have elucidated several roles for the released reactive oxygen which include halting growth of the fungus and signaling apoptosis. In addition using corals naturally infected with fungus, we have described cellular immune mechanisms such as amoebocyte aggregation, activation of the prophenoloxidase cascade, apoptotic events and increased production of anti-oxidants to reduce the potential for self harm. The successful use of the sea fan as a model for uncovering resistance and immune mechanisms and relationships to other coral diseases will also be summarized.

## 7-26

**Production of Cyanotoxins by Black Band Disease Cyanobacteria**

**Laurie RICHARDSON*[1]**, Miroslav GANTAR[1], Jamie MYERS[1], Aaron MILLER[1]

[1]Biological Sciences, Florida International University, Miami, FL

Black band disease (BBD) of corals is a cyanobacterial dominated microbial mat that migrates across coral colonies, killing and lysing coral tissues. While it is known that sulfide, produced by sulfate reducing BBD bacteria, is lethal to coral, inhibition of sulfate reduction in active BBD infections does not stop tissue lysis or disease progression. Therefore, there must be additional toxin(s) produced. Using HPLC/MS we detected the cyanotoxin microcystin in 22 field samples of BBD collected from five coral species on nine reefs of the Florida Keys and Bahamas. Two cyanobacterial cultures isolated from BBD, *Geitlerinema* and *Leptolyngbya* spp., contained microcystin based on HPLC/MS, with toxic activity confirmed using the protein phosphatase inhibition assay. DGGE analysis revealed that the cultured *Geitlerinema* and *Leptolyngbya* strains were present in BBD field samples. HPLC analysis identified the microcystin variants -LY, -LR, -LF, -LW and –RR in the field and laboratory samples. Exposure of coral fragments to purified microcystin resulted in tissue stress, which was exacerbated by co-exposure with sulfide. Cyanobacterial toxicity was further tested on a comparative basis using 10 strains that were isolated from BBD and 10 strains from non-BBD sources on coral reefs, including benthic mat forming cyanobacteria and non-pathogenic cyanobacterial patches on healthy corals. Toxicity was measured using cell extracts and included ELISA, the protein phosphatase inhibition assay, and HPLC. We found toxicity in both BBD and non-BBD strains, with levels that varied from non-detectable to 3.5 ug/g of dry biomass within each group (BBD and non-BBD). The ELISA assay was microcystin and nodularin congener-independent, and discrimination between these two toxins is underway. The variant and relative toxicity of microcystins and other cyanotoxins can be dependent on cyanobacterial physiology and environmental factors, which may play a role in the pathogenicity of BBD.

## 7-27

**Significance Of Immunological Responses in The Black-Spined Sea Urchin, *diadema Antillarum*, To Caribbean-Wide Mass Mortality**

**Gregory BECK*[1]**, Robert MILLER[2], Aaron ADAMS[3], John EBERSOLE[1]

[1]Biology, University of Massachusetts - Boston, Boston, MA, [2]Marine Science Institute, University of California - Santa Barbara, Santa Barbara, CA, [3]Mote Marine Laboratory, Pineland, FL

Mass mortality of the grazer *Diadema antillarum*, probably caused by a water-borne pathogen, was a major factor leading to a phase shift from coral to algal domination of Caribbean reefs. Recovery or restoration of *Diadema* may be critical to reef restoration. Recent initiation of recovery of *Diadema* in St. Croix allows research that addresses basic questions on how recovery/restoration may be influenced by immunological processes. What are the basic features of immunological responses in *Diadema*? How does strength of immune responses in *Diadema* compare to other Caribbean urchins that did not die off (*e.g.*, *Tripneustes ventricosa*, *Echinometra lucunter*, or *Echinometra viridis*)? How does strength of immune response vary among reefs with strong versus weak recovery, large versus small individuals, healthy versus sick/dying individuals?

We used coelomic fluid and coelomocytes (blood cells) extracted from *Diadema* and other urchins from several locations on St. Croix to test humoral immune responses. Coelomocyte concentrations did not differ consistently between *Diadema* and the other urchins. Protein levels in coelomic fluids were higher in *Diadema* than the other urchin species. All urchins released O2-, antimicrobial peptides, and phenoloxidase when stimulated by various agents - with one conspicuous and statistically significant exception: *Diadema* from all locations did not respond as efficiently as other urchins to lipopolysaccharide (a typical component of bacterial cell walls). These results suggest a defect in immune response that is specific to *D. antillarum* and independent of stressors associated with particular environments.

These studies will provide the information required to understand whether a weakened immune system was responsible for the mass mortality, and how much strengthening of immune systems has occurred since. Effective management of a recovery may depend on knowing whether diseases continue to impact *Diadema* population growth due to weak immune responses, and whether an abundant recovered/restored population could experience another die-off.

## 7-28

**Cleaner Shrimp *periclemenes Pedersoni* Reduce Ectoparasite Loads On A Caribbean Reef Fish**

Amber MCCAMMON[1], **Donna NEMETH*[2]**, Paul SIKKEL[3]

[1]Department of Biology, Florida Atlantic University, Boca Raton, FL, [2]Science and Math, University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.), [3]Department of Biology, Centre College, Danville, KY

Reef fish are known to make regular visits to 'cleaning stations', yet the benefit to the fish is not well studied in Caribbean species. *Periclemenes pedersoni* cleaner shrimp associate with the anemone *Bartholomea annulata*, and have been hypothesized to participate in cleaning symbioses. Experiments were conducted in a seminatural environment to determine the effectiveness of these cleaner shrimp at removing parasitic monogeneans trematodes from host reef fish, *Acanthurus coeruleus*. Wild-caught fish were exposed to seawater flow from an open system aquarium exhibit containing high densities of monogenean eggs and larvae (*Neobenedenia*). Fish were assigned to one of two treatments: one giving fish access to cleaner shrimps that also included the anemone *Bartholomea annulata* for cover, and one that included anemones with no shrimps. After 15 days, fish were fresh-water dipped to remove parasites, which were preserved in ethanol and counted under a microscope. Average monogenean loads were 4 times higher on fish without access to cleaners, compared to fish with access to cleaners (monogeneans load per fish averaged 101 vs. 26, respectively, ANOVA $p<0.001$). Ectoparasite size was also significantly smaller on fish that had access to cleaners, compared to those that did not visit cleaner shrimp. These results suggest that anemone-shrimp cleaning stations can play a significant role in the biological control of ectoparasites on Caribbean reef fishes. Through their effect on ectoparasite size, cleaning shrimp could potentially reduce monogenean parasite populations by reducing numbers of larger, more fecund, individuals from the population. Density of shrimp cleaning stations may thus be an important factor to consider in studies of reef 'habitat quality' because of their ability to reduce ectoparasites loads and influence fish health.

## 7-29

**Can the Presence of Disease Signs Explain Levels of Tissue Fragmentation on Colonies of the Genus *Montastraea* spp.?**

**Adán JORDÁN-GARZA*[1]**, Eric JORDÁN-DAHLGREN[1]

[1]Laboratorio de Sistemas Arrecifales Coralinos, Universidad Nacional Autónoma de México, Puerto Morelos, Mexico

A disease is a disruption of the normal structure or function of an organism. On scleractinian corals diseases are diagnosed through signs on the coral tissue with an associated rate of partial mortality. In a coral with low resistance to the pathogen(s), disease progression may result in dead. Otherwise if progression rate is low or halted, the original coral might have been fragmented into smaller colonies (sensu Connell), with reduced fecundity and higher probability of dead by infections or other causes. This study quantified the degree of tissue loss associated to different disease signs in fragmented and non-fragmented corals. On *Montastraea faveolata*, *M. annularis* and *M. cavernosa* permanent marks were laid along the colony edge in order to measure lateral tissue growth or loss. The presence of disease signs on the edge-tissue was recorded and the sign was classified as typical (known to be potentially lethal) or non-typical (might be potentially lethal or harmless). A total of 546 marks on *M. faveolata*, 79 on *M. annularis* and 161 on *M. cavernosa* were followed for a year. Rates of tissue loss depended on the disease sign, time of year and habitat. In general, prevalence of signs and tissue loss was higher on *M. faveolata* (rate of tissue loss -2.44±6.9 mm/y, MEAN±SD, n=382) than on *M. annularis* (-0.52±0.5 mm/y, n=69) and *M. cavernosa* (-0.1±0.8 mm/y, n=96) but colonies of *M. faveolata* with low prevalence of disease signs, showed lower rates (-0.56 ± 1.4 mm/year). A continuous trend of tissue loss, like the one observed during this study, leads to colony shrinkage and fragmentation and a simulation shows that it can have serious effects on populations of this key reef-building corals.

## 7-30

**White Band Syndromes in *Acropora cervicornis* off Broward County, Florida: Transmissibility and Rates of Skeletal Extension and Tissue Loss**

**Abraham SMITH*[1]**, James THOMAS[2]

[1]Oceanographic Center, Nova Southeastern University, Hollywood, FL, [2]Oceanographic Center, Nova Southeastern University, Dania Beach, FL

The high latitude thickets of *Acropora cervicornis* off Broward County flourish despite the presence of natural and anthropogenic impacts. These populations provide a unique study opportunity which stands out against the disease stricken areas of the Florida Keys. This study uses time sequenced photographs to examine how *A. cervicornis* is coping with white band syndrome stressors. Variables being monitored include healthy colony skeletal extension rates, diseased colony skeletal extension rates, and tissue loss. The transmissibility of the white band syndromes is being examined through tissue grafting including healthy controls. Healthy skeletal extension rates rage from 0.3-5.2 mm/month. Diseased skeletal extension rates range from 0.5-4.8 mm/month. Tissue loss from disease signs range from 0.6-4.5 mm/day. Transmission experiments show that not all direct tissue contact results in the transfer of white band syndrome signs. Up to 60% show mild to no disease sign transmission. The *A. cervicornis* thickets in Broward County are growing slower compared to most studies in other areas of the Western Atlantic. Tissue loss is also low compared to other reports. White band syndromes are always present in Broward County, but the low incidence of transmission of the syndromes seems to limit its affect on the thickets.

## 7-31

**Dynamics And Ecological Relevancy Of A Viral Disease in Caribbean Spiny Lobster**

Mark BUTLER[1], **Behringer DONALD*[2]**, Thomas DOLAN[1], Jeffery SHIELDS[3], Robert RATZLAFF[1]

[1]Department of Biological Sciences, Old Dominion University, Norfolk, VA, [2]Department of Fisheries & Aquatic Sciences, University of Florida, Gainesville, FL, [3]Virginia Institute of Marine Science, Glouchester Point, VA

Coral diseases have deservedly garnered much attention, yet ecologically significant diseases also occur among reef-dwelling motile taxa within which disease dynamics may be quite different from corals. In 2000, we discovered a deadly virus (PaV1) that infects Caribbean spiny lobster (Panulirus argus), and we have confirmed infections in Florida, Mexico, Belize, and the US Virgin Islands. PaV1 is the first viral disease known for any species of lobster, and it alters the behavior and ecology of this species in fundamental ways. The prevalence of infection varies with ontogeny, with most infections occurring among the smallest size classes. In Florida, mean prevalence of PaV1 in early benthic juvenile lobsters approaches 25% compared to < 1% in adults. The virus is pathogenic with successful transmission demonstrated via injection of hemolymph from infected donors, ingestion of infected tissue, contact with infected lobsters, and – among the smallest lobsters – over short distances in the water. Decapods that co-occupy dens with lobster (stone crab, Menippi mercenaria; channel clinging crab, Mithrax spinomosissimus; spotted lobster, P. guttatus) do not harbor the virus. Most remarkable is that healthy lobsters, which are normally social, chemically detect and avoid diseased conspecifics prior to their becoming infectious. This behavior along with lethargy in infected lobsters may break the expected density-dependence of infection. Traditional epizootiological models are not applicable in this and presumably other situations because of their dependence on mass-action principals, so we developed a unique spatially-explicit, individual-based model simulating PaV1 dynamics among lobsters in the Florida Keys. We are using the model to examine the: (a) role of risk avoidance behavior in pathogen transmission, (b) effect of fishing on PaV1 transmission, and (c) effect of large-scale degradation of nursery habitat structure on disease dynamics in lobster.

## 7-32

**Blood Parasite Infection Dynamics Of Fish in The Indo-Pacific Region**

**Lynda CURTIS*[1]**, Angela DAVIES[2], Nico SMIT[3], Alexandra GRUTTER[1]

[1]School of Integrative Biology, University of Queensland, Brisbane, Australia, [2]Biomedical and Pharmaceutical Sciences, Kingston University, Kingston, United Kingdom, [3]Department of Zoology, University of Johannesburg, Johannesburg, South Africa

To date there has been little work done on Haemogregarine blood parasites in coral reef fish. Traditionally, haemogregarines have a two host life-cycle with a vertebrate intermediate host and an invertebrate definitive host vector. This study conducted a survey between March 2005 and August 2007 throughout the Indo-Pacific to determine the variability in intensity and prevalence of haemogregarine infections, spatially and temporally. To test whether gnathiid isopods are the vector of blood parasites in coral reef fish transmission experiments were conducted at Lizard Island on the Great Barrier Reef, Australia. Gnathiid isopods, not previously exposed to blood parasites, were allowed to feed on the blood of fish infected with blood parasites. The gut contents of these gnathiid isopods were then examined from one to ten days post-feeding to determine if transmission had taken place. While there were variations in the intensity of the blood parasite infection over time in triggerfish at Lizard Island this was not associated with season. Therefore water temperature does not appear to play a role in the differences detected. There was also a difference in the intensity of the blood parasite infection in the triggerfish sampled at different geographical locations. These variations could be related to the distribution of the potential vector, the gnathiid isopod, at particular sites. We found convincing evidence for the theory that gnathiid isopods are the vector, as various stages of development of the blood parasites were found from four days post feeding in the gnathiid gut contents. This study is the first quantitative investigation into the blood parasites of coral reef fish and will hopefully increase our understanding of coral reef fish blood infections and their impact on host ecology.

## 7-33

**Dynamics Of A Back Band Disease Outbreak At Pelorus Island On The Great Barrier Reef**

**Yui SATO*[1]**, David BOURNE[2], Bette WILLIS[1]

[1]School of Marine and Tropical Biology, and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]Australian Institute of Marine Scinece, Townsville, Australia

Black band disease (BBD) is challenging the health of reef building corals worldwide and reaching outbreak proportions for the first recorded time at several sites on the Great Barrier Reef (GBR). Although abundance of BBD on the GBR is generally low, long term monitoring of infected coral populations is required to assess the potential consequences of the disease for this reef system. This study examined detailed dynamics of a BBD outbreak in plating *Montipora* species at Pelorus Island, located at approximately 18°33′N, 146°30′E, in the central section of the Great Barrier Reef Marine Park. Individual diseased colonies were tagged and monitored over 2 years within permanent quadrats, each of which was 10m x 10m. Abundance of BBD-infected colonies and linear progression rate of the BBD band across colonies were recorded approximately monthly. Temporal patterns in BBD abundance were striking and tightly correlated with seasonal changes in seawater temperature. Abundance was higher in the Austral summer (15 cases/100m2) than winter (0 case/100m2), and it was stable at low levels during cooler months. Similarly, progression rate of the BBD band was greater in summer (3.0 mm/day) than winter (0.5 mm/day). Temporal patterns in progression rate were positively correlated with seasonal patterns of seawater temperature and light levels. Results suggest that both water temperature and light incidence are environmental drivers of BBD activity. If seawater temperatures continue to rise with global warming, the consequences of BBD for host coral populations is likely to be severe, even in this well-managed coral reef system. Knowledge of seasonal variability of BBD prevalence and environmental drivers is essential to provide accurate assessment of reef health and to develop effective reef management.

## 7-34

**Dynamics Of The Coral Disease White Plague; Insights From A Simulation Model**

**Marilyn BRANDT*[1]**, John MCMANUS[1]

[1]Division of Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science (RSMAS), University of Miami, Miami, FL

Understanding the dynamics of coral diseases among the heterogeneous populations in which they act is critical for determining how the structure of reef communities has changed as a result of enzootic or epizootic levels of these important sources of mortality. This information can also form a basis for predicting the impact of disease in the near future. The work presented here combined field studies with the development and testing of a spatially-explicit, individual-based epizootiological computer model with the aim of providing a useful tool for exploring disease dynamics in reef communities of the past, present and future. This study focused on the disease white plague, a significant source of mortality on reef-building corals in the Caribbean. Field studies focused on the incidence and distribution of all sources of coral mortality, including white plague (type II) *in situ*, at Little Cayman Island (Cayman Islands, British West Indies). Results indicated that white plague was the most significant source of mortality during the monitoring time period, and that it is likely contributing to major structural changes. The simulation model was developed using this data, and results of model calibration indicated that white plague on these reefs is transmissible between colonies within a limited field and requires a yearly input from an outside source, and that host susceptibility to infection is low and likely not variable among species. Parameters describing the distribution and composition of the simulated coral population were then varied, and results showed a significant effect of colony density, aggregation, and mean size on the impact of disease. Scenario testing of various disease management strategies indicated that should local prevention measures be developed in the future, it is they, and not treatment, that will likely be the most effective in limiting the impact of disease.

## 7-35

**Metapopulation Dynamics Of Coral Infectious Disease**

**Susanne SOKOLOW*[1]**, Patrick FOLEY[2], Janet FOLEY[1], Alan HASTINGS[1], Laurie RICHARDSON[3]

[1]University of California Davis, Davis, CA, [2]California State University Sacramento, Sacramento, CA, [3]Florida International University, Miami, FL

Adaptation of epidemiological models to the study of marine diseases represents an underdeveloped field and a research priority for understanding and managing emerging diseases in the world's oceans. Recent evidence suggests that metapopulation models may provide an appropriate framework for modeling coral populations at the regional scale, and we expand this approach to investigate the effects of infectious disease. Some key features that characterize many coral disease systems include: (1) coral reefs are generally patchy, (2) adult coral are predominantly sessile and new recruits represent the main mode of host dispersal to new patches, (3) the pathogens have a hypothesized reservoir which can move widely and independently of the hosts, and (4) environmental factors such as water temperature and seasonality may affect pathogen survival and transmission. Testable predictions emerge when considering coral disease in a metapopulation framework, including thresholds for regional epidemic and endemic disease dynamics. Model results are compared with an original coral disease dataset which spans a decade of patch-level monitoring for white plague type II (WPII) on coral in the Florida Keys, and some qualitative patterns predicted by the model are consistent with empirical evidence. By exploring a mechanistic model with minimal complexity, this research offers preliminary insight for the ecology and epidemiology of coral diseases on reefs, and allows critical evaluation of the long-term effects that disease pressure, environmental change, and management may have on coral health and persistence.

## 7-36

**Applying Medical Geography To Identify Spatial Hotspots Of Coral Diseases**

**Jennifer LENTZ*[1]**, Andrew CURTIS[2,3], Paul SAMMARCO[4], Philippe MAYOR[5]

[1]Oceanography & Coastal Sciences, Louisiana State University, Baton Rouge, LA, [2]Geography, Louisiana State University, Baton Rouge, LA, [3]Geography, University of California, Los Angeles, [4]Louisiana Universities Marine Consortium, Chauvin, LA, [5]Buck Island Reef National Monument, U.S. National Park Service, Christiansted, Virgin Islands (U.S.)

Given the current world-wide decline in coral reef health, it is important to understand those factors contributing to, or directly causing, this decline, so that we can attempt to stabilize our reefs and hopefully restore some of what has been lost. The problem is highly complex, and requires the use of stringent multi-disciplinary analytical techniques. Here, we apply some of the methods of Medical Geography to the problem of coral disease; specifically those used to map and spatially analyze epidemics and general public health concerns to further our understanding of coral reef health. This study compares the results of several spatial analytical techniques applied to the same dataset. We used data regarding white-band diseased (WBD) *Acropora palmata* at Buck Island Reef National Monument, initially presented by Mayor et al's 2006 study. Overall, we found that the Disease Mapping and Analysis Program (DMAP) was the strongest of the spatial analyses performed, resulting in detailed maps of the rates of WBD clustering and Monte Carlo estimated areas of statistically significant ($p<0.05$) and highly significant ($p < 0.01$) WBD clustering. An important difference between DMAP and some of the other methods used was that DMAP utilizes both the WBD (numerator) and underlying *A. palmata* population (denominator) data; while some of the other methods that are based exclusively on the numerator data, such as the Kernel Density Analysis, revealed far less spatial information about WBD. It is our hope that the spatial analyses presented here will provide insight into the spatial nature of WBD and facilitate further epidemiological studies of the disease.

## 7-37

**Developing An Expert System For Predicting Coral Disease Risk On Indo-Pacific Reefs**

**Bette L. WILLIS*[1]**, Scott F. HERON[2], Cathie A. PAGE[3], William J. SKIRVING[2], C. Mark EAKIN[2], C. Drew HARVELL[4], Dean M. JACOBSEN[5], Gregg COLEMAN[6], Ian MILLER[6], Hugh P.A. SWEATMAN[6]

[1]School of Marine and Tropical Biology and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]NOAA Coral Reef Watch, Silver Spring, MD, [3]School of Marine and Tropical Biology and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Queensland, Australia, [4]Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, NY, [5]College of the Marshall Islands, Majuro, United States Minor Outlying Islands, [6]Australian Institute of Marine Science, Townsville, Queensland, Australia

Coral disease outbreaks represent an emerging risk on Indo-Pacific reefs that is likely to escalate with ocean warming due to climate change. Building on a recent model that links the abundance of coral disease with elevated temperature anomalies and percent cover of coral hosts, we further refine temperature metrics to include both the duration and magnitude of temperature anomalies and to differentiate between the effects of warm versus cool seasonal anomalies on disease risk. Using a 9-year data set of disease records for white syndrome on 48 reefs spanning more than 1000 km along the Great Barrier Reef, we explore patterns in disease abundance with percent coral cover and with deviations from both mean summer and mean winter sea surface temperatures. Analysis showed that each of these factors is necessary but not sufficient to explain patterns in disease abundance. The addition of winter temperature anomalies to the model improved its explanatory power. Disease abundance was greatest in summers following mild winters that deviated by less than 5 °C-weeks from mean winter conditions. We suggest that cold winters may reduce pathogen loads, and consequently the likelihood of disease outbreaks in the following summer. It is less clear why warm winters are correlated with reduced disease abundance, but they may result in enhanced disease resistance of the coral host. Our results indicate that predicting disease risk on Indo-Pacific reefs is complex; nevertheless predictions based on satellite-derived sea surface temperatures can be reasonably accurate, given knowledge of coral cover. With the incorporation of further factors, such as current speed and host susceptibility, our aim is to provide reef managers with an expert system for predicting disease risk on coral reefs.

## 7-38

**A Large Semi-Open Aquarium As A Proxy For Natural Coral Reef Ecosytems: Insights And Implications For The Causes Of Coral Disease**

**Shelley L. ANTHONY*[1]**

[1]Marine and Tropical Biology, James Cook University, Townsville, Australia

Changing water quality parameters of ocean waters have been implicated in the occurrence of some coral diseases, and are an ongoing concern for the future health of coral reefs. However, it is difficult and somewhat haphazard to monitor water quality accurately and continuously in natural reef settings.

The Coral Reef Exhibit (CRE) at Reef HQ Aquarium in Townsville, Australia is the world's largest living coral reef aquarium, containing almost 3,000,000 litres of natural seawater that is open to the atmosphere. The CRE supports thousands of scleractinian and soft coral colonies, as well as other associated reef species, in a semi-closed system that simulates a natural reef environment. This system is constantly monitored for temperature, salinity, pH, alkalinity, dissolved oxygen, turbidity, trace elements, and inorganic nutrients, among others. Additional and potentially complicating factors in coral disease observations - such as snail predation - are easily controlled, making it more efficient to examine the effects of varying conditions on the corals, fish, and other marine organisms.

Analysis of coral mortality data from 1996-2006 in the CRE system clearly shows that White Syndrome is the single leading cause of death for acroporids (the most sensitive group). Extensive water quality records over the same time period were thoroughly examined and compared to mortality data to look for correlations with White Syndrome outbreaks. No significant correlations were apparent for any single water quality parameter, including high temperature. Rather, I suggest that a combination of factors may create a stressful environment, resulting in White Syndrome occurring after a prolonged period. Preliminary evidence also indicates that episodes of poor water circulation are a trigger for tissue sloughing in individual acroporid colonies.

## 7-39

**Ecosystem Function And Disease Resistance in Coral Reefs: What Happens When We Remove Key Players?**

**Laurie RAYMUNDO*[1]**, Aileen MAYPA[2], Andrew HALFORD[1]

[1]University of Guam, Mangilao, Guam, [2]University of Hawaii, Honolulu, HI

The ecological drivers of disease outbreaks are poorly understood. We tested the hypothesis that intact, trophically-diverse marine ecosystems are less likely to sustain disease outbreaks than over-fished systems. Marine Protected Areas (MPAs) are a best practice for managing fish communities, so an additional benefit of this primary tool is a win-win situation for coral reef conservation. This is challenging to test; few MPAs are consistently well-managed so that significant increases in fish diversity can occur. We surveyed 7 reefs containing both an MPA and a fishing ground in the central Philippines for coral disease prevalence and fish taxonomic distinctness. All MPAs had less disease and taxonomic distinctness on par with, or richer than, expected. Conversely, fished reefs contained more disease and fish assemblages of higher variability and lower distinctness. Our findings show that protection from fishing confers protection from disease outbreaks. At present, this is the only option available for managing coral diseases.

## 7-40

**Advancing The Global Coral Disease Database**

**Emily CORCORAN*[1]**, Andy BRUCKNER[2], Nicola BARNARD[3], Michael STRONG[4], Craig MILLS[5]

[1]One Ocean Programme, UNEP-WCMC, Cambridge, United Kingdom, [2]Coral Reef Conservation Program, NOAA, Silverspring, MD, [3]ICRAN, Cambridge, United Kingdom, [4]Informatics, UNEP-WCMC, Cambridge, United Kingdom, [5]Spatial Analysis, UNEP-WCMC, Cambridge, United Kingdom

The Global Coral Disease Database (GCDD) was launched by NOAA and UNEP-WCMC in 2000. Over the last seven years, this partnership has worked to compile and organise published data on the occurrence of coral disease, benefiting managers, scientists and other stakeholders through the provision of the first compilation on the global observations of coral diseases. The database currently contains 7813 data points from 66 countries across the world since 1970, 25% of these data points are observations since 2000.

Whilst excellent advances have been made in developing the GCDD (http://www.unep-wcmc.org/GIS/coraldis/), there exists a need to address the recurrent challenges of quality, accessibility, and completeness of the data, to ensure that this unique GIS tool meets its fulfil potential as a critical global repository for coral reef disease information.

A new twelve-month phase of work will be initiated at ICRS 11 to improve the relevance and importance of the database to users through consultation and a comparative analysis of user needs, information holdings, and data collection. Through partnerships with data collection programmes, and the establishment of an expert advisory group, the project will raise the profile and value of the GCDD to stakeholders, build confidence in the holdings, and provide a mechanism for quality assurance of the data collected. A new visual interface will be demonstrated which will enhance the visibility and functionality of the GCDD with an improved look, feel and progression towards a more sophisticated online analysis. Such analysis would allow ad-hoc spatial querying and analysis, and the manipulation of the coral disease data alongside key biodiversity datasets, such as the World Database on Protected Areas.

## 7-41

**Linking Environmental Factors With Coral Disease Events in The Caribbean**

**Tyler R. L. CHRISTENSEN*[1]**, Scott F. HERON[2], William J. SKIRVING[2], C. Mark EAKIN[2], Bette L. WILLIS[3], C. Drew HARVELL[4], Cathie A. PAGE[3], Peter J. MUMBY[5], Laurie J. H. RAYMUNDO[6], Ernesto WEIL[7], Eric JORDÁN DAHLGREN[8], John F. BRUNO[9], Dwight K. GLEDHILL[1], Alan E. STRONG[2], Jessica A. MORGAN[1], Gang LIU[1]

[1]IMSG at NOAA Coral Reef Watch, Silver Spring, MD, [2]NOAA Coral Reef Watch, Silver Spring, MD, [3]James Cook University, Townsville, Australia, [4]Cornell University, Ithaca, NY, [5]University of Exeter, Exeter, United Kingdom, [6]University of Guam, Mangilao, Guam, [7]University of Puerto Rico, Mayaguez, Puerto Rico, [8]Universidad Nacional Autónoma de México, Puerto Morelos, Mexico, [9]University of North Carolina at Chapel Hill, Chapel Hill, NC

Recent evidence indicates that some coral disease outbreaks are linked to occurrences of elevated water temperature, compounding other risk factors such as high coral cover and nutrient enrichment. NOAA's Coral Reef Watch is investigating whether environmental conditions conducive to outbreak events can be predicted using satellite sea-surface temperature (SST) data. With other members of the Coral Reef Targeted Research working groups for Coral Disease and Remote Sensing, we examined the relationship between several novel thermal stress metrics and various disease-related impacts. Previous studies have counted the number of warm SST anomaly occurrences and shown links to disease events. Here we include both warm and cold SST anomalies, and the accumulation of these values; recent extreme anomalies; and accumulations weighted by duration of the anomaly. Increased understanding of the causal factors in coral disease outbreaks will open the door for operational satellite monitoring of disease risk on coral reefs globally.

## 7-42

**Environmental Effects Of Sewage Disposal Practices in Bermuda**

**Ross JONES*[1]**

[1]Bermuda Institute of Ocean Sciences (BIOS), St George's, Bermuda

Coral disease has played a significant role in shaping the present day coral reef communities of Florida and the Caribbean, yet the pathology, etiology and epizootiology of most coral diseases remain poorly understood. In particular, the link between anthropogenic effects, decreased water quality and disease prevalence is not well known. In the wider Caribbean region, domestic wastewater represents the largest point source contributor (by volume) of land-based point sources of marine pollution. The disposal of raw or improperly treated sewage can introduce suspended solids, excessive nutrients, industrial chemicals, pharmaceutically active compounds, personal care products and potential pathogens into the marine environment. In Bermuda, about 2.5 million litres of untreated sewage (about 15% of the sewage generated daily) is disposed of at a single outfall located on a sandy bottom 300 m away from the nearest reefs of the main terrace. A Remotely Operated Vehicles (ROV) was used in addition to Acoustic Doppler Current Profiler (ADCP) and drogue tracking studies to examine and characterize the flow dynamics around the outfall, and select study reefs that are regularly inundated with sewage. Video-surveys were used to quantify benthic cover and species compostion on sewage-exposed and more remote (control) reefs, and reefs in different physiographic reef zones (i.e. lagoonal patch reefs, outer rim reefs etc). Black Band Disease (BBD) and White Plague Type II (WP) in the dominant reef building coral species was also quantified at multiple locations across the platform including those close to, and distant from, the sewage outfall. Overall, there is little or no evidence to suggest any environmental effect on the reefs - in terms of changes in species composition and abundance or coral disease prevalence - caused by the nearby release of millions of litres per day of untreated sewage over the past decade.

## 7-43

**Effects of Fishing and Macroalgae on Coral Disease Dynamics**

**John BRUNO*[1]**, Ivana VU[1], Ernesto WEIL[2], Hugh SWEATMAN[3]

[1]UNC Chapel Hill, Chapel Hill, NC, [2]University of Puerto Rico, La Parguera, Puerto Rico, [3]Australian Institute of Marine Science, Townsville, Australia

Outbreaks of infectious and non-infectious (e.g., bleaching) coral diseases are the primary cause of recent coral losses around the world. There are several potential explanations for the widely observed increase in the severity and frequency of coral epizootics. For example, there is evidence that nutrient enrichment and anomalously high ocean temperature can increase within- and among-colony disease spread rates. Another widely discussed explanation is that decades of overfishing have disrupted the balance of coral reef ecosystems, making them more susceptible to disease outbreaks and other disturbances. More specifically, the removal of herbivores has led to increases in benthic macroalgae that could promote disease outbreaks either by acting as pathogen reservoirs or vectors or by increasing the concentration of Dissolved Organic Carbon. We performed a series of field manipulations in Puerto Rico to test the hypothesis that fishing and macroalgae affect the severity of Caribbean yellow band disease of Montastraea faveolata. The results from all three experiments indicate that macroalge has no effect on yellow band disease prevalence or incidence. In a second case study, we performed a longitudinal epidemiological analysis on the effects of macroalgae, fish density, and ocean temperature on outbreaks of white syndrome across the Great Barrier Reef from 1996 through 2006. Even after accounting for the effect of coral cover, macroalgal cover was strongly negatively related to white syndrome frequency. There was a clear threshold of macroalgal cover of roughly 5%, above which outbreaks never occurred. Thus macroalgae or some factor or process related to macroalgal cover (e.g., grazer density, identity or behavior), may protect coral populations and communities from disease outbreaks. Our results indicate that macroalgae are not the cause of coral disease outbreaks and coral losses and that coral epizootics cannot be effectively controlled with local fisheries management designed to limit algal biomass.

## 7-44

**Temperature-dependent Induction of Virulence Factors in the Coral Pathogen *Vibrio coralliilyticus***

**Nikole E. KIMES*[1,2]**, Lisa KILPATRICK[2,3], Pamela J. MORRIS[1,2]

[1]Marine Biomedicine and Environmental Sciences, Medical University of South Carolina, Charleston, SC, [2]Hollings Marine Laboratory, Charleston, SC, [3]National Institute of Standards & Technology (NIST), Charleston, SC

Coral ecosystems have experienced unprecedented declines due in part to the increased emergence and frequency of diseases throughout the Caribbean region. Increasing ocean temperatures is one of the contributing factors thought to be driving this phenomenon. It is well established that warmer temperatures can increase the abundance and virulence of some pathogens, including water-born *Vibrio* spp. *Vibrio coralliilyticus*, is a temperature-dependent coral pathogen first isolated from the Red Sea and the Indian Ocean. This Gram-negative bacterium has been shown to infect the coral *Pocillopora damicornis* when temperatures reach above 24.5°C, resulting in coral bleaching and lyses. While a previous study correlates increased protease activity with *V. coralliilyticus'* increased virulence when water temperatures rise to 26°C or above**,** we hypothesize that a broader temperature-dependent induction of multiple virulence factors is the mechanism underlying *V. coralliilyticus*' virulence. This study used two-dimensional liquid chromatography coupled with tandem mass spectrometry (2D-LC-MS/MS) to identify proteins produced by *V.coralliilyticus* grown at 24°C and 27°C. We identified 523 proteins expressed by *V. coralliilyticus* at 24°C and 839 proteins expressed at 27°C. Of those proteins, 504 were produced at both growth temperatures; whereas, 19 and 335 proteins were unique to the 24°C and 27°C growth conditions respectively. Additionally, we identified 37 possible virulence factors unique to 27°C, while identifying only two unique virulence factors at 24°C. Our results provide sufficient evidence to conclude that *V. coralliilyticus* cultivated at the higher temperature (27°C) produces more proteins, including known virulence factors, compared to cultivation at the lower temperature (24°C). Recent climate change predictions calling for increases in ocean temperatures and research studies indicating increased observations of infectious diseases in marine ecosystems enhance the significance of this study.

## 7-45

**The Effect Of Sediment And Heat Stress On The Initiation And Spread Of Black Band Disease**

**Aaron MILLER*[1]**, Laurie RICHARDSON[1]

[1]Biology, Florida International University, Miami, FL

Experiments were conducted to determine the effects of heat and sediment stress on the properties of mucus from the coral *Montastraea cavernosa*, and how this relates to the initiation and spread of black band disease (BBD). Three fragments of *M. cavernosa* were placed into each of four treatments: a control (26°C, no sediment), heat stress (30°C, no sediment), sediment stress (26°C, twice daily 150mg/cm$^2$ sediment loading), and a combination of the two stressors (30°C, plus sediment loading). After the three-week experimental period, mucus was collected from each fragment to determine the number of cyanobacterial filaments isolated from BBD (two strains) that adhere to the mucus after one hour. At the end of the experiment, fragments were inoculated with fresh BBD, and were observed for eight days.

There was a significantly greater number of cyanobacteria adhering to the heat stressed mucus than to the controls, while the other treatments did not differ significantly. The control corals showed little spread of the BBD consortium eight days after inoculation. Those fragments exposed to heat stress had complete coverage of the fragment by a biofilm of the BBD microbial consortium within the eight days. In the sediment stressed corals and corals exposed to the combination of stressors there was progressive skeletal exposure (tissue lysis) associated with a very thin line of BBD which was more pronounced with the combination of sediment and heat stress. After the eight day observation period, the control fragments were then placed into the 30°C treatment, and observed for an additional six days. The consortium started to spread in 2/3 of the fragments only after day four. These results indicate that the environmental stressors cause the host coral *M. cavernosa* to be more susceptible to BBD infection.

## 7-46

**Temporal Dynamics Of The Ongoing Caribbean Yellow Band Epizootic Event: Potential Link To Increasing Water Temperatures.**

**Ernesto WEIL*[1]**

[1]Department of Marine Sciences, University of Puerto Rico, Lajas, Puerto Rico

Geographic and local epizootic events affecting corals, octocorals, sponges and other reef organisms have become more frequent and damaging. Two of these events affecting acroporid corals and the urchin Diadema antillarum produced substantial ecological changes in coral reefs throughout the Caribbean in the 1980's. However, the ongoing epizootic event of Caribbean Yellow Band Disease (YBD) could be the most devastating yet. This disease is rapidly killing colonies of three of the four Montastraea species, the most important reef building genus in the region. Eight years of data and observations throughout the region indicate that YBD (1) is present in almost every single coral reef throughout the region, (2) prevalence have increased significantly in most reefs with higher numbers of infected M. faveolata (20-65%) and M. franksi (2-35%) colonies, (3) YBD significantly decreases colony reproductive output (fecundity) and therefore, the potential for recovery, (4) has produced significant coral cover loss (up to 45%) and killed very old (>1000 y) colonies in a relative short time, and (5) etiology has changed through time: a- from a seasonal, sporadic problem to a perseverant, year-long, common affection, b- band advance rates (mortality rates) have increased significantly from 0.7 to 4 cm/month, c- increase in the number of lesions per colony (up to 36), and d- lesion signs (bands) are wider, more white (less zooxanthellae?) with new wide yellow tissue areas now common in most colonies. Most of these changes seem to be correlated with increased monthly average minimum sea water temperature and/or might reflect the disease dynamics over time or epizootic dynamics in high density populations. YBD is today the worst threat to Caribbean coral reefs.

## 7-47

**Coral Diseases After The 2005 Caribbean Bleaching Event: Did Prevalence Increased Accordingly With Bleaching Severity?**

**Aldo CROQUER*[1]**, Ernesto WEIL[2]

[1]Biologia de Organismos, Simon Bolivar University, Caracas, Venezuela, [2]Marine Sciences, University of Puerto Rico, La Parguera, Puerto Rico

In the GBR temperature anomalies are correlated with coral diseases, but in the Caribbean, this hypothesis remains controversial. In 2005, a bleaching event affected corals throughout the region but mostly in the eastern and northern areas. Surveys were conducted over permanent belt-transects along a latitudinal gradient from Bermuda to Grenada where bleaching severity (i.e. percentage of corals affected) varied significantly. Surveys were done again in 2006 to test the hypothesis that localities with higher bleaching prevalence in 2005 will show a significat increase in disease prevalence. A 3-way ANOVA with site and depth as crossed and fixed factors and time as a repeated measure, was performed for bleaching and the overall prevalence of coral disease. To look at which specific diseases explained differences between particular sites and depths between years, a one-way ANOSIM and SIMPER analyses were used. Bleaching prevalence significantly decreased by the summer of 2006 at all sites and depth intervals. There was a significant interaction between reef sites, depth and years with significant reductions in the prevalence of coral diseases in 2006 in all sites and depths except in Flamingo Bay (Grenada) where yellow band disease (YBD) prevalence at intermediate and deep habitats significantly increased. All other diseases significantly decreased in 2006 at all sites and depths that had different bleaching levels in 2005. While sites with low bleaching prevalence in 2005 (i.e. Curacao and Bermuda) had less diseases compared to sites where bleaching was more severe (Grenada and Puerto Rico), in 2006 all sites and depths (except deeper and intermediate habitats in Flamingo) experienced a significant reduction in the prevalence of coral diseases regardless of bleaching severity. Thus, our results partly support the hypothesis of coral bleaching as a factor promoting coral epizootics.

## 7-48

**Testing the compromised-host hypothesis during the 2005 Caribbean coral-bleaching and disease event**

**Erinn MULLER*[1]**, Caroline ROGERS[2], Jeff MILLER[3], Robert VAN WOESIK[1]

[1]Department of Biological Sciences, Florida Institute of Technology, Melbourne, FL, [2]United States Geological Survey, St. John, Virgin Islands (U.S.), [3]South Florida/Caribbean Network, National Park Service, St. John, Virgin Islands (U.S.)

Anomalously high-water temperatures can increase coral-disease prevalence by either influencing pathogen concentrations or virulence, or by increasing host susceptibility through bleaching. The 2005 Caribbean coral-bleaching event provided the opportunity to test the compromised-host hypothesis on two species in the US Virgin Islands. At Hawksnest Bay, from 2004-2007, 60 randomly selected *Acropora palmata* colonies were examined monthly for bleaching, disease prevalence, and disease-associated mortality. Also, the number of disease-induced lesions was examined in 20, 2 m by 10 m belt transects, in five *Montastraea* spp.-dominated reefs, from 2005-2007. The prevalence of disease on both bleached and unbleached *A. palmata* colonies was positively related with water temperature; however, bleached *A. palmata* colonies suffered greater disease-associated mortality than unbleached colonies. By November 2005, >98% of the *Montastraea* spp. had bleached, and within five months disease incidence had increased 51 fold. The lack of unbleached *Montastraea* prohibited a comparison between bleached and unbleached colonies, however, disease incidence returned to pre-bleaching conditions once colonies partially recovered (July 2006). These studies indicate disease prevalence and severity increases when colonies bleach, at least for *A. palmata* and *Montastraea* spp., supporting the compromised-host hypothesis.

## 7-49

**The Role Of Injury And Temperature in The Initiation And Prevalence Of The Coral Disease, Skeletal Eroding Band**

**Cathie A PAGE*[1,2]**, Bette L WILLIS[1,2]

[1]ARC Centre of Excellence for Coral Reef Studies, Townsville, Australia, [2]School of Marine and Tropical Biology, James Cook University, Townsville, Australia

Skeletal eroding band (SEB) is the most prevalent coral disease on the Great Barrier Reef (GBR) and affects a greater range of host species than any other coral disease globally to date, yet little is known about its etiology or the environmental factors influencing its prevalence. In this study, both field surveys and experimental studies indicate that warm temperatures enhance the prevalence of SEB. Prevalence was greatest in summer in seasonal disease surveys between 2002-2007 in the northern GBR, supporting a link between warm temperatures and disease prevalence. Moreover, enhanced prevalence when temperatures were greater than summer seasonal means suggests that elevated summer water temperatures drive increases in SEB. This hypothesis is supported by evidence from artificial injury experiments designed to test the role of injury and temperature in the initiation of this disease. Colonisation of injuries by *Halofolliculina corallasia,* the putative pathogen of SEB, was significantly greater on corals maintained in aquaria at 30°C than on those maintained at both 24°C and 27°C. However, summer water temperatures in the northern GBR were not always sufficiently high to enhance ciliate colonisation rates in field experiments. Moreover, ciliates failed to form migrating disease bands accompanied by tissue lysing on any of three coral species tested experimentally, irrespective of water temperature, suggesting that although *H. corallasia* is an early coloniser of recently exposed coral skeleton, it may not be the causative agent of tissue loss. Alternatively, interactions with additional environmental or microbial agents may be required before ciliates become pathogenic. When migrating bands of *H. corallasia* were present, they were however associated with whole colony mortality as well as reduced growth and reproductive output in acroporid colonies in the northern GBR.

## 7-50

**A Disease Outbreak On A Healthy Reef: A Mechanism For Recruitment And Increased Diversity**

**Kathryn ROSELL*[1]**, Laurie RAYMUNDO[2]

[1]Silliman University, Dumaguete, Philippines, [2]University of Guam, Mangilao, Guam

In the Philippines, coral disease outbreaks and impacts to reefs over time have been poorly documented. Here, we present data from a year-long monitoring of an outbreak of Black Band Disease (BBD) in the Marine Protected Area of Apo Island, Negros Oriental. In June 2006, four large colonies of *Echinopora lamellosa* with an average mean diameter of 8.4 ± 5.9 m were observed with multiple Black Band lesions. These colonies were marked, and all other *E. lamellosa* colonies within a 50 m radius from this original reef area were located, mapped and examined for lesions. Disease progression on marked colonies was monitored for one year and other potential hosts were examined periodically. Three of the four original *Echinopora* colonies showed 90-95% mortality at 12 mo, and no other colonies had developed signs of disease. At 12 mo, a large lesion was observed on a nearby colony of *Coeloseris mayeri,* progression was rapid and the colony died within a month later. Therefore, this particular infection showed rapid progression and high mortality limited to very few colonies, in spite of the proximity of other potential hosts. At present, BBD is still progressing on the remaining tissues of the colonies. The exposed skeleton of the dead *E. lamellosa* colonies has begun to show signs of recovery via regrowth of small remaining patches of healthy tissue and via coral recruitment. Disease outbreaks are often catastrophic, resulting in widespread mortality of reef-building corals. However, our observations describe an episode of Black Band Disease in a marine reserve which greatly impacted very few colonies has opened up new substrates for recruitment. We speculate that such an epidemiological pattern may reflect the behavior of a disease on a relatively unimpacted reef and can act as a mechanism for opening up new substrate for recruitment.

## 8-1

**From Bacterial Bleaching To The Hologenome Theory Of Evolution**

Eugene ROSENBERG[1], **Eugene ROSENBERG*[2]**

[1]Mol. Microbiology & Biotechnology, Tel Aviv University, Ramat Aviv, Israel, [2]Mol Microbiol & Biotechnology, Tel Aviv University, Ramat Aviv, Israel

In 1995 we demonstrated that Vibrio shiloi was the causative agent of bleaching the coral Oculina patagonica. Subsequently, it was shown that Vibrio coralliilyticus was responsible for bleaching the coral Pocillopora damicornis in the Indian Ocean and Red Sea. From 1996 to 2002 we studied the infection of O. patagonica by V. shiloi both in the field and laboratory and reported that the pathogen is chemotactic to the coral mucus, adheres to a galactose-containing receptor on the coral surface, and penetrates into the exoderm where it differentiates into the VBNC state, multiplies intracellularly and produces a peptide photosynthesis inhibitor. The marine fireworm Hermodice carunculata is a winter reservoir and spring-summer vector for transmitting the bleaching disease. Starting in 2003, we observed that O. patagonica developed resistance to V. shiloi. Healthy corals taken from the sea could no longer be infected with the pathogen, and V. shiloi could no longer be isolated from corals. When we inoculated corals with V. shiloi, the bacteria adhered, penetrated and then were killed, aborting the infection. To explain these findings we presented the coral probiotic hypothesis, which posits that the corals acquired bacteria in their mucus and/or tissues that can kill V. shiloi. We now generalize from this hypothesis and present the hologenome theory of evolution-the role of symbiotic microorganisms in the evolution of animals and plants.

## 8-2

**Tools For Investigating Nutrient And Signal Exchange Between Corals And Their Associated Microbes**

**Max TEPLITSKI*[1]**, Kim RITCHIE[2], Mengsheng GAO[1], Cory KREDIET[3], Stephanie HALBIG[4], Ali AL AGELY[4]

[1]Soil and Water Science, University of Florida, Gainesville, FL, [2]Mote Marine Laboratory, Sarasota, FL, [3]Interdisciplinary Ecology, University of Florida, Gainesville, FL, [4]University of Florida, Gainesville, FL

The stability of symbioses depends on precisely timed signal exchange among symbiotic partners. To contribute to the development of tools for investigating interactions between corals and associated microbes we 1) developed assays to identify components of Acropora palmata mucus, 2) optimized reporters for identifying bacterial quorum sensing signals and their inhibitors, and 3) developed a broad host range plasmid-reporter for quantifying gene expression in vivo. Because induction of lytic enzymes depends on the availability of a substrate, the identification of enzymatic activity indicates presence of the corresponding substrates and bonds in a complex mixture (such as coral mucus). Incubation of Serratia marcescens with A. palmata mucus resulted in the differential activities of N-acetyl-b-D-galactosaminidase, a-D-galactopyranosidase, b-D-galactopyranosidase, a-D-glucopyranosidase, a-L-arabinopyranosidase, and a-L-fucopyranosidase. These data provide hints about the structure of coral mucus and offer an opportunity to investigate dynamics of coral mucus colonization by pathogens and symbionts. Many symbioses between bacteria and their eukaryotic hosts require a bacterial cell-to-cell communication system called "quorum sensing" (QS). Libraries of coral-associated bacteria were screened for their ability to activate or inhibit bacterial QS reporters. Activities that induced or inhibited QS receptor-based reporters were detected. These observations suggest QS signals, antagonists, or other inhibitory molecules, are present. Since little is known about in situ interactions between bacteria and coral/algal hosts, a portable RIVET (recombinase-based in vivo expression technology) reporter plasmid was developed. RIVET can be used to document and quantify bacterial gene expression in ecological niches that are un-accessible to other common reporter systems.

## 8-3

**Regulation Of Quorum Sensing By Gorgonian Corals: Stimulation And Antagonism**

**Laura HUNT*[1]**, Kelsey DOWNUM[1], Laura MYDLARZ[1]

[1]Biology, University of Texas at Arlington, Arlington, TX

Gorgonian corals synthesize many novel secondary metabolites that may mediate coral-bacterial interactions. One mechanism of control may be to regulate prokaryotic cell-to-cell communication, known as quorum sensing (QS). Many bacteria use QS signals to facilitate colonization of higher organisms. In the present study, we are examining extracts of various healthy gorgonian corals, from the Caribbean for QS regulatory activity, using a specific *Pseudomonas aeruginosa* JP2 QS-*gfp* biosensor system sensitive to long chain acyl homoserine lactones (AHL). Preliminary results using lipid-based extracts of a subsample of our gorgonian collection (*Plexaura flexuosa, Briareum sp., Pseudoplexaura sp.,* and *Eunicea laciniata*) showed a range of activity. *Briareum* and *P.flexuosa* ethanol extracts had the most potent inhibitory effect on QS, with a 90% and 80% reduction in signal respectively. Less pronounced effects (20% signal reduction) were observed with *E.laciniata* extracts. All of these extracts showed a dose-response effect. Interestingly, *Pseudoplexaura* ethanol extracts stimulated QS activity in the absence of AHL with a striking 10-fold increase in signal over background fluorescence. The stimulation of QS by *Pseudoplexaura* or other elements of the holobiont, may encourage colonization or recruitment of specific microbial species. Active coral extracts will be further tested for specific processes controlled by QS that are relevant to the marine environment, such as biofilm formation. The presence of stimulatory and inhibitory compounds, in corals, may indicate ongoing crosstalk between the coral-prokaryotic boundary and interspecies bacterial communication. Overall this has potential implications for microbial ecology and host-pathogen interactions.

## 8-4

**The Host As A Habitat Divided**

**Nathan D. OLSON*[1]**, Tracy AINSWORTH[2], Mali'o KODIS[1], Ruth D. GATES[3], Misaki TAKABAYASHI[1]

[1]Marine Science, University of Hawaii at Hilo, Hilo, HI, [2]University of Queensland, Brisbane, Australia, [3]Hawaii Institute of Marine Biology, Kane`ohe, HI

Scleractinian corals are now viewed as complex holobiont systems comprising the animal host and a consortium of microbial symbionts. This conceptual shift has led us to consider the coral host as a habitat. When viewed as a habitat, the coral can be subdivided into three compartments or interacting systems; the endolith, tissue, and mucus. Microbes in these compartments are speculated to be linked to the rest of the holobiont community through nitrogen interdependency. In order to assess the identity and potential roles of symbiotic microbes in the nitrogen cycle of the coral holobiont, we examined the microbes present in each of these three compartments of Hawaiian corals of genus *Montipora*. The prevalence of endolithic fungi in *Montipora capitata* was analyzed across an environmental gradient present in Kaneohe Bay through the use of culturing techniques. The results indicate a mean prevalence of 75% (n = 120) with no statistically significant difference in prevalence at sites that cross the gradient. The mean prevalence of endolithic fungi is higher in Kaneohe Bay, Hawaii than reported for other reef systems. Within the coral tissue compartment, *nif*H sequence data obtained from *M. capitata* tissue indicates the presence of bacteria capable of nitrogen fixation belonging to the taxa *Vibrio*. Fluorescent *in situ* hybridization of tissue sections of *M. capitata* using probes specific to the bacterial genus *Vibrio* revealed that the bacteria are localized within the coral epidermal tissue layer. Lastly, the diversity of microbial ribotypes present in the mucus of *M. patula* was analyzed using molecular approaches. Collectively, these data contribute a more thorough characterization of the complexity of microbial communities in corals and allow for the generation of hypotheses regarding the role of each microbial member in the nitrogen cycling within the coral holobiont.

## 8-5

**Biofilms: Coral Surface Mucus Layers, Settlers And Their Bacterial Inhabitants**

**Reia GUPPY*[1]**, John BYTHELL[1]

[1]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom

There is growing evidence that the surface mucus layer (SML) bacterial community on corals is deterministic. However, although this community appears to be quite different from the one in the water column, all surfaces support a distinct community to the water column and the extent to which the SML bacterial community is 'cultured' by its host and/or represents a settler community has not been greatly explored. An initial assessment of the 16S rRNA gene bacterial diversity of coral SML taken from five species of coral (*Montastraea faveolata, Diploria strigosa, Goniastrea aspera, Acropora aspera,* and *Porites lutea*) and biofilms developing on glass plates was conducted using a combination of gel profiling and sequencing techniques. Species differences were observed, and non-metric multidimensional scaling (nMDS) of DGGE fingerprints suggested that some overlap exists (~30 %) between the coral SML and biofilm surfaces, but sequencing and ARDRA techniques suggest otherwise (~10%). The presence in the coral SML and not the glass biofilm of several bacterial ribosomal sequences from bacteria that inhabit mucus layers of other organisms also point to a mucus-specific bacterial community rather than passive settlement from the water column.

## 8-6

**Visualising The Coral Surface Mucus Layer**

**John BYTHELL*[1]**, Reia GUPPY[1], Amita JATKAR[1], Barbara BROWN[1], Nick MORRIS[2], Jeff PEARSON[3]

[1]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]School of Biomedical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom, [3]Institute for Cell and Molecular Biosciences, Newcastle University, Newcastle upon Tyne, United Kingdom

The coral surface mucus layer (SML) plays a number of roles in the biology of reef corals including ciliary-mucus transport and protection from desiccation, pollutants and microbial invasion. Importance of the SML is demonstrated by the fact that the coral invests such a substantial proportion of its carbon and nitrogen budget into mucus production. Recent work also indicates that while there are variations in depth, a mucus layer is continuously present on the coral surface, suggesting that protection is one of the key roles. While there have been numerous studies investigating coral mucus, all of these have used artificial collection techniques or histological techniques that do not preserve the in situ mucus layer in its native state. This is particularly important for understanding the spatial structure and dynamics of microbial communities of the SML. Here we report novel techniques for the preservation and analysis of the SML.

## 8-7

**Bacteria-Bacteria Antagonism Within The Coral Surface Mucus Layer**

**Jessica WARD*[1]**, Farooq AZAM[1]

[1]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla, CA

The discovery of high prokaryote diversity associated with scleractinian corals and consistent associations between coral species and certain bacteria suggest that bacteria may form close associations with corals, including symbioses. One hypothesized role of coral-associated bacteria is disease resistance. Coral-associated bacteria may interact with each other and with 'non-native' bacteria to influence the ability of potential pathogens to colonize and/or proliferate within the mucus layer. Here we test the hypothesis that bacteria-bacteria antagonism occurs among coral-associated bacteria and between coral-associated bacteria and potential pathogens. We further test the effects of temperature on these interactions. Bacteria were isolated from the surface of healthy Montastrea annularis collected in the Florida Keys, USA and 69 were tested for antagonism using Burkholder agar diffusion assays. Of the tested isolates, 47.8% of isolates tested were antagonistic against at least one other isolate. Temperature exerted variable effects on antagonism – 32 isolates were more susceptible to antagonism at 25°C than at 31°C while 12 were more susceptible at 31°C than at 25°C. Three of the isolates obtained from the healthy coral are potential coral pathogens including *Thalassomonas loyana*, a proteobacterium associated with black band disease, and *Vibrio coralliilyticus*. Bacteria-bacteria antagonism may be an important structuring force, both in terms of diversity and spatial structure, within the coral mucus layer. The presence of potential pathogens on apparently healthy coral coupled with our observation that many isolates are antagonistic suggests that antagonistic interactions among bacteria within the community may be an important factor in keeping potential pathogens at bay.

## 8-8

**Potential For Transport Of Bacteria Between Fish Farms And Coral Reefs**

**Melissa GARREN*[1]**, Steven SMRIGA[1], Farooq AZAM[1]

[1]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla, CA

To better understand the interactions between a coral and its associated microbial community, it is useful to examine the microbial environment in which the holobiont exists. Coastal coral reefs are under pressure from many environmental stressors, one of which is pollution. Fish farming is a growing industry that can create point sources of pollution directly on or adjacent to coral reefs. To understand how the presence of fish farms influences coral-microbe interactions, we examined the relationship among a milkfish (*Chanos chanos*) farm, water quality, microbial communities, and coral reefs in Bolinao, The Philippines. We found steep gradients in the concentrations of dissolved organic carbon (70-160µM), total dissolved nitrogen (7-40µM), chlorophyll *a* (phytoplankton biomass proxy; .25-10µg/l), particulate matter (106-832µg/l), bacteria (5x105-1x106 cells/ml), and viruses (1-7x107/ml) that correlate with distance from the fish farms. Dominant members of the microbial communities found on corals, as determined by denaturing gradient gel electrophoresis (DGGE) of 16S rRNA genes, were distinct from the dominant members of the water column community. However, we also observed rare phylotypes (not detected by DGGE) from the water column community using culturing and isolation techniques. Some of these rare water column phylotypes (belonging to the orders alteromonadales and vibrionales) isolated from the fish pens were dominant community members on healthy corals as far as 10km away from the pens. Thus, while corals may exclude many water column microbes from their surfaces, some bacteria phylotypes, present at undetectable levels in the water column by DGGE analysis, may be associated with corals. Fish farms and other point sources of pollution may introduce bacteria to the water column that have the potential to associate with and become abundant on corals. Our study raises the question whether these bacteria may alter the 'normal' coral microbial community, and whether such changes might have important ecological effects.

## 8-9

**Milkfish Feces Share Common Bacteria With Coral Holobiont**

**Steven SMRIGA*[1,2]**, Melissa GARREN[1,2], Farooq AZAM[1]

[1]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla, CA, [2]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla

Effluent from intensive milkfish (*Chanos chanos*) aquaculture is among several environmental stressors that may impact coral reefs near Bolinao, Pangasinan, Philippines. Fish feces are part of this effluent, and since the effects of effluents on coral-associated microbial communities may provide a mechanistic link between fish farms and coral reefs, it is of interest to consider the potential effects of fish feces on corals. We hypothesized that distinct bacterial groups found in fish feces can also be found on corals. Feces were collected from the distal intestines of milkfish, bacterial isolates were obtained from water samples, and coral tissue slurries were collected from diverse coral genera along a quantifiable gradient of effluent. Community 16S rDNA gene profiles from feces were dominated by *Vibrio sp*., while profiles from each of four coral samples were considerably more diverse. Despite these differences, some 16S rDNA genes from feces and corals were >99% similar including *Ralstonia sp.* and *Acinetobacter sp.*. Furthermore, some *Vibrio sp.* sequences were >99% similar among feces, corals, and isolated bacteria. The findings suggest that among these diverse sample types, specific microenvironments may select for the same microbial phylotypes. Alternatively, fish feces may select for specific microbial phylotypes that are then transported into coral ecosystems via water effluents and introduced into the coral holobiont. Fish feces should be considered within conceptual and experimental approaches that address coral-microbial interactions, including those that address coral disease.

## 8-10

**Functional Change in Microbial Communities On Four Coral Atolls**

**Elizabeth DINSDALE*[1]**, Olga PANTOS[2], Robert EDWARDS[3], Steven SMRIGA[4], Florent ANGLY[3], Dana HALL[3], Linda WEGLEY[3], Enric SALA[4], Stuart SANDIN[4], Rebecca VEGA THURBER[3], Bette WILLIS[5], Farooq AZAM[4], Nancy KNOWLTON[4], Forest ROHWER[3]

[1]Biology Department, San Diego State University, San Diego, CA, [2]University of Queensland, Brisbane, Australia, [3]San Diego State University, San Diego, CA, [4]Scripps Institution of Oceanography, San Diego, CA, [5]James Cook University, Townsville, Australia

Replacement of corals by algae is a reoccurring trend on today's coral reefs. The role of microbes in these phase shifts is unknown. Microbial communities were quantified in the water column across four coral atolls displaying different levels of coral cover, using metagenomic, microscopic, and culturing techniques. A 10-fold increase in abundance of virus-like particles, Bacteria, and Archaea and a doubling of the number of protists in the overlying waters occurred from the coral reefs with the highest coral cover to the coral reefs with the lowest coral cover. The metagenomic taxonomic analysis showed that Bacteria and Archaea changed from a balanced community of autotrophs and heterotrophs to a predominantly heterotrophic community where coral cover was low. On the coral reefs with the lowest coral cover the heterotrophic microbes were dominated by potentially pathogenic strains. The relative proportions of the functional genes on each atoll confirmed the non-linear change in the microbial community. On the coral reef with the highest coral cover, the proportion of genes associated with photosynthesis was 3.4 %; they increased to 44.3 % on the coral reef with a moderate coral cover; and decreased to only 0.3 % on the reef with the lowest coral cover. In contrast, genes associated with carbon utilization comprised 24 % on the impacted reef. Where coral cover was high, microbial numbers were low and metabolically providing a diverse range of functions, including photosynthesis and nutrient recycling. Conversely, where coral cover was low, microbial numbers were high and restricted to functions that focused on consuming carbon and nutrients. Corals that remain alive on algae dominated reefs are bathed in water that contains high numbers of heterotrophic microbes. Not surprisingly the health of many of these remaining corals was compromised.

## 8-11

**Exploring Bacterial Community Dynamics in Early Life Stages Of The Caribbean Corals *porites Astreoides* And *montastrea Faveolata***

**Koty SHARP*[1]**

[1]Smithsonian Marine Station, Fort Pierce, FL

Like other marine invertebrates, scleractinian corals have been shown to harbor diverse assemblages of microbes, but neither the specificity of these associations nor the mechanisms that maintain them across host generations is well understood. Bacterial communities in planula larvae of the Caribbean coral *Porites astreoides* were characterized in this study. Molecular techniques were used to identify bacteria associated with *P. astreoides* larvae, and sequence-specific oligonucleotide primers were designed to survey multiple samples for the presence of particular bacterial species. Fluorescence in situ hybridization (FISH) and microscopy revealed the presence of particular localizations of specific bacteria within the larvae, and the relative abundance of various groups of bacteria in the larvae was estimated. In contrast, gamete bundles from the mass-spawning corals *Montastrea spp.* and *Acropora spp.* did not contain bacteria or archaea. Molecular analysis on post-settlement stages of *M. faveolata* was used to characterize the bacterial communities present in juvenile feeding polyps. This study reveals new insights into mechanisms by which microbial assemblages associated with corals are maintained and regulated during host embryogenesis and early development. In addition, these results present the possibility for a bacterial role in larval ecology of some coral species.

## 8-12

**Dom Assimilation By A Coral Reef Sponge And Its Associated Prokaryotes: A Carbon Isotope Tracer Study**

Jasper DE GOEIJ[1,2], Leon MOODLEY[3], Nestor CARBALLEIRA[4], **Fleur VAN DUYL*[1,5]**

[1]Royal Netherlands Institute for Sea Research, Den Burg, Netherlands, [2]The Carmabi Foundation, Curacao, Netherlands Antilles, [3]Netherlands Institute of Ecology, Yerseke, Netherlands, [4]University of Puerto Rico, San Juan, Puerto Rico, [5]Royal Netherlands Institute for Sea Research, Texel, Netherlands

We studied the dissolved organic matter (DOM) assimilation by the common encrusting coral reef sponge *Halisarca caerulea*. *H. caerulea* is found predominantly on the walls and ceilings of coral cavities in the fore reef slope of the coral reefs of Curaçao (Netherlands Antilles) and harbors sponge associated prokaryotes (2.1 *109 prokaryotes.cm-3 sponge). The assimilation and respiration of 13C-enriched glucose and diatom derived dissolved organic matter was followed in incubations. DOM was readily processed by the sponge with assimilation being the major fate. The 13C- enrichments patterns in fatty acid biomarkers revealed that the dissolved organic 13C assimilation by *H. caerulea* was both direct and mediated by sponge associated prokaryotes. Tracer carbon was recovered both in bacteria-specific and non-bacteria specific fatty acids. Phytanic acid was ascribed to the sponge. This is the first direct evidence of DOM incorporation by sponge cells. The sponge-microbe consortium of *H. caerulea* processes bulk dissolved organic matter, meeting up to 90% of their organic carbon demand. Because sponges dominate live cover in cryptic habitats on coral reefs, DOM assimilation by cryptic reef sponges represents an important, largely overlooked, ecological function of coral reefs.

## 8-13

**Assessment Of Coral Microbiota: The Impact Of Untested Assumptions, Unintended Biases, And Undefined Variables**

Shawn POLSON[1,2], Sara POLSON[1], Julie HIGGINS[1], **Cheryl WOODLEY*[1]**

[1]Center for Coastal Environmental Health and Biomolecular Research, NOAA National Ocean Service, Charleston, SC, [2]Marine Biomedicine and Environmental Sciences Center, Medical University of South Carolina, Charleston, SC

The study of microbiology has emerged as an important component of coral biology, with numerous studies examining coral-associated microbial ecology in hopes of understanding the dynamic nature of these communities. Such studies have provided numerous insights into the composition of these communities, but a significant level of project-to-project variability is apparent when reviewing these results. The study presented here utilized culture-dependent (~650 isolates) and independent (~25,000 sequences from 88 16S rDNA libraries) analyses to assess the microbial community structure associated with acroporid corals of the Florida reef tract (USA). The study was designed to allow for the impact of multiple sample variables including sample collection/processing methodology, disease state, acroporid species, regional geography, and limited temporal variation to be simultaneously assessed. Sample processing methodology was found to introduce significant bias into the resulting microbial community composition detected. Lumping coral health states into defined "diseases", based solely upon field observations of similarity in disease signs, was also demonstrated to be a potential source of variation found in the past literature. The existence of marked temporal variation within a population of corals was also detected. The results of this study indicate that future studies of coral-associated microbial communities must take great care to control for numerous variables (many of which are currently poorly understood). Key among these factors is an in depth assessment of the physiological state of the coral during sample collection. Without increased efforts to address the role of such secondary variables on microbial community composition (both actual and detected) it is likely that increased fragmentation in the body of literature will occur, hampering efforts to understand the nature of this important component of the coral holobiont.

## 8-14

**Changes in Coral Associated Microbial Communities During A Bleaching Event**

**David BOURNE*[1]**, Yuki IIDA[1], Sven UTHICKE[1], Carolyn SMITH-KEUNE[1,2]

[1]Australian Institute of Marine Science, Townsville, Australia, [2]Centre of Marine Studies, University of Queensland, Brisbane, Australia

Environmental stressors such as increased sea surface temperatures are well known for contributing to coral bleaching, however the effect of increased temperatures and subsequent bleaching on coral associated microbial communities is poorly understood. Colonies of the hard coral *Acropora millepora* were tagged on a reef flat off Magnetic Island (Great Barrier Reef) and surveyed over 2.5 years, which included a severe bleaching event in January/February 2002. Daily average water temperatures exceeded the previous 10-year average by more than 1ºC for extended periods with field based visual surveys recording all tagged colonies displaying signs of bleaching. During the bleaching period, direct counts of coral zooxanthellae densities decreased by ~64%, before recovery to pre-bleaching levels after the thermal stress event. A subset of three tagged coral colonies were sampled through the bleaching event and changes in the microbial community elucidated. DGGE analysis demonstrated conserved bacterial banding profiles between the three coral colonies confirming previous studies highlighting specific microbial associations. As coral colonies bleached, the microbial community shifted and redundancy analysis (RDA) of DGGE-banding patterns revealed a correlation of increasing temperature with the appearance of *Vibrio*-affiliated sequences. Clone libraries hybridised with *Vibrio*-specific oligonucleotide probes confirmed an increase in the fraction of *Vibrio*-affiliated clones during the bleaching period. Post-bleaching, the coral microbial associations again shifted, returning to a profile similar or identical to the fingerprints prior to bleaching. This provided further evidence for corals selecting and shaping their microbial partners. For non-bleached samples, a close association with *Spongiobacter* related sequences were revealed by both clone libraries and DGGE profiling. Despite *Vibrio* species being previously implicated in bleaching of specific coral species, it is unsure if the relative increase in retrieved *Vibrio* sequences is due to bacterial infection or an opportunistic response to compromised health and changing environmental parameters of the coral host.

## 8-15

**Metagenomic Analysis Of The Microbial Community Associated With The Coral Porites Astreoides**

Linda WEGLEY[1], **Robert EDWARDS*[2]**, Forest ROHWER[1]

[1]Biology, San Diego State University, San Diego, CA, [2]San Diego State University, San Diego, CA

The coral holobiont is a dynamic assemblage of the coral animal, zooxanthellae, endolithic algae and fungi, Bacteria, Archaea and viruses. Zooxanthellae and some Bacteria form relatively stable and species-specific associations with corals. The symbiontic algae, or zooxanthellae, that reside within the coral tissues have been studied extensively, however very little is understood about the other microbes within the coral holobiont. To better understand the roles of the microbes associated with corals, a fractionation procedure was used to separate the microbes, mitochondria, and viruses from the coral animal cells and zooxanthellae. The resulting metagenomic DNA was sequenced using pyrosequencing. Fungi, Bacteria, and phage were the most commonly identified organisms in the metagenome. Three of the four fungal phyla were represented, including a wide diversity of fungal genes involved in carbon and nitrogen metabolism, suggesting that the endolithic community is more important than previously appreciated. In particular, the data suggested that endolithic fungi could be converting nitrate and nitrite to ammonia, which would enable fixed-nitrogen to cycle within the coral holobiont. The most prominent bacterial groups were Proteobacteria (68%), Firmicutes (10%), Cyanobacteria (7%), and Actinobacteria (6%). Functionally, the bacterial community was primarily heterotrophic and included a number of pathways for the degradation of aromatic compounds, the most abundant being the homogentisate pathway. The most abundant phage family was the ssDNA Microphage and most of the eukaryotic viruses were most closely related to those known to infect aquatic organisms. This study provides a metabolic and taxonomic snapshot of microbes associated with the reef-building coral Porites astreoides and presents a basis for understanding how coral-microbial interactions structure the holobiont and coral reefs.

## 8-16

**Comparison of bacterial communities on corals containing different Symbiodinium (Zooxanthellae) clades**

**Raechel LITTMAN*[1]**, David BOURNE[2], Bette WILLIS[1]

[1]Marine and Tropical Biology, James Cook University, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

Reef-building corals host a variety of micro-organisms, including symbiotic dinoflagellates, Symbiodinium (zooxanthellae) and an array of bacteria. Previous studies have suggested that bacteria can provide many benefits to corals through fixation and passage of nitrogen and carbon to the coral host and production of secondary metabolites such as antibiotics. Many of the coral's nutritional needs are supplied by Symbiodinium, and it has been shown that different genetic types of this algal symbiont differentially affect the physiology of the coral host. For instance, corals containing Symbiodinium clade D tend to be more tolerant to heat stress. However, little is known about how Symbiodinium affects the entire holobiont. Arguably, changes in the algal symbionts may lead to differences in the bacterial populations on corals. For instance, Symbiodinium contributes to the mucus layer, providing nutrients to potentially important bacterial inhabitants. To aid in our understanding of possible interactions between bacterial and Symbiodinium communities, this study compares bacteria community profiles of juvenile Acropora millepora and A. tenuis experimentally infected with two different clades of Symbiodinium, C1 and D. Moreover, bacterial communities are compared on corals containing C1 and D that have been experimentally bleached to determine whether coral-associated bacterial communities are more resilient to change on corals containing heat tolerant algal symbionts. This will aid in understanding the relationships between microbial inhabitants and how these communities can be destabilized if Symbiodinium is lost from the host.

## 8-17

**Bacteria Associated With Symbiodinium Spp. in Culture**

**Kim RITCHIE*[1]**, Roxanna MYERS[2], Carmel NORMAN[3], Joel THURMOND[3]

[1]Mote Marine Lab, Sarasota, FL, [2]University of Guam, Mangilao, United States Minor Outlying Islands, [3]Mote Marine Laboratory, Sarasota, FL

Most dinoflagellates are difficult to grow axenically. These include the red tide toxin producing dinoflagellate, *Karenia brevis*, and the coral endosymbiont, *Symbiodinium* spp. Historically, attempts to achieve axenic cultures using antibiotic treatment, in combination with other physical methods, initially interfere with growth of the dinoflagellate. Over time, bacteria reemerge within successful cultures. It has been suggested that the antibiotic cocktail used in purification may hinder dinoflagellate growth. An alternative hypothesis is that bacteria present in dinoflagellate cultures are required for dinoflagellate growth. To date, no survey of bacteria present in *Symbiodinium* cultures has been undertaken. Bacteria associated with ten *Symbiodinium* cultures, representing 6 different *Symbiodinium* clades, were examined using culture-based methods, denaturing gradient gel electrophoresis (DGGE) analysis and terminal restriction length polymorphism (TRFLP) analysis. Although phylogenetic variation exists among bacterial groups associated with *Symbiodinium* cultures, of interest is that bacteria frequently identified in all ten *Symbiodinium* cultures include members of the Roseobacter clade, *Marinobacter* species, and members of the Cytophaga-Flavobacterium-Bacteroides (CFB) group. These findings indicate a potential mutualistic role for these bacteria with *Symbiodinium* spp.

## 8-18

**Abundance of Zooxanthellae degrading or suppressing bacteria in a High-latitude Coral community and their Effect on Zooxanthellae and Coral host**

**Shashank KESHAVMURTHY*[1]**, Kimio FUKAMI[1]

[1]Graduate School of Kuroshio Science, Kochi University, Japan, Kochi, Japan

Studies carried out on bleaching in corals in the last decade have linked bacteria (bacteria-mediated bleaching) as one of the causes of coral bleaching as a result of degradation/necrosis of zooxanthellae due to bacterial activity. Though many bacterial species have been linked with coral bleaching, it is still not clear about the abundance, diversity and effect of such bacteria on compromised coral holobiont. This study looks at presence of such bacteria that are capable of degrading/suppressing zooxanthellae and their effect on zooxanthellae and coral host. The study was carried out in a high-latitude coral community at Nishidomari, Otsuki (N 32o 46' 45" and E 132o 43' 59") situated in the south of Kochi Prefecture, Shikoku, Japan. Our results showed presence of bacteria effective against zooxanthellae in the order of 102 cells/L. Most of the isolated zooxanthellae degrading/suppressing bacteria belonged to *Gammaproteobacteria*. The effect of three strains of algicidal bacteria (1B, 4-2DW-1 and 4-1SW-1) on temperature stressed zooxanthellae showed 53-86% cell degradation. There was no such strong effect of these strains on the temperature stressed corals. However, tissue loss, reduction in zooxanthellae abundance and lowered pigment concentration was observed in the coral fragments that were incubated for two weeks with zooxanthellae degrading/suppressing bacteria. This study is the first report on the abundance of bacteria that are able to degrade/suppress zooxanthellae. Initial results on their effect on two coral species has shown that they have ability to bleach the coral that were subjected to stress. We conclude that such bacteria that are present in the coral reef areas might be acting as opportunistic pathogens on stressed corals thereby contributing to the coral bleaching phenomenon.

## 8-20

**Microbial Diversity Associated With The Deep-Water Scleractinian *lophelia Pertusa* in The Gulf Of Mexico**

**Christina KELLOGG*[1]**

[1]U.S. Geological Survey, St. Petersburg, FL

Bacteria and archaea are beginning to be recognized as an important part of the total biology of shallow-water corals. Deep-sea corals have a fundamentally different ecology due to their adaptation to cold, dark, high-pressure environments, and as such they have novel microbiota. The goal of this study was to characterize the microbial communities of the deep-sea coral *Lophelia pertusa* in the Gulf of Mexico. This is the first study to include both culture-based and molecular data on deep-sea coral-associated bacterial communities. This is also the first study to detect archaea associated with a deep-sea coral. Additionally, we present a novel method to collect coral samples in individual insulated containers and preserve them at depth in an effort to maintain *in-situ* microbial diversity by minimizing contamination and thermal shock.

There are a few similarities between *Lophelia*-associated bacteria and bacteria from shallow-water corals and deep-sea octocorals. However, both cultured isolates and 16S rDNA clone libraries reveal many novel bacteria associated with *Lophelia*. Many of these bacteria are similar to prokaryotic symbionts of fish, squid, and methane-seep clams. In particular, one bacterial sequence, VKLP1, that is present in all *Lophelia* colonies analyzed to date (n=6), is genetically similar to a sulfide-oxidizing gill symbiont of a seep clam. This apparently *Lophelia*-specific bacterium may link the coral to cold seep communities. Molecular analysis of bacterial community diversity showed a marked difference between the two study sites, even though they are less than 20 nautical miles apart. The dissimilarity between the dominant members of the bacterial communities at these two sites may be evidence of diseased *Lophelia* or thermal stress at one site, or may indicate biogeographical differences.

## 8-21

**Cross-Kingdom Amplification Using Bacterial-Specific Primers: Implications For Coral Microbial Ecology**

**Julia GALKIEWICZ*[1]**, Christina KELLOGG[2]

[1]College of Marine Science, University of South Florida, Saint Petersburg, FL, [2]USGS, Saint Petersburg, FL

In the field of coral microbial ecology, polymerase chain reaction (PCR) amplification of pure bacterial DNA is vital to the study of bacterial interactions with corals. Previous studies of coral-associated bacteria from the Caribbean have used 16S primers 8F or 27F and 1492R to amplify prokaryotic rDNA. Primers 8F and 27F are described as bacterial-specific, while primer 1492R universally amplifies prokaryotic, archaeal, and eukaryotic DNA. In combination, 8F/1492R and 27F/1492R should amplify only bacterial rDNA. However, recent trials have shown that these common primer sets also amplify eukaryotic 18S rDNA.

Samples of the Pacific scleractinian Pocillopora damicornis were collected in American Samoa and preserved in a DMSO/EDTA/salt buffer. Community DNA was extracted using the MoBio Powersoil™ DNA Isolation kit. This extraction procedure was adapted from published procedures that amplified coral-associated bacteria from Caribbean corals but had not been previously applied to Pacific coral tissue. When the resulting clones were sequenced and compared to the GenBank nucleotide database, they were most closely related to Cnidarian 18S rDNA. The 18S sequences were examined and found to contain short sequence homology (12 bp out of a total length of 20 bp) to primers 8F and 27F. This homology apparently allows amplification of coral 18S rDNA, creating an amplicon length of 1.3 kbp, almost identical to that of bacterial amplicons resulting from the 8F/1492R primer set. Because the amplicon lengths are so similar, gel extraction techniques to separate bacterial from cnidarian amplicons are difficult. To circumvent this problem, a different primer set was employed. The bacterial primers 63F and 1542R amplify a bacterial sequence 1.4 kbp in length, whereas coral DNA sequences amplified with these primers have a length of 0.6 kbp, allowing distinct separation on the gel and targeting of bacterial DNA for further analysis.

## 8-22

**Microbial Dynamics of Kiritimati Atoll**

**Tracey MCDOLE*[1]**, Rob EDWARDS[2], Liz DINSDALE[1], Sheila WALSH[3], Mary DONOVAN[4], Forest ROHWER[1]

[1]Cell and Molecular Biology, San Diego State University, San Diego, CA, [2]Math and Computer Sciences, San Diego State University, San Diego, CA, [3]Scripps Institution of Oceanography, UCSD, La Jolla, CA, [4]University of California, Santa Barbara, Santa Barbara, CA

Potential anthropogenic stressors that contribute to coral reef decline include global warming, eutrophication, and overfishing. It is becoming clear that microbes are important factors in all of these scenarios. In 2005, the coral reef-associated microbial community were surveyed in the northern line islands archipelago in the central pacific. A ten fold increase in microbial numbers from kingman (human population = 0), to kiritimati (population ~ 10,000) was observed. This increase in microbial abundance in the water column was correlated with an increase in coral disease prevalence. Kiritimati island itself also provides a gradient of human disturbance, without the latitudinal gradient of the 2005 survey. In 2007, water column samples were collected from 10 meters using scuba from a total of 22 sites encircling the island. At each site, the abundance of microbes and virus-like particles were enumerated using fluorescence microscopy. Increasing microbial and viral density was directly correlated with increasing human population. The maximum fold increase between sites for microbes and virus-like particles was 20 and 40 fold respectively, with the highest numbers of bacteria (5 x 106 cells/ml) and virus-like particles (2 x 107 cells/ml) occurring at the same site. The number of bacteria colonies that grew on media selective for the known pathogens *staphylococcus* spp and *vibrio* spp, as well as enteric bacteria also supported this trend. The abundance of microbes and viruses will be correlated with numbers of fish, prevalence of coral disease, number of coral recruits, and concentration of organic and inorganic nutrients to help develop a model of coral reef microbial and macrobial interactions.

## 8-23

**Reef Community Structure Of Hawaiian Reefs: From The Microscopic To The Macroscopic World**

**Florent ANGLY*[1]**, Mark VERMEIJ[2], Sheila WALSH[3], Stuart SANDIN[4], Meghan DAILER[2], Celia SMITH[5], Forest ROHWER[1]

[1]San Diego State University, San Diego, CA, [2]University of Hawaii, Lahaina, HI, [3]University of California, San Diego, San Diego, CA, [4]Scripps Institution of Oceanography, San Diego, CA, [5]University of Hawaii, Honolulu, HI

The acceleration of coastal urbanization in Hawaii this last decade has resulted in increased nutrient runoff to the ocean and has led to a decrease in coral cover. Such coral reef decline has important ecological as well as economical repercussions that need to be prevented. Recent evidence suggests a role of microbes in the trajectory of decline of coral reefs worldwide. The Line Islands archipelago in the central Pacific, including atolls ranging from uninhabited to moderately inhabited, was previously surveyed and microbially-driven food chains were reported for the most populated islands. We hypothesize that microbial abundance and composition are also a fundamental to understanding the trajectory of decline of Hawaiian coral reef ecosystems. To this end, benthic cover, fish species composition and microbial and viral abundance were assessed for 17 reefs of Maui and Lanai. Water parameters, including dissolved organic carbon and nutrient levels, were also recorded. The data indicated that the reef ecosystems of Maui were overall more degraded and algal-dominated than those of the nearby less populated island of Lanai. Viruses and microbes (including the potentially human pathogenic Vibrio bacterial genus) were more prevalent at degraded sites and their abundance ranged from about the same to twice as many as compared to remote, central Pacific atolls. The larger variation or patchiness in benthic composition of more degraded reefs could be interpreted as a departure from a healthy stable state. Basic functional relationships that are supposed to occur, like herbivorous fish control by fish predators, were mostly lost. The current structure of Hawaiian coral reef ecosystems depicts an intricate relation between the microscopic and the macroscopic world, that together with the very complex history of these reefs largely drives today's observations.

## 8-24

**Biogeography Of Reef Water And Coral-Associated Bacterial Communities Across The Hawaiian Archipelago And Greater Pacific Basin**

**Jennifer L. SALERNO*[1,2]**, Michael S. RAPPE[3]

[1]Zoology, University of Hawaii at Manoa, Honolulu, HI, [2]SOEST, Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kaneohe, [3]SOEST, Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kaneohe, HI

The bacterial community structure within coral and seawater samples collected from six islands and atolls within the Hawaiian archipelago was investigated using a suite of molecular biological and statistical techniques. Overall, we observed significant overlap in bacterial communities associated with the reef-building coral, *Porites lobata*, from the majority of islands and atolls within the Hawaiian archipelago and uncovered significant variation amongst different colonies within an island or atoll. However, microbial communities associated with *Porites lobata* colonies from French Frigate Shoals atoll were more similar to one another than to any other colonies located within the archipelago. These communities also shared some similarities with samples collected from Kaneohe Bay, Oahu, within the main Hawaiian Islands. These observed differences have important management implications, as corals with different assemblages of resident bacteria may respond differently to environmental changes. Seawater samples from sites within the Hawaiian archipelago, Johnston Atoll, and American Samoa were analyzed using similar techniques. Overall, seawater bacterial communities from the Hawaiian Islands were more similar to one another than to the other locales examined. Seawater bacterial communities from American Samoa were quite variable, but distinct from Hawaii, Johnston Atoll shared similarities with both Hawaii and American Samoa, and samples from Kaneohe Bay, Oahu grouped separately from all other locales. Overall, the biogeographic patterns of bacterial communities physically associated with the coral *Porites lobata* differed from those observed in planktonic bacterial communities, indicating that the underlying factors affecting the dispersal and proliferation of bacteria associated with a benthic host versus those within the plankton are different.

## 8-25

**Microbial Profiling For Coral Restoration**

**Camille DANIELS*[1]**, Mya BREITBART[1], Ilze BERZINS[2], Craig WATSON[3]

[1]University of South Florida, College of Marine Science, St. Petersburg, FL, [2]The Florida Aquarium, Tampa, FL, [3]University of Florida, Tropical Aquaculture Laboratory, Ruskin, FL

Coral aquaculture and transplantation are currently being employed to address worldwide decline of coral reefs and promote reef ecosystem recovery. Issues that arise with these restoration strategies include possible introduction of diseases onto natural reefs and the vulnerability of transplanted corals to bleaching and disease. While visual and histological assessments are currently being used to determine if aquacultured coral fragments are suitable for restoration, analyses of coral-associated microbes have yet to be incorporated as a health indicator before transplantation. Before microbial community composition can be incorporated into assessments of coral health, it is necessary to understand the spatial and temporal variability of coral-microbe associations.

This project uses culture-based (TCBS plating and EcoPlate carbon utilization profiling) and culture-independent (ARISA) methods to determine the composition and variability of the microbial community associated with corals used for restoration. Spatial sampling on a large Diploria clivosa parent colony revealed differences in microbial communities found in mucus from different locations on the coral surface. Following fragmentation of this parent colony, individual 2x2 cm fragments were sampled over time, allowing for increasing time intervals between mucus sampling. Rapid changes in the coral-associated microbial community were observed over time, with a significant increase in the number of culturable Vibrio sp. following removal of the coral mucus. Subsequent experiments revealed that the corals (or their associated microbes) adapt to reduce Vibrio numbers upon repeated sampling. The mechanism of this adaptation is currently unknown, but will be a focus of future studies. Results from this project will provide insight into the stability of coral-bacterial associations, and allow us to develop a microbial baseline for coral species used for restoration in the Florida Keys. Understanding microbe-coral interactions is critical for the future incorporation of microbial community profiling into coral health assessments, which has direct implications for coral restoration and conservation.

## 8-26

**Photosynthetic Microorganisms Colonized Within *goniastrea Aspera***

**Seitaro S. YAMAZAKI*[1]**, Takashi NAKAMURA[1,2], Yeong Shyan YUEN[1], Hideo YAMASAKI[1]

[1]Faculty of Science, University of the Ryukyus, Okinawa, Japan, [2]Amakusa Mar. Biol. Lab., Kyushu University, Kumamoto, Japan

Reef building corals have established obligate symbiotic relationship with dinoflagellates commonly known as "Zooxanthella". It is widely known that corals harbor multiple species of microalgae within their endoliths. However, its ecological function as well as impacts on the host corals has remained as a subject to be explored. In addition to the zooxanthella, it has been suggested that the flora of photosynthetic microorganisms colonized within coral endoliths is more complicated than that of described previously. Here, we characterize the photosynthetic microorganisms' flora in the endoliths of corals inhabiting in eutrophic and oligotrophic environments. *Goniastrea aspera* colonies were collected from eutrophic and oligotrophic environments in Okinawa (Japan) and Great Barrier Reef (Australia). We analyzed the species profile of photosynthetic microorganisms with the PCR-DGGE method, extracting total genomic DNA from coral endoliths. The diversity of 16S rDNA of cyanobacteria and chloroplasts in the samples collected from oligotrophic environments was much higher than that of eutrophic environments. The diversity of 18S rDNA of eucaryotic algae was lower than the 16S rDNA, and it was similar in both sites. These results suggest that diversity of cyanobacteria colonized within *G. aspera* in oligotrophic environment is higher compared to eutrophic environment. In contrast with cyanobacteria, fewer species of eucaryotic algae colonized within *G. aspera* and their diversity may not be affected by nutrient conditions. Our findings lead us to conclude that the diversity of cyanobacteria colonizing *G. aspera* endoliths can be altered by nutrient conditions of the environment.

## 8-27

**The Roles Of Viruses in Corals.**

**Rebecca VEGA THURBER*[1]**, Forest ROHWER[2]

[1]Biology, San Diego State University, San Diego, CA, [2]San Diego State University, San Diego, CA

The coral holobiont is a symbiotic community of animal host, zooxanthellae algae, and microbial flora and fauna. Using a combination of manipulation experiments, metagenomic analysis, and real-time PCR, we have found that this diversity of organisms is thus reflected in the viral consortia present within the tissues and mucus of *Porites compressa* corals. We have identified representatives of viruses that infect many protozoan and metazoan phyla, as well as Bacteria and Archaea. We hypothesize that these viruses infect different compartments within the holobiont and therefore affect the coral host in a variety of ways. Of particular interest are three groups of viruses: the herpes-like viruses, single-stranded DNA plant viruses, and Bdellovibrio phages which are elevated in abundance after corals were exposed to increases in temperature, nutrients, and dissolved organic carbon, respectively. To further characterize the role(s) that these viral groups play in coral health and homeostatis, we have conducted analysis on the relative abundance of viral target genes and members of the holobiont. For example, *Symbiodinium* (as measured by a *Symbiodinium* psbA chloroplast gene) abundance was found to be negatively correlated with a putative Geminivirus recently identified in our libraries, suggesting that as this virus is produced, zooxanthellae abundance is reduced, indicative of viral infection and lysis of the zooxanthellae. Also, Bdellovibrio phage (viruses that infect bacterivorous Bacteria) abundance was negatively correlated with groups of heterotrophic bacteria suggesting that Bdellovibrios may play a unique role in regulating bacterial colonization of the holobiont. Lastly, herpes-like virus genes were positively correlated with coral tumor incidence indicating that these viruses may be culprits of coral disease. These and other data suggest that viruses may play important roles in coral biology and coral reef health.

## 8-28

**Microalgae From The Mucus Layer Of Two Massive Corals in The South-Eastern Caribbean, Venezuela**

**Francoise CAVADA*[1]**, Rene AYALA[1], Luis TROCCOLI[2], Juan CRUZ-MOTTA[1]

[1]Departamento de Estudios Ambientales, Universidad SimÃ³n BolÃ-var, Caracas, Venezuela, [2]Departamento de Acuicultura, Universidad de Oriente Nucleo Nueva Esparta, Isla de Margarita, Venezuela

The mucus layer of healthy scleractinian corals contains a variety of eukaryotic and prokaryotic microorganisms. It has been hypothesized that these communities confer some benefits to the coral, specifically the pathogenesis development. However, little is known about the eukaryotic fraction of these communities. This study addresses the description of the patterns of spatial and temporal distribution of microalgae assemblages in the mucus layer of two massive corals in a pristine reef patch in the south-eastern Caribbean, using a sampling design that allowed testing specific hypotheses in relation to: 1) differences between coral species and 2) the generality of the observed patterns. To accomplish this, samples of mucus were haphazardly taken from 72 healthy colonies, 36 *Diploria strigora* and 36 *Colpophyllia natans* plus 3 samples of water and sediment on a monthly basis between January and June 2004. Multivariate analysis, based on similarity matrices, showed that microalgae assemblages present in the mucus samples had no relation with those from the water column or sediment, and that variation in the assemblages of microalgae from the mucus throughout the study period was dependent on the coral species, but changes in both coral species occurred in the same direction through time. The results show that the association observed between corals and the microalgae on the mucus layer may not constitute an opportunistic interaction with the surrounding plankton and/or microphytobenthos. However, it is necessary to carry out further studies to identify the possible factors that affect these assemblages, their relative importance and the way they may interact, as well as the incorporation of other assemblages that inhabit the mucus layer in the sampling design to characterize the mucus microbiota and test specific hypothesis about their role in the coral biology.

## 8-29

**Competition between Caribbean Corals and Macroalgae: Is there a Detrimental Impact on Symbiotic Coral-Bacterial Associations?**

**Kathleen MORROW*[1]**, Mark LILES[1], Nanette CHADWICK[1]

[1]Biological Sciences, Auburn University, Auburn, AL

Long-term studies on Caribbean reefs have revealed declines in live coral cover and increases in algal abundance, resulting in increased physical contact between corals and algae. Macroalgae may gain a competitive edge over scleractinian corals by manipulating coral-associated microorganisms. We used culture-dependent and -independent methods to determine the microbial communities associated with both competing and isolated corals (*Montastraea faveolata*) and macroalgae (*Halimeda* green and *Dictyota* brown algae). Syringe samples were taken from >1 m apart and included: 1) *M. faveolata* not in contact with macroalgae (coral control), 2) *M. faveolata* interacting with macroalgae, at 5cm from the interaction zone, 3) *M. faveolata* surfaces that directly contacted each macroalga, 4) macroalgal thalli interacting with *M. faveolata* and finally, 5) epiphytic *Halimeda* and *Dictyota* not in contact with corals (algal control). Initial plate counts suggest that microbial abundance increases in a step-wise fashion from isolated corals (~500 CFU $ml^{-1}$), to coral-macroalgal interaction zones (~1,500 CFU $ml^{-1}$), to within macroalgal thalli (~3,500 CFU $ml^{-1}$). Microbial community samples were extracted using a bead-beating method to recover DNA, and the 16S-23S rRNA intergenic spacer region was PCR-amplified using universal Eubacteria primers and resolved on a polyacrylamide gel (ARISA method). Bacterial community profiles revealed significant variation in composition between sample types, with considerable intra-sample consistency (n=3). In particular, a dominant bacterial taxon found on the coral controls was observed to decrease dramatically in corals that interacted with macroalgae. We conclude that microbial communities associated with these corals and macroalgae are dynamic and appear strongly impacted by competitive interactions. Coral-algal interactions may directly mediate the stability and function of microbial symbionts on coral surfaces, and have major implications for observed patterns of competitive dominance and disease susceptibility on coral reefs.

## 8-31

**Coral Associated Protists: Additional Partners in The Holobiont**

**Esti KRAMARSKY-WINTER*[1]**, Moshe HAREL[2], Nachshon SIBONI[3], Etan BEN DOV[3], Diana RASOULOUNIRIANA[3], Ariel KUSHMARO[3], Loya YOSSI[1]

[1]Dept. of Zoology, Tel Aviv University, Tel Aviv, Israel, [2]Dept. Plant and Environmental Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel, [3]The Department of Biotechnology Engineering and The National Institute for Biotechnology, Ben Gurion University, Beer Sheva, Israel

Recent investigations on coral associated communities have revealed that microbial communities covering coral surfaces play important roles in colony well-being. A large number of "aggregate" like organisms were recently observed covering the surface of large-polyp corals such as Fungiids and Faviids from a number of geographic locations. These organisms are dispersed in a patchy distribution on the polyp surface, with the highest density occurring in the area of the polyp mouth. They can not be removed from the coral surface by antibiotics, or by bleaching the corals in the dark. To identify these organisms, mucus visibly containing aggregates, was gently scraped or milked from the surface of the solitary Red Sea coral *Fungia granulosa* and examined microscopically, and molecularly (using 18S rRNA gene and 16S mitochondrial rRNA gene sequences). Microscopic investigation revealed that the organisms are embedded in the mucus and in the tissue layers of this coral. They are approximately 5-30 µm in diameter, made up of unique coccoid bodies and contain a nucleus, mitochondria and golgi. Both morphological and molecular data lead us to identify these organisms as stramenopile protists. To further characterize these organisms, samples of aggregate containing mucus were diluted and plated and grown on a variety of media. Some of the resulting colonies of microorganism were similar in gross morphology to those from the coral surface. Pure cultures were grown to follow life cycle attributes, and were identified morphologically and molecularly as belonging to the family Thraustochytridae, a group of protists known for their ability to produce poly-unsaturated fatty acids (PUFA). The presence of this group of microorganisms on the surface of many large polyp coral species from different geographic locations may indicate their importance in coral holobiont health.

## 8-32

**Global Diversity And Distribution Of Coral Associated Archaea And The Possible Role in Coral Nitrogen Cycle**

**Nachshon SIBONI*[1]**, Eitan BEN-DOV[1], Alex SIVAN[1], Ove HOEGH-GULDBERG[2], Ariel KUSHMARO[1]

[1]Biotechnology Engineering, Ben-Gurion University, Be'er-Sheva, Israel, [2]Centre for Marine Studies, University of Queensland, Brisbane, Australia

Corals harbor diverse and abundant prokaryotic communities (bacteria, archaea and protozoa) that may have co-evolved with them. To date, only little attention has been given to studies on the diversity and roles of archea in the coral holobiont. This research focuses on the diversity and distribution of 424 coral-associated Archaeal sequences associated with the surface mucus of three coral genera: *Acantastrea*, *Favia* and *Fungia* sp. from Red Sea, Israel and from Heron Island, Australia. Sequencing of 16S rRNA gene revealed dominance of Crenarchaeota (80% in average) in most of the coral associated sequences. In the Crenarchaeota, 87% were similar (≥97%) to Thermoprotei, of this class 76% were similar (≥97%) to candidatus *Nitrosopumilus maritimus* (DQ085097), an ammonium oxidizer. Most of the Euryarchaeota sequences (73%) were related to marine group II and other clades were related to anaerobic methanotrophic archaea (8%), anaerobic nitrate reducer archaea (16%) and marine group III (3%). Many of the Crenarchaeota and Euryarchaeota corals-associated archaeal sequences from Heron Island GBR Australia (61%) and Gulf of Eilat, Red Sea (71%) were closely (≥97%) related to sequences derived from Virgin Islands corals, Caribbean. This suggests that coral-associated Archaea play an important role in holobiont physiology presumably by acting as a nutritional sink of excess ammonium trapped in the mucus layer, by nitrification and denitrification process.

## 8-33

**Occurrence Of Epidermal Bacteria in The Scleractinian Coral *montastraea Cavernosa***

**D. Abigail RENEGAR*[1]**, Genelle F. HARRISON[2], Patricia L. BLACKWELDER[1,3], Joel E. THURMOND[2], Kimberly B. RITCHIE[2], Bernardo VARGAS-ANGEL[4]

[1]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Dania, FL, [2]Center for Coral Reef Research, Mote Marine Laboratory, Sarasota, FL, [3]RSMAS, University of Miami, Miami, [4]Coral Reef Ecosystem Division, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI

*Montastraea cavernosa* is an important scleractinian reef-building coral, found throughout South Florida and the Caribbean. Examination of numerous field-collected and experimental specimens of this coral with transmission electron microscopy (TEM) revealed the presence of bacteria exclusively in the epidermal tissue. To identify these bacteria, DNA was isolated from coenosarc tissue followed by DGGE analysis of the 16S-V3 rDNA genes. Cloning and 16S rRNA sequence analysis identified the predominant bacteria as members of the *Lactobacillus/Lactococcus* bacterial groups. These Gram-positive bacteria are commonly associated with sewage. *Lactobacilli* are anaerobic bacteria, found in the human digestive tract and rotting plant matter that convert lactose and sugars into lactic acid. *Lactococcus* are motile bacteria common in dairy. The occurrence of bacteria within the epidermis of *M. cavernosa* raises the question of the role of bacteria within coral tissue. It is unknown if these bacteria are normal endosymbionts or represent a pathologic condition; in some corals the bacterial population appeared to completely overtake the tissue. Additionally, individual amoebocytes were observed both in the epidermis and in mesoglea adjacent to the epidermis. The amoebocyte cells in the epidermis were often actively engaged in bacterial phagocytosis. The possibility that innocuous bacteria may become pathogenic under stress highlights the importance of understanding and quantifying how environmental stress may affect the nature of the coral/zooxanthellae/bacterial association. This study represents ongoing research directed at the development of monitoring and predictive indices based on TEM and fluorescence in-situ hybridization (FISH) assessment of amoebocyte/bacteria ratios. FISH analyses are also being employed to aid in the identification and localization of these bacteria in other species.

## 8-34

**Bacterial Communities On Healthy And Diseased Corals: Associations With Rapid Tissue Loss (White Plague)**

**Geoffrey M. COOK*[1]**, Masoumeh SIKAROODI[1], Patrick M. GILLEVET[1], Paige ROTHENBERGER[1], Esther C. PETERS[1,2], Robert B. JONAS[1]

[1]Environmental Science and Policy, George Mason University, Fairfax, VA, [2]Tetra Tech, Inc., Fairfax

Although diseases of hermatypic corals, some of proven or suspected bacterial origin, pose a serious global threat to coral reefs, the composition of bacterial communities on healthy corals and those exhibiting signs of disease remains poorly understood. This investigation compared bacterial communities associated with multiple pairs of apparently healthy and diseased *Montastraea annularis* (species complex) colonies from offshore reefs in The Bahamas, U.S. Virgin Islands, Cayman Islands, Bermuda, the Florida Keys National Marine Sanctuary, and the Flower Garden Banks National Marine Sanctuary. Bacterial communities from apparently healthy colonies and nearby colonies exhibiting signs consistent with white plague type II (WPL II) were evaluated using both molecular and culture-dependent methods. Length heterogeneity PCR (LH-PCR) molecular fingerprints were used to interrogate the diversity and relative abundance of both whole and culturable communities. Bacterial communities associated with diseased corals, regardless of geographical location, were more similar to each other than to communities from apparently healthy tissue on either diseased or healthy colonies. A comparison of the whole-bacterial community molecular fingerprint, regardless of tissue type, with the culturable community revealed far greater similarities than expected. Comparison of amplicon lengths and relative abundances suggest that many of the bacterial taxa in coral communities are culturable and that these represent the most abundant bacteria. Dominant microbial taxa include the genera *Vibrio* and *Pseudoalteromonas*. Strains of *Pseudoalteromonas* are known to produce toxins that lyse dinoflagellates and diatoms. These data imply an association between complex bacterial communities and rapid tissue loss diseases.

## 8-35

**Tissue Loss And Tropical Storms: An Investigation Of Bacterial Community Dynamics in *montastraea Annularis* Corals in St. Croix, Usvi**

**Paige ROTHENBERGER*[1,2]**, Masoumeh SIKAROODI[3], Geoffrey COOK[3], Patrick GILLEVET[3], Esther PETERS[3,4], Robert JONAS[3]

[1]Division of Coastal Zone Management, U.S. Virgin Islands Department of Planning and Natural Resources, Frederiksted, Virgin Islands (U.S.), [2]Department of Environmental Science and Policy, George Mason University, Fairfax, [3]Department of Environmental Science and Policy, George Mason University, Fairfax, VA, [4]Tetra Tech, Inc., Fairfax

Tissue loss, consistent with white plague type II (WPII), affects at least 18 species of reef building corals throughout the Caribbean and Western Atlantic. This disease destroys apparently healthy tissue rapidly thus having the potential to dramatically alter coral composition on large reef tracts. This investigation examined bacterial communities on diseased and apparently healthy *Montastraea annularis* (complex) colonies at Sprat Hole in St. Croix, U.S. Virgin Islands. Triplicate core samples from multiple pairs of healthy and diseased colonies were collected in August 2002 and September 2004, immediately following the passage of Tropical Storm Jeanne to the southwest of St. Croix. Tissue loss on colonies exhibiting signs of WPII was at epizootic levels at this site during the summer of 2004. However after the storm only one diseased colony, of five sampled, appeared to be actively losing tissue. Three of the sampled colonies were accumulating sediment at the apparent recent disease margin suggesting no active tissue loss, and one colony had a bleaching margin. Samples were analyzed using microbial culturing, molecular fingerprinting and partial 16S rRNA gene sequencing. Amplicon Length Heterogeneity PCR (LH-PCR) fingerprints indicated that bacterial communities differed significantly between healthy tissue and recently diseased margin samples. There was no evidence that a specific bacterial taxon dominated any of the tissue types sampled. Neither cultures nor the amplicon characteristic of *Aurantimonas coralicida* were found in any samples, although it might have been present at levels below the method's limit of resolution (e.g. 1%). Results of this study highlight the role of local environmental conditions in the WPII disease process and provide an important description of bacterial community composition and dynamics in this reef system.

## 8-36

**Heat-Induced Toxin Production in Vibrio Species Associated With Yellow Band Disease**

James CERVINO[1,2], **Elizabeth LORENCE*[3]**, Fabiano THOMPSON[4], Konrad HUGHEN[5], Jessie KNEELAND[5], Garriet SMITH[6]

[1]Geochemistry, Woods Hole Oceanographic Inst., MA, MA, [2]Biological Sciences, Pace University, NY, [3]Biological Sciences, Pace University, NY, NY, [4]Department of Genetics, Federal University of Rio de Janeiro, Ilha do Fundão, Brazil, [5]Geochemistry, Woods Hole Oceanographic Inst., Woods Hole, MA, [6]Biological Sciences, University of South Carolina, Aiken, SC

The expression of virulence factors induced from heat stressed yellow band *Vibrio* pathogens were investigated by infecting *Symbiodinium* zooxanthellae CLADES A, B1, C1, and D1 subtypes *in vivo*. Heat treatments were performed on both the bacteria and the algae at 33C for three hours. A supernatant was subsequently extracted after centrifugation at 12,000 RPM for 10 minutes. The isolated toxin was then purified using a 2.2 mm millipore filter and re-introduced to non-heat-treated zooxanthellae CLADE subtype cultures at 26C. Exposure times of 8, 24, 48, 72, 96 and 120hrs to the purified supernatant isolated from the *Vibrio* bacteria, indicate that the most severe algal cell necrosis was evident in CLADE subtype C1. However, all heat treated *Symbiodinium* in the presence of *Vibrio* bacteria show severe necrotic cell-death pathways compared to non-heat treated *Symbiodinium.* Supernatant toxin was also inoculated onto *Aptasia pallida* during high temperature exposure of 33C and low temperature exposure of 26C to determine the different cell-death mechanisms during toxin exposure. *Aptasia pallida* death was detected after exposure to purified toxins at ambient temperatures following 96 hr. However, when *Symbiodinium* subtypes were exposed to thermal stress coupled with *Vibrio* toxin, morphological and cellular dysfunction occured at 48hr. Cytological analysis and TEM analysis indicate that the initiation of YBD infection in symbiotic algae may not be exclusively caused by the weakened state of heat-stressed zooxanthellae. To the contrary, infection seems to be independent of environmental stress. Rising temperatures also are associated with lesion advancement that leads to a much faster cell-death in all *Symbiodinium* CLADE subtypes. In addition, we found that instead of *Symbiodinium* being wholly expelled from the gastroderm of *A. pallida*, internal cell-death occurs rather than expulsion from the gastrodermal tissues as seen in thermal coral bleaching.

## 9-1

**Herbivore Diversity And Feeding Complementarity Affect The Structure Of Caribbean Reefs**

**Mark HAY*[1]**, Deron BURKEPILE[2]

[1]School of Biology, Georgia Institute of Technology, Atlanta, GA, [2]Department of Ecology and Evolutionary Biology, Yale University, New Haven, CT

On coral reefs, herbivorous fishes have strong top-down effects on community structure, macroalgal abundance, and coral resilience. However, the longer-term direct and indirect effects of herbivore species richness on reef communities are inadequately understood. To evaluate the effects of herbivore species richness on community structure, we enclosed equivalent densities and masses of either single-species or mixed-species of herbivorous fishes in replicate, 4 m2 cages on a reef in the Florida Keys. The experiment ran for 8-10 months in two separate years. We found strong effects of herbivore richness on seaweed abundance, coral growth and survivorship, and community structure due to feeding complementarity between herbivores. In Year 1, ocean surgeonfish and redband parrotfish synergistically suppressed cover and biomass of upright macroalgae by 54-76% compared to single-species treatments due to complementary feeding on different seaweeds. One herbivore appeared deterred by chemical, the other by structural, seaweed defenses. The mixed-species treatment also increased cover of crustose coralline algae by 23-117%, increased coral cover by 22%, and decreased coral mortality from the 8-24% in single-species treatments to 0%. In Year 2, redband parrotfish and princess parrotfish fed on different algal functional groups with redbands suppressing upright macroalgae and princesses suppressing filamentous algae, again increasing cover of crustose coralline algae. When nonmetric multidimensional scaling was used to compare all treatments across both years, the morphologically and taxonomically dissimilar princess parrotfish and ocean surgeonfish had more similar effects on macroalgal community structure than did the two parrotfishes. Herbivores play functionally diverse roles on reefs, and these differential feeding abilities prevent macrophytes from escaping control and suppressing corals.

## 9-2

**Are Tropical Herbivores More Tolerant Of Chemically-Rich Seaweeds Than Are Temperate Herbivores? A Test Of Seaweed-Herbivore Coevolution.**

**Erik SOTKA*[1]**, Amanda MCCARTY[1]

[1]Grice Marine Laboratory, College of Charleston, Charleston, SC

Lipophilic secondary metabolites produced by seaweeds increase in strength and diversity as one moves toward the tropics. Coevolutionary theory predicts that tropical herbivores should more readily tolerate chemically-rich seaweeds and their metabolites, however, data supporting this prediction are largely correlative and rarely evaluated experimentally. We examined feeding tolerance for chemically-rich seaweeds among populations of a single species, the herbivorous amphipod, *Ampithoe longimana* collected along the eastern coast of North America from New England (41ºN) to southern Florida (26º N). In contrast with coevolutionary predictions, geographic patterns of feeding preference were not correlated with latitude. Rather, populations in North Carolina (34ºN) were far more tolerant of the diterpene-producing seaweed *Dictyota* than were New England or Florida populations. Field-surveys across multiple seasons indicate that *Dictyota* represents an important host to North Carolina populations, but that *Dictyota* is not used as a host by either New England or Florida populations. Thus, geographic patterns of feeding tolerance by *A. longimana* are best explained by the relative importance of *Dictyota* in the ecology of local populations. In spite of prevailing assumptions, our results indicate tropical herbivores will not necessarily be more tolerant than temperate herbivores for lipophilic chemical defenses produced by seaweeds.

## 9-3

**Organic Matter Release By Coral Reef Associated Benthic Algae -Implications For *in-Situ* Oxygen Dynamics**

**Andreas HAAS*[1]**, Malik NAUMANN[1], Florian MAYER[1], Christoph MAYR[2], Mohammed AL-ZIBDAH[3], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center LMU München, Munich, Germany, [2]Department of Earth and Environmental Science, GeoBio-Center LMU München, Munich, Germany, [3]Marine Science Station, Yarmouk University, Aqaba, Jordan

Recent research indicates that coral reef associated benthic algae may affect important processes in the reef ecosystem via organic matter release, but yet no information is available about the quantity, quality and fate of these exudates. For this reason first fundamental studies were conducted at fringing reefs in the Northern Red Sea during two expeditions in fall 2006 and summer 2007. For the most abundant reef associated benthic algae (representing nearly 100% of total benthic algae coverage), green algae of the genus *Caulerpa*, red algae of the genus *Peyssonnelia* and several typical turf algae consortia, the release of dissolved and particulate organic carbon (DOC and POC) was quantified. All investigated benthic algae exuded high rates of DOC, but also POC in amounts of up to 5430 and 360 mg organic C $m^{-2}$ algae surface area $d^{-1}$, respectively. Release of DOC was highly variable between seasons, with one order of magnitude higher release rates in fall compared to summer. High DOC:POC ratios of up to 22 indicated that most of the exuded algae-derived organic matter immediately dissolved in reef waters, thereby stimulating planktonic microbial oxygen consumption as verified experimentally. In-situ experiments in high spatial resolution using dissolved oxygen loggers confirmed lower daily mean oxygen concentrations in the water close to algae dominated reef areas compared to those dominated by hermatypic corals. Thus, this study supports the hypothesis of microbial involvement in coral-algae interactions, indicates relevance for in-situ processes and also provides a fundamental data set for further required ecosystem studies.

## 9-4

**Nutrient Distribution Across the Insular Shelf of Puerto Rico: Assessment by Algal Tissue Nitrogen**

**Brandi TODD*[1]**, David L. BALLANTINE[1], Ernesto OTERO[1]

[1]Ciencias Marinas, University of Puerto Rico, Mayaguez, Puerto Rico

A survey was conducted to investigate possible presence of an inshore to shelf edge gradient in %N and δ15N tissue content of *Acanthophora spicifera, Lobophora variegata, and Dictyota sp.* in coastal waters of La Parguera, southwest Puerto Rico. Percent N (1.26% ± 0.08 to 3.25% ± 0.10) and δ15N (2.06ppt ± 0.04 to 8.16ppt ±0.14) of *Acanthophora spicifera* was highly variable along the shoreline. The highest inshore values of δ15N occurred at two stations influenced by secondary sewage input and a bird rookery and lower values (0.81ppt ± 0.06) were observed at mid-shelf locations. *Dictyota sp.* and *L. variegata* did not display trends in %N across the insular shelf, however δ15N for *Dictyota sp.* was significantly higher inshore (3.48ppt ± 0.087) versus mid-shelf and shelf edge (0.00ppt ± 0.08) and δ15N for *L. variegata* was significantly higher at mid-shelf (2.13ppt ± 0.25) versus shelf edge locations (0.34ppt ± 0.24). These results indicate that anthropogenic impacts on tissue nutrients are greatest along the shoreline, moderate at mid-shelf, and not evident at the shelf edge.

## 9-5

**Evaluation Of Biotic And Abiotic Factors That Facilitate And Maintain Cyanobacteria Blooms And Phase Shifts in Coral Communities**

**Kathleen SEMON*[1]**, Valerie PAUL[1], Mark CLEMENTZ[2], John Michael TRAPP[3], Karen ARTHUR[1]

[1]Smithsonian Marine Station at Fort Pierce, Smithsonian Institution, Fort Pierce, FL, [2]University of Wyoming, Laramie, WY, [3]Rosenstiel School, University of Miami, Miami, FL

The functional stability of coral communities is currently threatened by recurrent cyanobacteria blooms. Cyanobacteria, such as *Lyngbya* species, are known to displace macroalgae in turf communities, inhibit coral recruitment through allelopathy, smother invertebrates, and alter nutrient and light regimes. Because cyanobacteria blooms impact many physical and biological characteristics of coral communities, damaged coral communities face altered community structure and reduced biodiversity. This study examined both the biotic and abiotic factors that facilitate and maintain cyanobacteria across Florida and Caribbean coral communities. *Lyngbya* spp. tissue and water samples were collected from areas known to be oligotrophic (the Belize Barrier Reef), and from areas adjacent to high human density and under significant anthropogenic influence (throughout south Florida). Stable C and N isotopic signatures reflect different sources contributing to cyanobacteria presence in Belize and Florida, and differences in ambient dissolved and total iron levels were reflected in patterns of cyanobacteria abundance. Correlations of ambient nutrient and temperature regimes and cyanobacteria presence and abundance were also examined from benthic surveys conducted in Belize. Multivariate analyses conducted in PRIMER v.5 revealed that *Lyngbya* spp. presence alone significantly influenced percent cover of stony coral and macroalgae recorded from benthic transects conducted in Belize. Crucial thresholds for coral community phase shifts are suggested based on data collected *in situ* and on preliminary data compiled by experimentally manipulating nutrient regimes in mesocosms known to influence cyanobacteria primary production and biomass accumulation.

## 9-6

**The Role Of Nutrients In *Lyngbya* Growth And Chemical Defense**

**Karen ARTHUR*[1]**, Valerie PAUL[1], Cliff ROSS[2], Hans PAERL[3], Jennifer JOYNER[3], Judith O'NEIL[4]

[1]Smithsonian Marine Station at Fort Pierce, Smithsonian Institute, Fort Pierce, FL, [2]Department of Biology, University of North Florida, Jacksonville, FL, [3]Institute of Marine Sciences, The University of North Carolina at Chapel Hill, Morehead City, NC, [4]Center for Environmental Science, University of Maryland, Cambridge, MD

Benthic cyanobacteria of the genus *Lyngbya* form harmful algal blooms (HABs) that occur on reefs and associated communities. They may be detrimental to other benthic organisms as they can smother corals and seagrass and because they are extremely prolific producers of biologically active secondary metabolites, many of which deter grazing by generalist herbivores. Nuisance blooms of *Lyngbya* may be triggered by terrigenous nutrient inputs and may grow unchecked as grazers avoid consuming the filaments containing secondary metabolites. In this study we examine the ecology of *Lyngbya* blooms in Broward Country, Florida and assess the effects of nutrient additions and light on *Lyngbya* growth and toxin production. We use a bioassay approach to assess the role of nitrogen, phosphorus, iron and low light conditions on the growth and secondary metabolite production of three species of *Lyngbya*. A significant increase in *Lyngbya polychroa* growth resulted from the addition of chelated iron; however, this was not the case for all *Lyngbya* species. *Lyngbya* spp. are also sensitive to light availability, with each species apparently having niche environments with specific light requirements. This study demonstrates the need to manage nutrient inputs into coral reef habitats to ensure that future reefs are not dominated by *Lyngbya* and other benthic cyanobacteria.

## 9-7

**Ecological Consequences Of Cyanobacterial Blooms On Coral Reefs**

**Valerie PAUL*[1]**, Cliff ROSS[2], Raphael RITSON-WILLIAMS[1], Linda WALTERS[3], Karen ARTHUR[1], Sarath GUNASEKERA[1], Theresa MEICKLE[1]

[1]Smithsonian Marine Station, Smithsonian Institution, Fort Pierce, FL, [2]Department of Biology, University of North Florida, Jacksonville, FL, [3]Department of Biology, University of Central Florida, Orlando, FL

A major concern on coral reefs worldwide is massive overgrowth by macroalgae and benthic cyanobacteria (blue-green algae). Benthic cyanobacteria are becoming increasingly abundant on reefs and produce nitrogenous secondary metabolites that can deter feeding by generalist herbivores. Nuisance blooms of *Lyngbya* and *Symploca* occur regularly throughout Florida and on the Belizean barrier reef. Crude extracts from some of these cyanobacteria deter feeding by a natural assemblage of fishes and the sea urchin, *Diadema antillarum*. In addition cyanobacterial secondary metabolites may be important for competition, and the function of allelopathy (chemical inhibition) in mediating the interactions between chemically rich species of cyanobacteria and different life history stages of the coral *Porites astreoides* was tested. Extracts and isolated compounds (microcolins A and B, curacin D) from *Lyngbya* spp. negatively influenced the settlement and metamorphosis of *P. astreoides* larvae. On reefs experiencing increased abundance of chemically defended benthic cyanobacteria, the restocking of adult coral populations may be slowed due to recruitment inhibition caused by cyanobacterial natural products. More research is needed on how to control these harmful algal blooms as they become more common on coral reefs around the world.

## 9-8

**The Good, the Bad, and the Smelly: Positive and Negative Settlement Cues for Coral Larvae**

**Raphael RITSON-WILLIAMS*[1]**, Valerie J. PAUL[1], Suzanne ARNOLD[2], Robert S. STENECK[2], Ilsa B. KUFFNER[3], Linda J. WALTERS[4], Mikel A. BECERRO[1,5]

[1]Smithsonian Marine Station at Fort Pierce, Fort Pierce, FL, [2]Darling Marine Center, University of Maine, Walpole, ME, [3]Florida Integrated Science Center, U.S. Geological Survey, St. Petersburg, FL, [4]Department of Biology, University of Central Florida, Orlando, FL, [5]Center for Advanced Studies, Blanes, Spain

How algal species proliferate in reef habitats and how they maintain "phase shifts" are critical questions to managing coral reef habitats. Some common reef algae (but not all) use chemical defenses to inhibit grazing by Caribbean reef fishes and the sea urchin *Diadema antillarum.* Algal natural products also mediate competitive interactions between algae and scleractinian corals. Some species of *Lyngbya* and *Dictyota,* as well as crude chemical extracts of some of these species, caused either recruitment inhibition or avoidance behavior in coral larvae. Conversely, coralline algae may be important indicators of suitable settlement substrata for coral larvae. The larvae of three spawning coral species, *Acropora palmata*, *A. cervicornis* and *Montastraea faveolata* were tested in the laboratory for their rates of settlement in response to different species of coralline algae. Some species of coralline algae were settlement facilitators, such as *Hydrolithon boergesenii*, *Neogoniolithon affine* and *Titanoderma prototypum*, but every coral species had the highest rates of settlement in response to a different species of coralline algae. Increased herbivory by more generalist consumers may shift the benthic community composition away from coral recruitment-inhibitors towards facilitators such as some species of coralline algae, thus improving the benthos for higher rates of coral recruitment.

## 9-9

**Natural Inducers For Larval Metamorphosis in Three Scleractinian Corals**

**Peter SCHUPP*[1]**, Makoto KITAMURA[2], Daisuke UEMURA[2]

[1]Marine Laboratory, University of Guam, Mangilao, Guam, [2]Department of Chemistry, University of Nagoya, Nagoya, Japan

Many benthic marine invertebrates, including corals, disperse among the plankton before settlement and metamorphosis. Finding a suitable habitat is especially important for larvae of sessile marine invertebrates that upon settlement cannot respond to changes in environmental conditions by moving to a more favorable environment. The ability of larvae to detect habitat-specific cues has been recognized in a range of phyla, but until recently, only a few studies identified the chemical structure of compounds involved in larval settlement and metamorphosis. This study was aimed at identifying compounds involved in the metamorphosis and settlement of three scleractinian corals. Experiments with whole crustose coralline algae (CCA) clearly demonstrated their ability to induce settlement in the scleractinian corals *Pseudosiderastrea tayamai, Acropora surculosa,* and *Leptastrea purpurea*. The previously reported bromotyrosine derivative, 11-deoxyfistularin-3, induced metamorphosis of *P. tayamai* larvae (approx. 28%) and the presence of the carotenoids fucoxanthinol and fucoxanthin increased metamorphosis to approximately 88%. However, experiments with these compounds did neither induce metamorphosis or settlement in *A. surculosa* and *L. purpurea* larvae from Guam. When we tested various chemical extracts of different CCA species from Guam, we only observed high rates of settlement with extracts from CCA of the genus *Hydrolithion* sp. Bioguided fractionation and subsequent structure elucidation of the *Hydrolithion* crude extract indicated a macrolactone as the active compound triggering metamorphosis in *L. purpurea* larvae. Further experiments testing the involvement of CCA biofilms, as well as biofilms from inert surfaces (e.g. tiles, bleached CCA), revealed that biofilms on *Hydrolithion* and biofilms on certain inert surfaces more than a week old repeatedly induced settlement in *L. purpurea* larvae. Experiments to determine the origin of the macrolactone (e.g. *Hydrolithion* itself or the associated biofilms) are ongoing.

## 9-10

**Effects Of Copper Toxicity On Three Species Of Scleractinian Corals**

**Gretchen BIELMYER*[1]**, Philip GILLETTE[2], Martin GROSELL[2], Ranjeet BHAGOOLI[2], Andrew BAKER[2], Chris LANGDON[2], Tom CAPO[2]

[1]Biology, University of North Florida, Jax., FL, [2]University of Miami, Miami, FL

Most corals thrive in a narrow range of water quality and temperature regimes and as such can be considered sentinels of our oceans' health. Globally, coral reefs have been declining at an accelerating rate. Caribbean reefs, in particular, have suffered an estimated 80% loss of reef cover in the last 30 years. Land-based sources of pollution and global warming have been identified as major stressors linked to these declines. Contaminants, such as metals, although noted as a concern have not been closely monitored in these sensitive ecosystems, nor have the potential impacts been characterized. There is a need to develop biomonitoring tools to assess potential effects of metal exposure. In this study, three species of laboratory-reared scleractinian corals, *Acropora cervicornis, Pocillopora damicornis,* and *Montastraea faveolata* were exposed to copper (ranging from 0-25 µg/L) for four weeks. At the end of the exposure period mortality, growth, copper accumulation, carbonic anhydrase activity, zooxanthellae density and electron transport rate were measured. The three coral species exhibited significantly different sensitivities to copper, with effects occurring at copper concentrations as low as 10 µg/L. The relationships between physiological/toxicological endpoints and copper accumulation within and between species will be presented as a means to elucidate the potential mechanism for effects and explain observed differences in sensitivity.

## 9-11

**Chemical Ecology is the Key to Understanding Sponges on Caribbean Coral Reefs**

**Joseph PAWLIK*[1]**

[1]Biology and Marine Biology, UNC Wilmington, Wilmington, NC

Sponges are now the dominant organisms on Caribbean coral reefs. Until recently, it was believed that consumers had little effect on reef sponges, because sponge-eating fishes were thought to spread their predatory activities over all available species to the detriment of none in particular. But research on the chemical ecology of this system has transformed our understanding of it. Laboratory and field experiments have revealed three distinct categories of sponges within the community: (1) defended species that are unpalatable to consumers because they contain secondary metabolites, (2) palatable species that sustain grazing by consumers yet are equally common as defended species on the reef, and (3) preferred species that are rapidly consumed when transplanted to the reef, and are found only in refuge habitats. The secondary metabolites responsible for the chemical defenses of several species have been isolated and identified using bioassay-guided fractionation and field experiments with natural populations of reef consumers. To counter the effects of grazing by fishes, palatable species appear to heal, grow or reproduce faster than defended species. Some sponge species compete with corals for space by producing metabolites that cause coral bleaching or that interfere with photosynthesis of coral symbionts. The predictive value of the foregoing is becoming evident: over-fishing may result in a release from predation of sponge species that are competitively superior to corals, reinforcing the current state of low coral cover on Caribbean reefs.

## 9-12

**Toxic Reef Syndrome: The Sponge-Seaweed Connection And The Consequences Of Allelopathic Impacts Of Sponges And Seaweeds On Degraded Caribbean Coral Reefs**

**Niels LINDQUIST*[1]**, Chris S. MARTENS[2], James L. HENCH[3], Jeremy B. WEISZ[4], Melissa W. SOUTHWELL[5], Brian POPP[6], Nyssa SILBIGER[1], Patrick GIBSON[2]

[1]Institute of Marine Sciences, University of North Carolina Chapel Hill, Morehead City, NC, [2]Department of Marine Sciences, University of North Carolina Chapel Hill, Chapel Hill, NC, [3]Environmental Fluids Mechanics Laboratory, Stanford University, Stanford, CA, [4]Department of Biological Sciences, Old Dominion University, Norfolk, VA, [5]Department of Chemistry and Biochemistry, University of North Carolina Wilmington, Wilmington, NC, [6]Department of Geology and Geochemistry, University of Hawaii, Honolulu, HI

Increasing global, regional and local stresses on coral reefs have resulted in a phase shift on Caribbean reefs from coral to sponge-seaweed dominance, yet little is know about the roles of sponges within the new ecology of degraded reefs. The goal of our sponge research, involving physical oceanographers, marine chemists and coral reef ecologists, is to rigorously determine how sponges alter the composition and abundance of small particles and dissolved chemicals in the seawater they process and how these changes impact reef ecology. On today's reefs, sponges can be exceptionally abundant, and with their high rates of filtration, contribute substantially to nutrient element cycling. We are finding that sponges re-mineralize much of the nitrogen in the particulate and dissolved organic matter they consume to ammonium and nitrate. Simultaneously, their high respiration rates substantially reduce levels of dissolved oxygen in the seawater they filter. The tremendous volumes of seawater many sponges exhale are hypoxic, rich in dissolved inorganic nitrogen, and likely sponge-produced toxins, all of which can harm corals. Sponge inputs of fertilizer to reefs have likely played a role in the proliferation of seaweeds on degraded Caribbean coral reefs, which along with the abrupt die-off of the once ubiquitous urchin *Diadema antillarum* have yielded an abundant algal community dominated by seaweeds and cyanobacteria chemically resistant to fish grazing. Chemicals exuded by these seaweeds and cyanobacteria further reduce benthic boundary layer water quality. While sponges can increase reef stability and provide food and shelter for other organisms, on degraded reefs with little coral cover, sponges likely interact with seaweeds to create an alternative stable state to coral dominated reefs and a chemically hostile environment that diminishes coral health and recruitment.

## 9-13

**Is Allelopathy Involved in Coral Death By Encrusting Excavating Sponges?**

**Andia CHAVES-FONNEGRA*[1]**, Leonardo CASTELLANOS[2], Sven ZEA[1], Carmenza DUQUE[2], Carlos JIMÉNEZ[3], Jaime RODRIGUEZ[3]

[1]Departamento de Biología and Centro de Estudios en Ciencias del Mar -CECIMAR-, Universidad Nacional de Colombia, INVEMAR, Cerro Punta de Betín, Santa Marta, Colombia, Santa Marta, Colombia, [2]Departamento de Química, Universidad Nacional de Colombia, Bogotá, Colombia, Bogotá, Colombia, [3]Departamento de Química Fundamental, Facultad de Ciencias, Universidade da Coruña, A Coruña, España, Coruña, Spain

The Caribbean encrusting and excavating sponges *Cliona delitrix* and *C. tenuis* successfully compete for space with reef corals, killing and displacing live coral tissue at rates of several cm per year. A bioassay guided fractionation of their extracts was carried out to find the compound(s) responsible, and a series of experiments to evaluate whether there is allelopathy involved and its possible mechanism. Ground and polished histological sections of the zone of sponge-coral contact revealed that coral polyp detachment does not seem to occur through erosion of their skeletal support. Healed sponge fragments placed directly over live coral for 1-2 days were killed by coral defenses for *C. tenuis* but not for *C. delitrix*; fragments of both sponges placed in close proximity to corals for 6 months did not have any effect on the adjacent coral tissue. The crude extract and the aqueous partition of both sponge species, and the *C. tenuis* pure compound [(-)-(5S)-2-imino-1-methylpyrrolidine-5-carboxylic acid)] (1), incorporated in gels at close to natural volumetric concentrations, killed coral tissue when brought into contact with live coral for 1-4 days. While compound 1 dissolved in seawater was only mildly toxic against live coral and dissociated coral cells, and killed coral larvae only at high concentration, the aqueous fraction of *C. delitrix* was toxic against live coral tissue, larvae and dissociated coral cells. Bioassay guided fractionation of *C. delitrix* aqueous fraction is under way. Although prolonged contact of compound 1 (and responsible compound(s) in *C. delitrix*) in the enclosed spaces of the coral skeleton may elicit polyp uplift or produce coral tissue death, other alternative mechanisms such as acid or enzyme secretion or histo-incompatibility cannot be ruled out.

## 9-14

**The Association Between The Orange Icing Sponge And Caribbean Corals-More Than A Mutualism?**

**Tse-Lynn LOH*[1]**, Joseph PAWLIK[1]

[1]University of North Carolina Wilmington, Wilmington, NC

Competition is intense on coral reefs due to limited resources, especially space. Contrarily, a mutualism has been reported between the Caribbean reef sponge *Mycale laevis* and scleractinian corals, with a putative advantage for the coral of protection from boring sponges and for the sponge of new substratum provided by the growing coral. Our past research has demonstrated that reef sponges can be categorized on the basis of their chemical defenses into defended, palatable, and preferred species, the last of which are restricted to physical refuges on the reef due to predation. *Mycale laevis* is described as having a semi-cryptic growth form, which predominates on reefs off Key Largo, Florida and the Bahamas. However, off Bocas del Toro, Panama, *M. laevis* is observed to grow with an unusually massive morphology. Crude extracts of both morphs of *M. laevis* are palatable to generalist fish predators, and surveys reveal that sponge-eating fish are very rare at Bocas del Toro compared to sites in the Florida Keys. Caging experiments will be conducted in the Florida Keys to determine the effects of predation on exposed fragments of *M. laevis*. The semi-cryptic habit of *M. laevis* growing under coral colonies or between coral branches could be the result of predation, and not a specific response to a mutualistic relationship.

## 9-15

**Phenotypic Plasticity in Chemical Defense And Growth Across A Depth Gradient in Caribbean Sponges**

**Marc SLATTERY*[1]**, Michael LESSER[2], Sridevi ANKISETTY[1], Deborah GOCHFELD[1]

[1]University of Mississippi, Oxford, MS, [2]University of New Hampshire, Durham, NH

Phenotypic plasticity represents one mechanism by which a species can expand its range across an environmental gradient while maintaining a positive energetic budget. The transition between shallow coral reef communities and deep reef communities in the tropics is characterized by reduced light, and consequently photosynthesis, resulting in potential trade-offs in energetic allocation. While reef-building coral diversity decreases with light, many sponges increase in abundance on reefs from shallow to deep depths. We examined these deep reef sponge communities (to 100m) in the Bahamas and the Cayman Islands over a period of five years using technical mixed gas diving. Biodiversity data from the deep reefs show a rich sponge fauna with approximately 15% endemism and more similarity to one another than to their respective shallow reef sponge communities. Agelas conifera and Plakortis angulospiculatus are two common sponge species that span the depth gradient from shallow to deep reefs. For both species, sponge size and growth rate increased with depth. Growth differences across the depth gradient can be explained by increased food availability at depth, but reduced levels of spongivory on the deep reefs might also result in an energetic trade-off from chemical defenses to growth. Feeding deterrence was higher in shallow water, whereas antimicrobial activity appeared to be greater at depth. Results to date indicate that different selective pressures in these ecosystems result in disparate phenotypes within sponge species that are manifested in plasticity between investments in chemical defense and growth.

## 9-16

**Antioxidant Activity Of Extracts And Secondary Metabolites From Pseudopterogorgia Sps**

**Maia MUKHERJEE*[1]**, Lyndon WEST[2], Howard LASKER[3], Gregory SCHMIDT[4], William FITT[1]

[1]Odum School of Ecology, University of Georgia, Athens, GA, [2]Pharmaceutical and Biomedical Sciences, University of Georgia College of Pharmacy, Athens, GA, [3]Department of Geology, University at Buffalo, Buffalo, NY, [4]Plant Biology, University of Georgia, Athens, GA

Oxidative stress has been proposed as a mechanism of photoinhibition of photosynthesis in zooxanthellae that could lead to bleaching in symbiotic cnidarians. In a previous study, The addition of exogenous antioxidants to cultured zooxanthellae cells at elevated temperatures, with and without exposure to UV radiation, has resulted in the partial recovery of photosynthetic performance, suggesting that the fluxes of reduced oxygen intermediates were causing damage to the photosynthetic apparatus (Lesser, 1996). Caribbean octocorals, unlike other zooxanthellate cnidarians, seem to possess greater resistance to bleaching. Species of the genus Pseudopterogorgia harbor zooxanthellae of clade B. Previous research (Perez et al, 2000) has shown that in the sea anemone Condylactis gigantea, which also forms a symbiosis with clade B zooxanthellae, elevated temperature was followed by massive algal expulsion. This response is not observed in Pseudopterogorgia elisabethae subjected to similar experimental treatments. Branching octocorals have been the subject of intense investigation by natural product chemists, and have proven to be rich in novel compounds with interesting ecological and pharmacological properties. In this study, we examine the antioxidant potential of semi-purified extracts and purified secondary metabolites isolated from shallow-water Caribbean octocorals of the genus Pseudopterogorgia. We employ both the "Oxygen Radical Absorption Capacity (ORAC)" assay and a qualitative assessment of damage to PS 2 during exposure to elevated temperatures and UV radiation based on measurements of cellular fluorescence capacity with and without the addition of extracts and purified compounds. The ORAC assay depends on the free radical damage to a fluorescent probe through the change in its fluorescence intensity. The inhibition of free radical damage by an antioxidant, which is reflected in the protection against the change of probe fluorescence, is a measure of its antioxidant capacity against the free radical.

## 9-17

**New Hemiketal Steroid From The Introduced Soft Coral *chromonephthea Braziliensis* Ofwegan As Chemical Defense Against Generalist Fishes**

**Beatriz FLEURY*[1]**, Bruno LAGES[1], Jussara BARBOSA[2], Carlos KAISER[2], Angelo C. PINTO[2]

[1]Departamento de Ecologia, Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Departamento de Química Orgânica, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Biological invasions in marine environments are one of the lesser understood aspects of global change (Occhipinti-Ambrogi & Savini, 2003). Recent studies, however, demonstrated that chemical defensive strategies may facilitate the invasion of the exotic soft coral *Chromonephthea braziliensis* Ofwegan (Nephtheidae, Alcyonacea) in the Brazilian Atlantic coast (Lages et al., 2006). We report for the first time, the detailed composition of the monohydroxylated sterol fraction, and a new hemiketal steroid, 23-keto-cladiellin-A, isolated from the unpalatable hexane extract from *C. braziliensis*. Bioassay-guided fractionation of this extract, incorporated into artificial food, revealed that this hemiketal steroid exhibits *in situ* potent feeding deterrent properties against generalist fishes, at the natural concentration. The major sterol fraction, containing the monohydroxylated sterols, was inactive in the bioassay. This result supports the enemy release hypothesis, the most commonly accepted theory to explain the success of invasive species in their new ranges.

## 9-18

**Uv Protective Sunscreen in Coral Reef Fish Mucus**

**Maxi ECKES*[1]**, Sophie DOVE[2], Alexandra GRUTTER[3], Ulrike SIEBECK[4]

[1]SIB, University of Queensland (UQ), St. Lucia, Queensland, Australia, [2]CMS, UQ, St. Lucia, Queensland, Australia, [3]SIB, UQ, St. Lucia, Queensland, Australia, [4]SBMS, UQ, St. Lucia, Queensland, Australia

Coral reefs typically have clear oligotrophic waters with a high UV transmission, which can damage tissues in marine organisms. The Great Barrier Reef (GBR), Australia has experienced a significant increase in the number of cloud-free days over the last 10 years causing an increase in UV-induced DNA damage in reef organisms. Fish were recently discovered to have sunscreen compounds in their external mucus suspected to be mycosporine-like amino acids (MAAs). Using High Performance Liquid Chromatography (HPLC), we examined epithelial mucus from the labrid *Thalassoma lunare* and 13 species of Scaridae. For the first time in fish mucus, MAAs were identified and quantified. In addition, to examine geographical variations, the MAAs from *T. lunare* were compared from three different latitudinal locations (Lizard Island, Heron Island, and North Stradbroke Island, Queensland) and from 13 species of parrotfish along a longitudinal gradient from inshore reefs (Lizard Island) to the outer edge reefs (GBR) to oceanic reefs (Osprey Reef). Depending on the species, different combinations and quantities of the MAAs asterina-330, palythene and mycosporine-N-methylamine serine were present. MAA levels from *T. lunare* decreased with distance from the equator. *Thalassoma lunare* from North Stradbroke Island had lower MAA levels (mycosporine-N-methylamine serine) or absent (palythene) compared with mucus from the more northern locations (Lizard Island and Heron Island). Furthermore, results from our longitudinal comparison showed that the MAA absorbance increased with distance from the mainland landmass to the more oligotrophic outer reefs, where UV penetration is higher. This study shows that the identity and quantity of MAAs in fish mucus not only varies among species but also within a species sampled in different locations. These suggest that the ecological role of MAAs in fishes is varied and complex and that several factors may affect the type and quantity of MAAs found in the mucus of reef fish.

## 9-19

**The Role Of Chemical Signals in The Feeding Behavior Of Crown-Of-Thorns Seastar, *acanthaster Planci***

**Ciemon Frank CABALLES*[1]**, Peter SCHUPP[1]

[1]Marine Laboratory, University of Guam, Mangilao, Guam

The crown-of-thorns seastar, *Acanthaster planci*, is a corallivore known for its capacity to cause large-scale coral mortality at high population densities and continues to be a reef management problem despite previous control efforts. There has been no active control of *A. planci* populations on Guam since the 1970's and manta tow surveys confirmed that *A. planci* continues to damage large areas of reef around Guam. Large aggregations, ranging from 23 to 336 individuals/ha of reef, were observed to feed mainly on Acroporids, especially encrusting *Montipora*. Preferential feeding by *A. planci* causes differential mortality among coral species, which can exert a major influence on community structure. However, the role of chemical signals in *A. planci* prey selectivity is still poorly understood. In this study, we tested the effectiveness of organic extracts from preferred coral species and α-linolenic acid, a previously identified feeding attractant. Feeding assays with *A. planci* were conducted in a Y-maze, using crude extracts incorporated into agar-based feeding plates at natural concentrations. *A. planci* individuals were attracted to crude extracts of *Montipora* sp. ($n=25$; $p<0.05$), *Acropora surculosa* ($n=25$, $p<0.01$), and 1% α-linolenic acid ($n=15$; $p<0.01$). We conclude that with further isolation and characterization, these feeding attractants could be incorporated into the design of traps or bait stations as a new tool for the management of potential *A. planci* population outbreaks.

## 9-20

**A New Role For Dimethylsulfoniopropionate (DMSP) As A Foraging Cue For Coral Reef Fishes**

**Jennifer DEBOSE*[1]**, Sean LEMA[2], Gabrielle NEVITT[1,3]

[1]Neurobiology, Physiology & Behavior, University of California - Davis, Davis, CA, [2]Biology and Marine Biology, University of North Carolina - Wilmington, Wilmington, NC, [3]Bodega Marine Laboratory, University of California - Davis, Bodega Bay

Planktivorous fishes must locate prey patches that can be widely-spaced and highly transient. The sensory cues that fish use to locate prey, however, are not well understood. While it has been speculated that some reef fishes use biogenic chemicals as aggregation or settlement cues, specific chemicals have yet to be identified. Dimethylsulfoniopropionate (DMSP) is a secondary metabolite produced by many species of marine algae. DMSP is released by algal cell lysis and zooplankton grazing, and its distribution in the ocean is commonly associated with areas of high primary productivity and foraging activity. While DMSP has been studied intensively for its role in oceanic sulfur cycles and global climate regulation, here we present the first experimental evidence that planktivorous reef fishes aggregate to controlled deployments of DMSP over coral reef habitat in the wild. We released DMSP (10-7 M) over the fringing coral reefs of Curaçao, Netherlands Antilles. We found that the density of three planktivorous fishes increased significantly over these DMSP release sites. Brown chromis (*Chromis multilineata*) numbers increased to nearly four times background levels ($\chi r2 = 9.66$, $P = 0.002$, $n = 8$). While creole wrasse (*Lepticus parrae;* $\chi r2 = 25.6$, $P < 0.001$, $n = 8$) and boga (*Inermia vitatta*) recruited to the release sites only in response to DMSP. The attraction of schooling planktivorous fishes to this specific, isolated chemical cue suggests that DMSP provides a sensory link between algal production and reef fish aggregations. DMSP is generally released by the natural foraging activity of zooplankton, and our finding that planktivorous fishes aggregated over experimental deployments of DMSP has important implications for our understanding of how fish locate productive patches for foraging and how chemically mediated behaviors may be impacted by changing global temperatures.

## 10-1

**Linking Herbivory To Coral Recruitment And Local Management**

**Suzanne ARNOLD*[1]**, Robert STENECK[1], Peter MUMBY[2], Valerie PAUL[3], Raphael RITSON-WILLIAMS[3]

[1]School of Marine Sciences, University of Maine, Walpole, ME, [2]Marine Spatial Ecology Laboratory, School of BioSciences, University of Exeter, Exeter, United Kingdom, [3]Smithsonian Marine Station at Fort Pierce, Fort Pierce, FL

Coral reefs worldwide have suffered reduced coral cover in response to large scale disturbances. Unfortunately, Caribbean reefs have shown little or no recovery following these disturbances, and while they decline, the debate over how to best manage for reef recovery persists. Coral recruitment is central to the recovery of corals reefs. Several studies (including our own) suggest that scraping herbivores, such as some species of sea urchins and parrotfish, correlate inversely with algal biomass and positively with juvenile coral abundance. This manipulative experiment tests the hypothesis that herbivory facilitates coral recruitment. We focus on herbivorous fishes, particularly parrotfishes, as regulators of fore reef macroalgae and ultimately the recruitment potential for Caribbean reefs. We chose reefs in Bonaire and Belize representing a gradient in parrotfish grazing from high to low, respectively. Within regions, we measured coral recruitment on terracotta tiles with and without stainless steel pegs that impede large parrotfish. The quantitative data on the frequency and intensity of grazing, the settlement of corals, and the algal biomass and community structure that developed surrounding the treatment and control tiles after one year (March 2007-March 2008) will be reported. With these data, we hope to provide further evidence for the link between healthy herbivorous fish populations, algal abundance, and coral recruitment, as well as timely scientific support for the need to protect parrotfish.

## 10-2

**The Effect Of Echinoids On Caribbean Coral Recruitment--A 20 Year Study**

**Harilaos LESSIOS*[1]**

[1]Smithsonian Tropical Research Institute, APO AA

The recruitment and survival of juvenile corals on natural substrates was followed at monthly intervals at the San Blas Islands (Caribbean Panama) on four reefs under four treatments from 1984 to 2004. One treatment consisted of complete removal of all echinoids, one of the presence of *Diadema antillarum* at pre-mass mortality densities, one of the presence of *Echinometra viridis*, and one of the presence of both species. Every 3-5 years, the treatments were rotated between reefs in order to separate treatment and reef effects. The results indicate that in the absence of sea urchins coral recruitment is reduced. *Diadema* (at 1 m-2) or *Echinometra* (at 14 m-2), or both (at these natural densities), have approximately equally positive effects for coral recruitment. *Siderastrea radians,* S. *siderea*, *Agaricia sp.*, *Favia fragum*, and *Porites astreoides* are the most frequently recruiting species, but they also show the highest post-recruitment mortality. *Diploria strigosa*, *Acropora palmata, Isophylastrea rigida, I. sinuosa*, *Montastraea annularis* and *M. cavernosa* recruit at much lower rates, but have higher per capita survival rates. Thus, echinoids play an important role in shaping Caribbean scleractinian communities.

## 10-3

**Coral Reef Resilience: Balancing Production And Herbivory**

**Fiona WEBSTER*[1]**, Russ BABCOCK[2], Mike VAN KEULEN[1], Neil LONERAGAN[1]

[1]School of Biology and Biotechnology, Murdoch University, Perth, Australia, [2]Marine Research, Commonwealth Scientific and Industrial Research Organisation, Floreat, Australia

The Ningaloo Reef provides a unique opportunity to investigate different components of a coral reef ecosystem without the confounding effects of poor water quality and severe overfishing. This research examined a) how macroalgae affects coral recruitment and b) the processes which drive macroalgal abundance. These experiments were conducted in the field using a series of caged, uncaged and partially caged treatments to examine herbivory and control for caging effects. It was identified for the first time, that both the pre- and post- settlement processes of coral recruitment were severely reduced by increased macroalgal biomass. In the presence of macroalgae - for the coral *Acropora millepora*: larval settlement was reduced by up to 93%, post settlement survival was approximately half and those which did survive were around 80% smaller compared to corals in uncaged plots which contained little macroalgae. This demonstrates that macroalgae can inhibit coral reef recovery by reducing coral recruitment.

Bottom up versus top down influences on macroalgal abundance were examined in a multifactorial study using slow release fertilizer and cages to manipulate herbivory. Nubbins of *Cyphastrea microphthalma* were used as a proxy for coral recruits. Nutrients had no effect on macroalgal biomass and coral calcification. Herbivores on the other hand had a strong overriding effect. The volume of macroalgae was up to 40 times greater in caged versus uncaged plots. Over a nine month period the growth of coral nubbins in cages beneath the macroalgae was reduced by approximately 50% compared to uncaged plots. Through video analysis it was identified that the most important herbivores for controlling macroalgal abundance were large parrot fish, in particular *Cholurus sordidus* and *Scarus schlegeli*. These results emphasize the importance of protecting herbivores, in particular larger scarids from overfishing to facilitate coral recruitment and promote coral reef resilience.

## 10-4

**Contrasting Effects of Benthic Algae on Coral Recruits in an Upwelling Reef from the Colombian Caribbean**

**Dagoberto VENERA-PONTON*[1]**, Guillermo DIAZ-PULIDO[2], Laurence MCCOOK[3], Alejandro RANGEL-CAMPO[1]

[1]Instituto de Investigaciones Tropicales-INTROPIC, Universidad del Magdalena, Santa Marta, Colombia, [2]Centre for Marine Studies and ARC Centre of Excellence for Coral Reef Studies, University of Queensland, Brisbane, Australia, [3]Great Barrier Reef Marine Park Authority-GBRMPA, Townsville, Australia

Reef degradation generally involves the replacement of hard corals cover by benthic algae. A successful recovery of coral populations will depend on the competitive ability of corals to settle, recruit, growth and survive on habitats dominated by benthic algae. Most studies on coral-algal interactions and on the impacts of algae on the recovery of coral populations have focused on the roles of algae on coral settlement and adult performance; however, there is very little known about the effects on the survival of coral recruits, a critical step in the resilience of coral reefs. Here we present the results of an experiment investigating 1) whether coral recruits actually compete for space with the surrounding benthic algae; 2) the effects of benthic algae on the growth and survival of coral recruits, and 3) the roles of algae on parrotfish predation on coral recruits. The study used recruits of the coral Porites astreoides and was carried out in the Tayrona National Natural Park in the Colombian Caribbean during two contrasting climatic and oceanographic seasons (upwelling and non-upwelling). We found that the growth of recruits of the coral P. astreoides was significantly increased when the surrounding algae were removed while a weak algal colonization occurred when the coral recruits were damaged. These results were consistent among the upwelling and non-upwelling seasons and constitutes an unequivocal proof for competition between algae and coral recruits. The coral recruits were bitten by parrotfishes only when the surrounding algae were removed and it was also consistent among the two seasons. This suggests that benthic algae may actually protect coral recruits from parrotfish damage. Our results illustrate the complexities of the effects of coral reef algae on the early life history stages of corals.

## 10-5

**The Influence Of Water Quality, Larval Supply And Surrounding Benthos On Coral Recruitment To Nearshore Reefs Of The Great Barrier Reef**

**Stephen J NEALE*[1]**, Damien THOMSON[1], Angus THOMPSON[1], Britta SCHAFFELKE[1]

[1]Australian Institute of Marine Science, Townsville, Australia

Ecological processes on nearshore coral communities of the Great Barrier Reef (GBR) are affected by agricultural and urban runoff. Elevated nutrient and sediment levels in runoff have detrimental impacts on many aspects of coral reproduction and may reduce the ability of nearshore coral communities to recover from other disturbances and hence, their resilience. Few studies have documented recruitment rates in nearshore waters of the GBR and it is unclear how recruitment varies across gradients of water quality and how the surrounding coral community influences spatial and temporal patterns in coral recruitment. As a part of a long-term marine monitoring program under the GBR Water Quality Protection Plan, hard coral recruitment has been monitored for three years (2005, 2006 and 2007). Terracotta settlement tiles were deployed on fringing reefs located along an assumed water quality gradient within each of four inshore regions, to examine the influence of water quality, larval supply and surrounding benthos on the recruitment success of corals. Numbers of hard coral recruits in this study were up to 10 times higher than previously recorded at the same locations, highlighting the large temporal variability of recruitment on GBR nearshore reefs. The influence of water quality on recruitment was variable, but recruitment did not generally increase with increasing distance away from the coast, where turbidity levels and nutrient availability are usually elevated. Characteristics of the surrounding adult hard coral communities, such as the taxonomic composition and the reproductive health (e.g., influenced by disturbance such as bleaching or mechanical damage in the previous year), also played an important role in determining both the quantity of recruits and their taxonomic composition. Sustained local larval supply is vital for the recovery of inshore coral communities from disturbances, and, conversely, large-scale disturbance such as coral bleaching have long-lasting negative effects on these communities.

## 10-6

**Complex Life Histories, Dynamic Populations And Multiple Disturbances: Can A Demographic Approach To Monitoring Help Conserve Coral Reefs?**

**James GILMOUR*[1]**

[1]Australian Institute of Marine Science, Perth, WA, Australia

Global decreases in coral cover resulting from an increasing combination of disturbances are directly related to changes in the rates of transition of life history stages of corals through their life cycle. Quantifying these transition rates for populations (vital rates) therefore provides a way to investigate the past and future consequences of disturbance regimes. However, disturbance regimes affect species and their life history stages differently. The quantification of vital rates in three studies provided evidence of the extent to which the contribution of stage transitions to population growth, and their variability following population decrease, depended on the coral and the disturbance regime. For example, in populations of a fungiid coral exposed to chronic disturbances, survival varied dramatically between sexual and asexual recruits of similar size, whereas survival varied little across all size classes in populations of *Acropora* free of chronic disturbances. Further, the relative importance of sexual recruits or other stages to population maintenance varied along a gradient of water quality in populations of *Acropora*, and for populations of fungiid coral according to whether disturbances were in the form of periodic cyclones or cyclones and chronic sedimentation. In these populations, demographic and temporal variability had implications for the application of their vital rates to projection models. In particular, changes in stage transitions were not independent, so that substituting transition values with those observed in other populations, time-steps, or experimental manipulations, further reduced the accuracy of projections aimed at simulating disturbance regimes. Nevertheless, the quantification of population vital rates and their application to simple matrix models was an effective means of understanding and summarising the impacts of complex regimes of disturbance, and the projection of population structure under a variety of hypothetical scenarios a useful means of illustrating the future consequences of not mitigating certain stressors.

## 10-7

**How Settlement Dynamics Determine The Abundance And Distribution Of Corals**

**Mark VERMEIJ*[1]**, Stuart SANDIN[2]

[1]Botany Department, University of Hawaii, Lahaina, HI, [2]Center for Marine Biodiversity and Conservation, Scripps Institution of Oceanography, La Jolla, CA

Studying the earliest life-stages of corals (i.e. settled planulae and recently metamorphosed polyps) is problematic due to their small size and cryptic behavior and therefore limited information exists on the earliest demographics of corals. Here we present a combination of field and laboratory studies from the Caribbean and Hawaii aimed at revealing the factors that determine settler abundance and subsequent settlement success. Local densities of heterospecifics (algae and microbes) and conspecifics have profound effects on rates of settlement and early post-settlement survivorship. The early benthic phase of corals represents a severe demographic bottleneck whereby >80% of the initial number of settlers will not survive for more than one year. During this period, density-dependent and density-independent effects of microbes and benthic algae have profound effects on settler survivorship laying a foundation for their future distribution. The effects of algae and microbes can be positive or negative and depended on a settler's developmental stage. Increasing adult cover causes higher local settlement rates but only when total cover is low (<10%). Early post-settlement survivorship decreases with adult cover, revealing structuring density dependence in coral settlers. Survival probabilities increase dramatically after a settler divided for the first time and forms a 2-polyp colony, however, the capability to do so decreases with age. Combined, settlers are interactively affected by the presence of conspecifics, algae and microbes driving local rates of settlement and subsequent settlement success. By the time that a coral settler reaches one year of age, most of the severe and structuring mortality and demographic bottlenecks have passed.

## 10-8

**Survivorship Of Juvenile Corals Depends On Distance From Adult, Microbial Abundance And Water Current Direction**

**Kristen MARHAVER*[1]**

[1]Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA

The recovery of Caribbean coral populations will depend largely on successful recruitment of juveniles. In many tropical and temperate tree species, mortality of seeds and seedlings increases with proximity to adults of the same species, a key prediction of the Janzen-Connell model of tropical tree diversity attributed to the action of host-specific predators and/or pathogens. If similar distance-dependent mortality occurs in coral populations, it will affect the rate and pattern of coral recruitment. To test for distance-dependent mortality and its potential causes, I examined the effects of water current direction, distance from adult colony and microbial abundance on the survivorship of *Montrastraea faveolata* juveniles in field and laboratory experiments. In field manipulations, newly settled coral recruits placed up-current from adult *M. faveolata* colonies had significantly higher survivorship than those placed down-current from adult colonies. Within up-current locations, survivorship was highest at 96 cm and 192 cm distances; this was significantly higher than survivorship at 24 cm and 48 cm distances. In laboratory manipulations, swimming coral larvae experienced significantly increased mortality in water collected within 4 cm of an adult colony compared to water collected 2 m up-current from the same colonies. This difference in survivorship was eliminated when water was filter-sterilized to remove microbes and particulate organic matter. The swimming behavior of pre-settlement larvae differed significantly between filtered and unfiltered water treatments. Together, these experiments reveal a distance-dependent pattern of mortality in *M. faveolata* juveniles and suggest that microbes from adult colonies are a likely driver of increases in mortality.

## 10-9

**Importance of Post-Settlement Mortality on Scleractinian Population Maintenance around Moorea, French Polynesia**

**Lucie PENIN*[1,2]**, Francois MICHONNEAU[1,2], Andrew H BAIRD[3], Sean R CONNOLLY[3,4], Morgan S PRATCHETT[3], Mohsen KAYAL[1,2], Mehdi ADJEROUD[1,2]

[1]Université de Perpignan, UMR CNRS EPHE UPVD 5244 Biologie et Ecologie Tropicale et Méditerranéenne, Perpignan, France, [2]UMS CNRS 2978, CRIOBE, Papetoai, French Polynesia, [3]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townville, Australia, [4]School of Marine and Tropical Biology, James Cook University, Townsville, Australia

At a fundamental level, spatial variation in the abundance and community structure of scleractinian corals must be influenced by patterns of larval settlement. However, spatial variation in early post-settlement mortality has the potential to greatly distort patterns established at settlement, and the relative influence of variation in settlement rates and post-settlement processes on spatial dynamics of coral assemblages remains largely unknown.

In this study, spatial variation in mortality of recruits (< 3 months of age) and juvenile corals (< 5 cm in diameter; ~1-4 years of age) was quantified in three depth zones at each of three locations and round Moorea, French Polynesia. Mortality of coral recruits was extremely variable and particularly high (50 % in 7 days), and is associated with the abundance of parrotfishes (Fam. Scaridae). Juvenile mortality was less intense (up to 40 % in 14 months), but also shows strong spatial variability, corresponding with variation in abundance of butterflyfishes (Fam. Chaetodontidae).

Spatial variability in early post-settlement mortality partly accounts for apparent differences in the abundance of coral recruits versus juveniles corals, highlighting the potential importance of post-settlement processes as a driver of spatial variation in the dynamics of coral assemblages. Moreover, variation in early-post settlement mortality of corals appears to be influenced mainly by local densities of Scaridae and Chaetodontidae, which each affect a different stage in the life-cycle (recruits versus juvenile corals, respectively).

## 10-10

**Reproductive Demography Of *siderastrea Radians* in The St. Martins Keys, Florida**

**Katherine LAZAR*[1]**, Thomas FRAZER[1], Charles JACOBY[1], Colette ST. MARY[2]

[1]Department of Fisheries and Aquatic Sciences, University of Florida, Gainesville, FL, [2]Department of Zoology, University of Florida, Gainesville, FL

The reproductive demography of corals plays a significant role in their population dynamics by influencing reproductive success. The objectives of this study are to quantify spatial variation in: 1) density, 2) size distribution, 3) fertility, and 4) sex ratio in a population of *Siderastrea radians* in the St. Martins Keys, Florida. Initially, corals were counted and measured in 10 quadrats placed at random points along one randomly oriented, 25-m transect at each of 81 sites arrayed in a 16-km2 grid. Results from the survey indicate that corals were distributed in patches (mean Morisita Index = 5.98; range = 0–20), with densities ranging from 0.0 to 86.0 individuals m–2 (mean = 7.0 individuals m–2). The size-frequency distribution was typical of other scleractinian populations, with the majority of individuals falling within the smallest size classes (positive skew). A statistically significant linear regression showed that numbers of individual polyps, i.e., recruits, increased with numbers of putative adults ($p < 0.001$). To quantify the relationships among density, aggregation, and sex ratio, corals were collected from 10 sites with different combinations of density and aggregation (i.e., high density/low aggregation, medium/low, low/low, low/medium, and low/high). Preliminary histological data corroborates previous reports of a female-biased sex ratio in this species. Overall, results point to the potential importance of small-scale, demographic patterns in determining the reproductive success and population dynamics of *S. radians*.

## 10-11

**Survival Dynamics Of Azooxanthellate Scleractinian Coral Larvae And Implications For Dispersal**

**Erin GRAHAM*[1]**, Andrew BAIRD[2], Sean CONNOLLY[3]

[1]School of Tropical and Marine Biology, James Cook University, Townsville, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [3]ARC Centre of Excellence for Coral Reef Studies, and School of Tropical and Marine Biology, James Cook University, Townsville, Australia

Survival of pelagic marine larvae is an important determinant of dispersal potential. For scleractinian corals, however, few studies of larval survival are long enough to provide accurate estimates of longevity. Moreover, changes in mortality rates during larval life have implications for connectivity among reefs and have not been quantified for any coral species. This study quantified the survival of larvae from five scleractinian corals (*Acropora latistella*, *Favia pallida*, *Pectinia paeonia*, *Goniastrea aspera*, and *Montastraea magnistellata*) to estimate larval longevity and test for changes in mortality rates as larvae age. Maximum lifespans ranged from 195-244 d, substantially exceeding those documented previously for azooxanthellate corals and predictions based on metabolic rates. In addition, larval mortality rates exhibited strong patterns of variation throughout the larval stage. Three periods were identified in four species: high initial rates of mortality; followed by a low, approximately constant rate of mortality; and finally, increasing mortality after approximately 100 d. The observed lifetimes suggest the potential for long-distance dispersal may be substantially greater than previously thought, probably because larvae regulate their energy use. Indeed, detection of increasing mortality rates late in life suggests that energy reserves do not reach critically low levels until approximately 100 d. Conversely, increased mortality rates early in life decrease the likelihood that larvae transported away from natal reefs will survive to reach nearby reefs, and thus decrease connectivity at regional scales. These results show how variation in larval survivorship with age may help to explain the seeming paradox of high genetic structure at metapopulation scales, coupled with extensive geographic ranges, observed in many coral species.

## 10-12

**The Effect Of Ultraviolet Radiation On Different Stages Of The Life Cycles Of Mass Spawning And Brooding Scleractinian Corals**

**Anastazia BANASZAK*[1]**, Ana Laura GARCÍA LÓPEZ[1], Braulio AVILA RAMÍREZ[1]

[1]Photobiology, Universidad Nacional Autónoma de México, Puerto Morelos, Mexico

Ultraviolet radiation (UVR, 280 to 400 nm) is an important physical factor affecting shallow water reef communities. The effect of ecologically relevant doses of UVR was determined on different stages of the life cycle of the reef-building corals Montastraea faveolata and Acropora palmata, both summer mass-spawning species, as well as on Favia fragum, a species that broods larvae to the planula stage and releases them on a monthly basis. Four different early-development life stages (blastula, gastrula, non-motile planula and motile planule) of Montastraea and Acropora were exposed to artificial solar UVR that was equivalent to a one day dose of natural solar radiation. The gastrula was found to be the most sensitive life cycle stage of Acropora whereas all stages of Montastraea were equally sensitive as determined by mortality during exposure to UVR in comparison to larvae exposed without UVR. Post-exposure mortality rates also differed, with the Acropora planula and Montastraea motile planula being the most sensitive of the four stages. Due to their small size and monthly reproduction, Favia colonies are more amenable to experimental manipulation. Favia colonies were exposed to natural levels of solar radiation over a 13 month period. Colonies in treatments with UVR filtered out produced 9 times as many larvae as colonies exposed to UVR. The larvae that were produced exhibited significantly higher mortalities during exposure to UVR as did juveniles when compared to exposures without UVR. Settlement rates, sites and preferences were also affected in the presence of UVR. Our date show that UVR is an important physical factor in the life cycle of mass spawning and brooding reef corals and should be considered in discussions on reef connectivity and ecology.

## 10-13

**Species Specific Habitat Selectivity Of *Acropora* Larvae In Subtropical Reefs**

**Go SUZUKI*[1,2]**, Takeshi HAYASHIBARA[3], Yoshihisa SHIRAYAMA[2], Hironobu FUKAMI[2]

[1]Division of Applied Biosciences, Graduate School of Agriculture, Kyoto University, Wakayama, Japan, [2]Seto Marine Biological Laboratory, Field Science Education and Research Center, Kyoto University, Wakayama, Japan, [3]Ishigaki Tropical Station, Seikai National Fisheries Research Institute, Ishigaki, Japan

*Acropora* is one of the most abundant and diverse genera of scleractinian corals in the Indo-Pacific reefs. Distribution of *Acropora* corals often showed a specific pattern of zonation particularly on reef slopes, with corymbose and table colony shapes dominating shallow waters (less than 5 m depth), and branch shaped colonies dominating deeper waters. Environmental factors such as wave action and light intensity have been shown to impact post-settlement survival of *Acropora* corals and play a role in the creation of this pattern. To date the role of larval settlement in establishing *Acropora* zonation has been rarely assessed because of the difficulty in species identification of new recruits. Here, to test the hypothesis that larvae settle selectively on species specific suitable habitat, we identified recruits with two-step molecular sorting process using mitochondrial and nuclear markers to successfully distinguish the seven most dominant species in the study area (Okinawa, Japan). The distribution of the larval settlement of the three dominant species *A. digitifera*, *A. hyacinthus* and *A. tenuis* was significantly related to distribution shown by adult colonies, suggesting that *Acropora* larvae selectively settle on suitable habitats. This is the first *in situ* evidence showing selective settlement of coral larvae. Although yet undocumented, pre-settlement behavior such as species specific swimming abilities may play a role in determining the pattern of reef corals.

## 10-14

**Influence Of Benthic Communities On The Settlement And Post-Settlement Survival Of Two Reef Corals in The Florida Keys**

**Maggy NUGUES*[1,2]**, Alina SZMANT[3]

[1]Dept. of Marine Ecology and Evolution, Royal Netherlands Institute for Sea Research, Den Burg, Netherlands, [2]Center for Marine Science, University of North Carolina Wilmington, Wilmington, [3]Center for Marine Science, University of North Carolina Wilmington, Wilmington, NC

Coral reef recovery depends on the ability of reef corals to recruit successfully to replenish depleted populations. Given the structural and ecological importance of reef-building corals, it is important to understand the factors that determine their ability to achieve successful sexual recruitment. To investigate the role of benthic communities on coral recruitment, we experimentally settled larvae of *Montastraea cavernosa* and *M. annularis* onto settlement plates pre-conditioned at three sites in the Florida Keys. The coral spat were mapped and the composition of the encrusting community characterized on each plate. The plates were then returned to their initial position in the field and retrieved at different time intervals for further monitoring of coral spat and community structure. Results showed that the side of the plates had a much larger effect than location on coral settlement. Although the plates were placed vertically during experimental settlement, the undersides had approximately 1 order of magnitude higher numbers of settlers. 87% of the spat settled directly on microfilm (single cell algae) and only 9% settled on crustose coralline algae, a well known cue for coral settlement. Post-settlement survivorship was 2% after 9 months, with 71% of the spat dying the first 30 days. Survivorship was not associated with the benthic community present on the plates during the first month. However, there was a negative association between survivorship and the cover of overgrowing invertebrates during the second and third months. Thus, biological interactions appear as major factors influencing coral settlement and post-settlement, but other factors must be sought to explain the high mortality of coral spat during the first month of settlement.

## 10-15

**Do Coralline Algae Influence Coral Recruitment On A Reef?**

**Nichole PRICE*[1]**

[1]University of California, Santa Barbara, Santa Barbara, CA

Settlement preferences of sessile invertebrates may be adaptations to local community interactions, particularly if selection of appropriate microhabitat influences early post-settlement survivorship. Laboratory studies indicate that many reef-building corals can be induced to settle by chemical cues in the cell walls of crustose coralline algae (CCA). However, it is unclear if the availability and location of cue-containing CCA on the reef can influence local recruitment patterns of scleractinian corals. This study examines biotic factors influencing the abundance and distribution of CCA and subsequent consequences for coral recruits using the settlement cue. Results of a field coral recruitment experiment indicated that Pocilloporid and Acroporid corals exhibit a hierarchical selection for substrate among five common CCA species. Electivity indices calculated for corals settling to coralline algae species with thin crusts (eg., *Titanoderma prototypum*) were significantly greater than for species with thicker thalli (eg., *Porolithon onkodes* and *Lithophyllum insipidum*). Pair-wise field competition experiments revealed that thick-crusted coralline species were superior space competitors when exposed to transient herbivores, but competitive dominance switched otherwise. CCA producing thin thalli were most susceptible to grazing and were scarred more deeply when exposed to herbivores. Therefore, Pocilliporid corals select to settle upon CCA species exhibiting particular morphological characteristics that may influence the survival and growth of settlers. Coral settlers may even be facilitated by *T. prototypum* as recruits found on this CCA were less likely to be overgrown by other CCA or macroalgae and survivorship was enhanced at least two-fold. *T. prototypum* can also influence coral recruitment indirectly by indicating microhabitat that is protected from incidental mortality by large herbivores. Thus, CCA that cannot withstand biotic disturbances and are competitive dominants in crevices may indicate or even provide spatial refuges that are most suitable for recruitment of reef-building corals.

## 10-16

**Fishing-Induced Changes in Fish And Sea Urchin Abundance Cause Reductions in Crustose Coralline Algae Cover And The Availability Of Coral Settlement Substrate**

**Jennifer O'LEARY*[1]**, Tim MCCLANAHAN[2]

[1]Ecology and Evolutionary Biology, University of California, Santa Cruz, Santa Cruz, CA, [2]Wildlife Conservation Society, Mombasa, Kenya

Fishing can have cascading effects on trophic structure that influence ecosystem processes such as primary production, calcification and reef stability. Crustose coralline algae (CCA) are a calcifying component of reef ecosystems that comprise the primary settlement substrate for corals. Using a 20-year dataset from coastal Kenya we demonstrate that a fishing-induced change in the dominant grazers can dramatically impact CCA cover. CCA is highest in long-term protected areas (reaching a percent cover similar to that of corals), intermediate in short-term protected areas, and lowest in fished areas. CCA cover is strongly positively correlated with fish biomass and negatively correlated with sea urchin biomass. We use a short-term experiment to investigate the direct impacts of fish and sea urchin grazing on CCA growth rates. While both fish and sea urchins affect CCA growth, the effects are in opposite directions: fish increase CCA cover, but sea urchins reduce CCA growth rates almost to zero. We conclude that on the Kenyan coast, fish have a strong indirect positive effect on CCA (through sea urchin predation) leading to high cover in marine protected areas, while sea urchins have a strong direct negative impact on CCA, greatly reducing CCA cover in fished areas. Fishing can thus lower the amount of settlement substrate available to corals, reducing the ability of reef systems to recover from disturbance. Our results are in contrast with those of previous studies on CCA from temperate systems that show a direct positive association between sea urchin grazing and CCA, and with studies in the Caribbean that show a direct positive association between fish grazing and CCA. Our study demonstrates an ecosystem effect of fishing on an understudied but ecologically critical reef component (CCA), while challenging existing paradigms regarding the relationship between grazers and CCA.

## 10-17

**The Influence Of Macroherbivores On The Macoralgal Dynamics Of A Caribbean Coral Reef**

**Stephen BOX*[1]**, Peter MUMBY[1]

[1]Marine Spatial Ecology Lab, University of Exeter, Exeter, United Kingdom

The spatiotemporal dynamics of macroalgae remain poorly understood despite being the spatial dominant on many Caribbean coral reefs. Whilst herbivores are recognised for their essential role in controlling the abundance and distribution of algae, how they affect macroalgal dynamics and the availability of potential settlement space for corals is less clear. Using transition matrices generated from the occupation states of small permanent quadrats, across successive months, we use generalised linear models to assess the factors controlling the dynamics of available space and those of two dominant macroalgal species, *Lobophora variegata* and *Dictyota pulchella*, on shallow forereefs in Honduras. Using exclusion cages the influence of macro-herbivores on these dynamics were then evaluated. The study found that the rapid occupation and transient dynamics of both macroalgal species across the surfaces of dead coral restrict available space. Unoccupied space was at a minimum in the sheltered microhabitats preferred by coral recruits, resulting in less than 0.06% of the total surface area of dead coral being both in sheltered habitats and free from algal occupation for six months continuously. This spatiotemporal limitation may severely restrict successful coral recruitment. When macro-herbivores were excluded, the availability and persistence of unoccupied space decreased, but the increase in cover by both macroalgal species investigated here were limited by competition from other benthic algae. Herbivory influenced algal dynamics across the surfaces, including the sheltered areas which they could not access. In reducing overall algal cover, herbivores reduce the reoccupation rate and persistence time of algae, affecting their dynamics even in the cryptic areas that cannot be grazed directly. However, the current parrotfish dominated herbivore regime of the study site may actually be beneficial to these two algal species by restricting competition from other algal groups.

## 10-18

**Environmental Stress Drives Seasonal Changes in Top-Down And Bottom-Up Regulation Of Coral Community Structure And Resilience**

**Peggy FONG*[1]**, Matthew WARTIAN[1]

[1]Ecology and Evolutionary Biology, University of California Los Angeles, Los Angeles, CA

Theory predicts that the strength and relative importance of processes structuring communities will vary predictably with changes in environmental stress. In this study, we used a comparative approach by performing two experiments to assess differences in bottom-up (nutrients) and top-down (herbivory) forces on changes in tropical eastern Pacific coral reef community structure and resilience during periods of increasing and decreasing environmental stress due to upwelling. We found that as upwelling intensity increased, herbivores were unable to limit increases in algal cover, which expanded into areas previously dominated by live coral. Additionally, experimental nutrient enrichment reduced coral and enhanced algal cover both in the presence and absence of herbivores at the beginning of the upwelling season. Nutrient additions initially shifted the algal community toward macroalgae, while later it favored turfs. In contrast, in the experiment conducted when upwelling intensity declined, herbivores effectively reduced algal cover and increased live coral cover while experimental nutrient enrichment effects were not significant. However, a combination of herbivory reduction and nutrient enrichment shifted the algal community to dominance by crustose forms. Based on our findings, we conclude that both nutrients and herbivory are important factors in determining coral community structure and resilience, although the relative importance of each was influenced by environmental stress. Large-scale increases in environmental stress decreased the relative importance of top-down forces, increased the dominance of bottom-up forces, and enhanced algal overgrowth of corals. However, once environmental stress was alleviated, herbivores strongly enhanced coral community resilience, reversing phase shifts to greater algal dominance.

## 10-19

**Environmental Stress Changes The Relative Importance Of Top-Down (Herbivorous Fishes) And Bottom-Up (Nutrients) Forces Regulating Community Structure And Resilience Of Coral Reefs**

**Matthew WARTIAN*[1,2]**, Peggy FONG[3]

[1]Weston Solutions, Carlsbad, CA, [2]Ecology and Evolutionary Biology, University of California, Los Angeles, Los Angeles, [3]Ecology and Evolutionary Biology, University of California, Los Angeles, Los Angeles, CA

Understanding the roles of top-down and bottom-up forces in determining community structure and resilience has increasingly become the focus of ecological studies as human influences on ecosystems have intensified, changing the strength of forces, and resulting in phase shifts to alternate states. Recent phase shifts of marine communities are attributed to human impacts, including nutrient enrichment, overfishing of predatory and herbivorous fishes, and increases in environmental stress. For coral reefs, many have hypothesized that herbivores are of primary importance to reef resilience, limiting the proliferation of macroalgae and enhancing coral recovery after stress. However, there have been few experimental studies testing this hypothesis. Here we provide evidence that an intact herbivore community reversed macroalgal overgrowth of coral following a period of environmental stress. Recovery of coral dominance after episodic low-temperature stress was dependent upon the presence of herbivores, a top-down force that removed algal proliferation and prevented further coral mortality. Without environmental stress, no phase shift was initiated indicating that reductions in herbivory alone may not cause community shifts. Rather, without environmental stress both herbivory and bottom-up forcing by nutrients regulated coral/algal dominance, although the magnitude of community changes was relatively modest. We conclude that the ability of coral communities to recover from environmental stress is undermined by overfishing, while maintenance of reef stability is also dependent on nutrients. Our results provide scientific support for the worldwide call for protection of reef fishes as a key management goal, especially in the face of increasing nutrification and environmental stress.

## 10-20

**A Biophysical Perspective Of Grazing in Pacific Parrotfish**

**Sonia BEJARANO*[1]**, Victor TICZON[2], Peter MUMBY[1]

[1]Marine Spatial Ecology Lab, University of Exeter, Exeter, United Kingdom, [2]Marine Science Institute, University of the Philippines, Manila, Philippines

Since grazing by parrotfishes plays a crucial role in processes of reef recovery, this study aimed to understand the way it is affected by important biophysical variables. Data collection took place in the Palau archipelago during May 2006. Individual bite rate within three contrasting reef locations was modelled as a function of time of day, tidal direction and height, species/genus and fish total length (TL). Individual bite area was estimated from jaw dimensions of parrotfish at the fish market. Bite area for each of the most abundant parrotfish genera was modelled as a function of TL. Bite rate and bite area models were combined with local fish census data to predict the grazing impact (m2 hour-1) of individuals of the most abundant species as well as of the whole assemblage of parrotfish. Most species focused their grazing on algal turfs but also included a broad range of substrates including live coral. In general, bite rate was negatively correlated with TL and lower in the morning. In particular, bite rate differences among species were detected in two sites, a different effect of body size depending on the genus in one of these sites and a significant effect of tidal height during midday in another site. Bite rate of initial phase Chlorurus sordidus also seemed to be moderated as tidal height increased in midday. Bite area of all genera was linearly related to TL, similar curves for these relationships were obtained for four genera. Output models identify the relative contribution of some species, species and size classes to overall grazing. We show that the conversion of fish census data to modelled grazing will potentially give a more insightful metric of grazing than using biomass as a simple surrogate.

## 10-21

**The Roles Of Nutrients And Herbivory in Controlling Micro-And Macrobioerosion Patterns in Eastern African Reefs**

**Marina CARREIRO-SILVA*[1,2]**, Timothy MCCLANAHAN[3], Victor KENNEDY[1], Joseph MIHURSKY[1], Marjorie REAKA[4]

[1]Chesapeake Biological Laboratory, Center for Environmental Science, University of Maryland, Solomons, MD, [2]Departamento de Oceanografia e Pescas, Universidade dos Açores, Horta, Portugal, [3]Wildlife Conservation Society, Bronx, NY, [4]Department of Biology, University of Maryland, College Park, MD

The roles of nutrients and sea urchin and fish herbivory in controlling patterns and rates of internal bioerosion by micro- and macroborers were studied on nine reefs along the East African coast. Bioerosion rates by microborers (algae, bacteria, and fungi) were measured at three to six months intervals using herbivore-exclusion cages and experimental substratum made of *Lambis chiragra* mollusk shells. Bierosion rates by macroborers (mainly worms, bivalves and sponges) were measured on branching *Porites* killed during the 1998 bleaching event, four and six years after their death. Hypotheses tested were that (1) rates of micro- and macrobioerosion would be correlated with the spatial variation in nutrient availability; (2) grazing by herbivorous fish and sea urchins would reduce measurable microbioerosion and macrobioerosion rates. In contrast to result of experimental studies in Glovers reef, Belize, no clear relationship was found between nutrient levels and microbioerosion and all reefs experienced high colonization and bioerosion rates by microbial endoliths. Instead, microborers' density of colonization and bioerosion rates were negatively correlated with current speed and cover of encrusting coralline algae. In contrast, macrobioerosion rates were positively correlated with chlorophyll *a* concentrations in reef waters. Microbierosion rates were more influenced by grazing fish whereas macrobioerosion rates were more influenced by sea-urchin biomass. A complex mix of physical, chemical and ecological processes interact in determining rates of bioerosion. Macroborers, which are predominantly suspension and filter feeders, are more influenced by particulate organic material and plankton in the water column. Microborers may be stimulated by inorganic nutrients, but coralline algae may inhibit colonization of microborers by reducing light availability.

## 10-22

**Vegetarians Are Shallow: Declining Herbivore Pressure With Depth**

**Eran BROKOVICH*[1,2]**, Shai EINBINDER[2,3], Inbal AYALON[4], Nitzan SEGEV[4], Yonathan SHAKED[4], Amatzia GENIN[3,4], Moshe KIFLAWI[5,6], Salit KARK[1]

[1]The Biodiversity Research Group, Department of Evolution, Systematics and Ecology, The Hebrew University of Jerusalem, Jerusalem, Israel, [2]Marine Twilight-Zone Research & Exploration (MTRX), The Interuniversity Institute for Marine Sciences at Eilat (IUI), Eilat, Israel, [3]Department of Evolution, Systematics and Ecology, The Hebrew University of Jerusalem, Jerusalem, Israel, [4]The Israel National Monitoring Program, The Interuniversity Institute for Marine Sciences at Eilat (IUI), Eilat, Israel, [5]Department of Life Sciences, Ben-Gurion University, Beer-Sheva, Israel, [6]The Interuniversity Institute for Marine Sciences at Eilat (IUI), Eilat, Israel

Coral reef herbivore fishes play an important role in mediating competition between fast growing benthic algae and relatively slow-growing corals. Herbivore abundance and composition may be affected by primary production levels which will decline with decreasing light levels along the depth gradient. Herbivory studies, even those related to depth gradients, have traditionally concentrated on shallow coral reefs. Hence, the importance of herbivory in deep coral reefs (> 30 m) remains largely unexplored. This study aims to examine herbivore assemblage-structure and potential pressure on turf and macro-algae down to a depth of 65 meters. The study combines visual census of fish assemblages; field measurements of turf algae growth rate; and in-situ evaluations of herbivore pressure using caged vs. exposed settlement plates and bioassays. The number of herbivore species dropped threefold between 5 m and 65 m; along with a decrease in their abundance and algal growth rate. At 65 m most individuals sampled where large roaming Scarids. The rate of macro-algae consumption was 2.25 gr dry algae/hour at one meter depth and dropped rapidly (as a function of the natural log of depth) to almost zero at 65 m. This pattern correlated with fish abundance and biomass. The percent of turf algae consumed increased from 30% in one meter to 60% in 10 m then declined to near zero in 50 m. The lower herbivory pressure in the deep reef suggests that the role of fishes in maintaining suitable algal-free substrate for coral recruitment is less significant than in shallow reefs. Whether or not algae can out-compete corals at these depths due to eutrophication and whether herbivorous fish can mitigate an increase in algal growth remains to be examined.

## 10-23

**The Role of Herbivory in Structuring Benthic Algal Communities on the Great Barrier Reef**

**Andrew HOEY*[1]**, David BELLWOOD[1]

[1]ARC Centre of Excellence for Coral Reef Studies and School of Marine and Tropical Biology, James Cook University, Townsville, Australia

We used a combination of visual census and algal transplants to examine the relationship between herbivore distribution and relative removal rates of macroalgae. The distribution of herbivorous fishes and removal rates of *Sargassum* sp. was quantified on two reefs in each of three cross-shelf regions on the northern Great Barrier Reef. *Sargassum* sp. collected from an inner-shelf reef flat was transplanted to the reef crest and back reef of each reef for a period of 24 hours. The rate of removal of *Sargassum* was greatest on mid-shelf reefs (57.5 – 79.9%.d-1), and decreased markedly on both inner- (10.8 – 16.9%.d-1) and outer-shelf reefs (10.1 – 10.4%.d-1). These relative rates of removal were poorly correlated with the abundance and biomass of macroalgal browsers and all herbivorous fishes, collectively. The biomass of macroalgal browsers on the outer-shelf reef crest was at least double that of any other habitat yet the rate of *Sargassum* removal was the lowest. In contrast, the mid-shelf reef crest displayed the highest rate of *Sargassum* removal yet the biomass of macroalgal browsers was an order of magnitude lower than that of the outer-shelf reef crest. These results highlight the potential difficulties of modeling ecosystem processes on correlative relationships alone.

## 10-24

**Size-Dependent Variation in The Functional Role Of The Parrotfish Scarus Rivulatus On The Great Barrier Reef, Australia**

**Roberta BONALDO*[1]**, David BELLWOOD[1]

[1]Australian Research Council Centre of Excellence for Coral Reef Studies and School of Marine Biology, James Cook University, Townsville, Australia

Biodiversity loss and fishing-induced changes in the size distributions of fishes can impact ecosystem function on coral reefs. These changes have led to an urgent need for studies on the particular roles of species, to underpin effective coral reef management. The present study focuses on the feeding ecology of six size classes (from 2.5 to 30 cm total length) of *Scarus rivulatus* (family Labridae), one of the most abundant parrotfishes on the Great Barrier Reef, Australia. Individuals in all six size classes strongly selected the epilithic algal matrix for foraging and rejected other substratum types, including coral, macroalgae and sand. The six size classes also had similar feeding rates (bites.min-1) and diel feeding patterns, with higher feeding activity during the afternoon. However, the size of grazing scars by *S. rivualtus* differed significantly among the six size classes, with small individuals scraping a greater substratum area per unit biomass and larger individuals taking greater volume of material per unit biomass. Thus, biomass can not be not be viewed as a proxy for ecosystem impact; different sized individuals of *S. rivulatus*, and probably other parrotfish species, have a markedly different impact on the benthic community. Selective harvesting of large individuals will therefore change the functional role of this species. These results emphasize the importance of considering the size of individuals when evaluating the role of reef species in ecosystem process. These intraspecific functional differences will be critical when formulating reef management strategies and evaluating the impact of fishing activity on reef ecosystems.

## 10-25

**Herbivory Under Altered Community States -Is What You See What You Get?**

**Rebecca FOX*[1]**, David BELLWOOD[2]

[1]ARC Centre of Excellence for Coral Reef Studies, School of Marine and Tropical Biology, James Cook University, Fadden, ACT, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, School of Marine and Tropical Biology, James Cook University, Townsville, QLD, Australia

Herbivorous fishes are widely acknowledged as a key element in maintaining the health and resilience of coral reef ecosystems. Quantifying the relative impact of individual species of herbivore is essential if we are to identify systems at risk of undergoing phase-shifts and develop an understanding of how such shifts could be reversed. Traditional approaches have used diver-based observations of herbivore abundance to quantify herbivory. But is what we see in terms of herbivore distribution really representative of all herbivorous activity occurring on coral reefs? We made use of remote underwater video cameras to observe the process of herbivory in the absence of divers under natural and altered community states, the latter being created using macroalgal transplants. Continuous recordings of the diurnal feeding activity of roving herbivores were made across different reef habitat zones and the impact (area of reef grazed per day) of each of the major species was quantified. While the overall pattern of relative grazing intensities across the reef under natural and degraded conditions coincided, the process of herbivory differed dramatically between the two states. Of the three dominant taxa recorded at the location under natural conditions, none played a role in the removal of macroalgae in the altered state. Instead, the agent of macroalgal removal was a species not previously recorded at the location. Our findings highlight that species critical to the healthy functioning and resilience of reef systems may have gone unnoticed in previous observations of natural foraging patterns. The implications of the differences in grazing activity among community states will be discussed in the context of herbivory as an agent of disturbance, and the potential roles of individual species in the resilience and recovery of coral reef ecosystems will be highlighted.

## 10-26

**Herbivory On Coral Reefs: The Challenge Of Change**

**David BELLWOOD*[1,2]**

[1]Marine Biology, James Cook University, Townsville, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, Townsville, Australia

This presentation will examine our understanding of the role of herbivorous fishes on coral reefs. Herbivory is widely accepted as one of the most important processes on coral reefs. Yet, despite over four decades of research on herbivory we are still at the stage of identifying the players and their respective roles. This apparent lack of progress reflects rapid changes in our understanding of the potential role of herbivorous fishes in ecosystem processes and the emergence of new challenges. Global warming and direct human activity are rapidly changing coral reef ecosystems. Herbivorous fishes have switched from animals that eat algae to critical functional groups with important roles in supporting reef resilience, preventing coral-algal phase shifts and underpinning reef regeneration. The key question now is: which of the herbivorous fishes are important for the future of coral reefs and why? In this presentation I will: a) provide an historical overview of research on fish based herbivory, with an emphasis on the Great Barrier Reef; b) examine the implications of recent methodological advances in the application of remote underwater video techniques; and c) explore our ability to critically evaluate the status of today's coral reefs.

## 10-27

**Continuing Decline Of *montastraea* Populations On Protected And Unprotected Reefs in The Florida Keys National Marine Sanctuary.**

**Struan SMITH*[1]**, Richard ARONSON[2], John OGDEN[3]

[1]Georgia State University, Atlanta, GA, [2]Dauphin Island Sea Lab, Dauphin Island, AL, [3]Florida Institute of Oceanography, St. Petersburg, FL

Coral populations in Fully Protected Zones and on adjacent unprotected reefs in the Upper and Lower Florida Keys were assessed in terms of percent cover, recruitment, and juvenile and adult colony survival rates from 1998 to 2005. Analysis of random video transects showed that, overall, percent coral cover has declined by 50% on both protected and unprotected reefs during this period. The framework-building corals *Montastraea* spp. have declined in absolute cover from 5% to 2% in the Lower Keys and from 2% to 1% absolute cover in the Upper Keys on both protected and unprotected reefs. Censuses of corals in permanent quadrats revealed that three coral genera recruited successfully every year: *Siderastrea* spp. (5-10 m-2 yr-1), *Porites* spp. (1-2 m-2 yr-1), and *Agaricia* spp. (0.5-1 m-2 yr-1). However, the *Montastraea annularis* species complex have shown very low recruitment rates (<0.02 m-2 yr-1), and high rates of colony shrinkage and mortality (5-40% per year, across different size classes). *Montastraea cavernosa* has recruited slightly more successfully (0.2-0.5 m-2 yr-1) but still suffered high mortality rates (2-26% per year, across different size classes). Transition-matrix population models based on these rates of change in different size classes predict a 50% decline in existing *Montastraea* populations in the next 7-10 years. The Fully Protected Zones thus have not improved the status of resident *Montastraea* populations.

## 10-28

**Relative Strengths Of Factors Affecting Community Structure in The Main Hawaiian Islands**

**Danielle JAYEWARDENE*[1]**

[1]Zoology, University of Hawaii at Manoa, Honolulu, HI

While Marine Protected Areas (MPAs) are an increasingly advocated tool for managing coral reefs, they represent manipulation of only one of several factors that influences the coral community, the level of predation. Beyond this factor, coral reef communities are structured by; 1) the dispersal of larvae to the reef; 2) physical conditions such as temperature, salinity, currents, wave energy; 3) resources such as space, light, habitat and food; 4) other biological interactions such as competition and mutualisms; and 4) disturbance regimes. The objective of this study was to determine which of these factors are primary influences on the structure of reef communities in the Main Hawaiian Islands. Principal Component Analyses were applied to analyze the relationships between the abundance of herbivorous fishes, the cover of macro-, filamentous- and crustose coralline algal, the composition of the coral community, and the relative difference in abundance of grazing versus boring urchins across 9 coral reef sites in the Islands. Results indicate that the principal component structuring the coral community is wave energy. Thus while MPAs across the globe and in Hawaii have been shown to promote the size and abundance of fish populations, the coral community seems to be strongly influenced by physical processes beyond that of the control of marine protection. Establishing MPAs will thus not necessarily protect these reef communities in the face of large scale threats such as global warming that increases the intensity of storms and thus wave energy which in turn suppresses coral cover and thus growth of the reef calcium carbonate framework.

## 10-29

**Coral Reef Assemblages and Diversity in the Volcanic Northern Mariana Islands**

**Peter HOUK*[1]**, John STARMER[1]

[1]CNMI Marine Monitoring Program, Saipan, Northern Mariana Islands

The volcanic Northern Mariana Islands (NMI) provide a unique opportunity to examine patterns in coral-reef assemblages, diversity, and reef growth due to varying island size, volcanic activity, and environmental regime. Initially, this study explores why patchy, inconsistent reef growth is evident throughout the archipelago by examining if there are linkages between 'reef types' and the modern assemblages growing upon them. The 'reef types' examined were: 1) volcanic boulders, 2) colonized boulders, 3) low-slope Holocene and sand, 4) complex, colonized Holocene, 5) complex, uncolonized Holocene, and 6) high-slope, sheltered Holocene. Replicated, quadrat-based surveys were conducted at 41 sites to gather coral colony size and taxon occurrence data. The initial results showed that 'reef type' acts as a good predictor of modern coral assemblages, however, taxon occurrence data showed less affiliation with 'reef type', rather an 'island effect' emerged. Most islands supported distinct populations of algae and invertebrate species. Building from this base, regressions between island size, volcanic disturbance, salinity, and species richness are interpreted to approach existing theories that explain diversity patterns. Notably, island size had a positive, log-log relationship with species richness across many phyla, including corals. The differing z-values, or rates of increase, suggest different levels of connectivity may exist between the local and regional populations for different phyla. Deviations from the expected species-area relationship for corals (e.g. residuals) were positively related to the number of years since volcanic activity has occurred. At a minimum, the presence of a favorable foundation is required for sustained coral growth, while coral populations and reef diversity rise on large islands that are less influenced by freshwater and volcanic disturbances. For the NMI specifically, the results provide a desirable context for developing management strategies to maintain and enhance the biological integrity of these remote islands.

## 10-30

**The Rise And Fall Of A Coral Reef Ascidian**

**Noa SHENKAR*[1]**, Omri BRONSTEIN[2], Yossi LOYA[1]

[1]Zoology Department, Tel Aviv University, Tel Aviv, Israel, [2]Tel Aviv University, Tel Aviv, Israel

Although ascidians constitute a minor benthic component on exposed surfaces on natural coral reefs they play an important role in the carbon and nutrients cycles in coral reef ecosystems. Eutrophication of these ecosystems may result in vast changes in the densities and distribution of colonial ascidians and their interaction with benthic biota. In the coral reefs of Eilat, a new colonial ascidian, *Botryllus eilatensis*, has been observed rapidly colonizing artificial substrates and overgrowing dead coral skeletons. Monthly monitoring of 50 - 70 tagged coral colonies interacting with *B. eilatensis* was conducted in order to study overgrowth dynamics and the relationship between coral morphology, size, and orientation and ascidian overgrowth. Results show that the rate of *B. eilatensis* overgrowth was influenced by the coral's morphology and orientation combined with a seasonal appearance of the ascidian. During spring (April - June) the average ascidian cover percentage was 27 ± 4.6 %; decreasing rapidly during summer months. This seasonality is linked to the vertical mixing phenomenon that occurs in Eilat every winter. This was corroborated when *B. eilatensis* fragments translocated to a nutrient rich site were observed to increase three fold in size and exhibited higher survivorship rates in comparison to the intact fragments remained in a reference site. Increased anthropogenic activity, particularly the eutrophication occurring along the Israeli coasts, creates favorable conditions for filter-feeding organisms such as ascidians, providing them with an advantage in competition for space with reef-building corals and other organisms.

## 10-31

**Population Dynamics Of The Corkscrew Anemone Bartholomea Annulata On Caribbean Coral Reefs: Implications For Anemoneshrimp Symbionts And Fish Cleaning Stations**

**Michael NELSEN*[1]**, Stephen RATCHFORD[2], Nanette E. CHADWICK[1]

[1]Auburn University, Auburn, AL, [2]University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.)

Large sea anemones are conspicuous components of coral reef communities, yet little is known concerning their population dynamics. On Caribbean coral reefs, the corkscrew anemone Bartholomea annulata hosts an assemblage of obligate shrimp symbionts, some of which are important cleaners of parasites from large reef fish. Thus, the stability and recovery from disturbance of anemone host populations may impact the coral reef community at several trophic levels. During 2006-2008, we monitored the dynamics of populations of B. annulata at 2 coral reef sites near St. Thomas, US Virgin Islands. The abundance and body size of individuals both were significantly higher at an inshore than an offshore reef site. At both sites, recruitment was rapid and populations were extremely dynamic. Rates of growth and mortality decreased with body size; small individuals tended to either grow rapidly or die, while large individuals either shrank or did not change in size, and rarely died. Some individuals in all size classes reproduced asexually to produce small buds (clonal replicates), resulting in a rapid potential expansion of populations. We applied matrix modeling and sensitivity analyses to determine which life stage most impacted change in these populations. Based on these demographic characteristics, we also provide recommendations for the support of a sustainable fishery on these anemones, which are heavily collected for the ornamental aquarium trade. We conclude that rapid population turnover in this sea anemone leads to radiating effects on the stability of obligate anemoneshrimps and the location of fish cleaning stations on Caribbean reefs.

## 10-32

**What Is The Future Of The Threatened *acropora Palmata*? Population Projections And Management Recommendations**

**Tali VARDI*[1]**, Dana E. WILLIAMS[2,3], K. Lindsey KRAMER[4]

[1]Scripps Institution of Oceanography, La Jolla, CA, [2]Cooperative Institute for Marine and Atmospheric Studies, University of Miami RSMAS, Miami, FL, [3]Southeast Fisheries Science Center, NOAA Fisheries, Miami, [4]Pacific Island Network Inventory and Monitoring Program, National Park Service, Kailua-Kona, HI

*Acropora palmata* was once the dominant hermatypic coral in shallow reef environments throughout the Caribbean, Florida, and Bahamas. Since the 1980s it has suffered a 97% decline in abundance throughout its range and was included on the US Endangered Species List in 2006. Despite the dramatic nature of this decline, and the loss of habitat that would be caused by an extinction, neither abundance nor rates of decline have been documented systematically throughout the Caribbean. In Autumn 2007, abundance of *Acropora palmata* was estimated in Florida, Puerto Rico, Jamaica, Virgin Gorda, and Curaçao. Abundance in Florida was dramatically lower than in other sites. The scarcity of *Acropora palmata* in Florida is explained by increased hurricanes and disease, problems that are difficult to manage. To explore population changes in more detail and to help identify life history stages most affected, a size-based population model was developed. Based on *Acropora palmata*'s population trajectory since 2004, as measured by a standardized, size-based demographic monitoring protocol in the Florida Keys, the local population will reach a stable distribution in 20 years. At that time, the current population structure, in which 35% are pre-reproductive and 45% are reproductive, will have become dominated by pre-reproductive individuals and only 20% of colonies will reproduce sexually. This loss of large individuals would also reduce the number of asexually derived fragments, leading to an overall decrease in abundance of colonies in Florida. Parallel data from the island of Curaçao from 2006-7, show both a greater overall abundance of *Acropora palmata* and no significant change in the relative abundance of larger individuals. Significant changes in size distribution can warn of impending phase shifts. These results suggest that determining and eliminating the causes of mortality in large adults are key conservation priorities for Florida reefs.

## 10-33

**Testing A Novel Functional Group Approach For Caribbean Hard Corals By Comparing Their Rank Abundances Across The Florida Reef Tract Also Refutes The Unified Neutral Theory**

**Thaddeus MURDOCH*[1,2]**, Richard ARONSON[3,4]

[1]BREAM: Bermuda Reef Ecosystem Assessment and Mapping Programme, Bermuda Zoological Society, Flatts Village, Bermuda, [2]Murdoch Marine Environmental Consultant Services Ltd., Paget, Bermuda, [3]Marine Science, Dauphin Island Sea Lab, Dauphin Island, AL, [4]Marine Science, University of South Alabama, Mobile, Alabama

A functional group approach can be used to categorize organisms by adaptive traits instead of phylogeny. One such approach, the "Adaptive Strategies Theory" (AST), originally developed for terrestrial plants, was modified to apply to reef corals. The coral AST predicts the assemblage structure of Caribbean reef corals from fundamental habitat characteristics. Accordingly, species and functional groups of coral differ in dominance in a predictable manner, depending upon the levels of resource and disturbance of the habitat they are in. Alternatively, the unified neutral theory (UNT) proposes that all coral species are functionally equivalent, and the ranking of any species will be random from site to site, regardless of the environmental conditions of the reef habitat.

Examination of patterns of rank abundance across 10 transects on each of 20 sites located across the Florida Reef Tract, encompassing a quantified gradient of disturbance, determined that eleven species out of a pool of at least 36 species were highly significantly more abundant than the rest. These 11 abundant species belonged to three different functional groups, and, for these species, the species members of each functional group were statistically more similar in rank and site affinity than were species belonging to other functional groups. The rarer species, alternately, showed rank-abundances and distributions across transects that were without apparent pattern. The functional-group differences in rank-abundance were also highly non-random. The dominance patterns of each functional group relative to the level of disturbance measured on each of the 200 transects fit the predictions of the newly proposed coral AST. These results indicate certain traits indicate functional responses in corals, that all coral species are not equivalent in their functional responses. As a consequence, the fundamental hypothesis of the UNT that all species of coral are functionally identical is also refuted.

## 10-34

**Spatial Dynamics Of Scleractinian Coral Populations in The Florida Keys**

**Dione SWANSON*[1]**, Mark CHIAPPONE[2], Steven MILLER[2], Leanne RUTTEN[2], Steven G. SMITH[1], Jerald AULT[1]

[1]Marine Biology and Fisheries, University of Miami, Rosenstiel School of Marine and Atmospheric Science, Miami, FL, [2]Center for Marine Science, University of North Carolina-Wilmington, Key Largo, FL

Natural and anthropogenic disturbances have caused major changes in reef species composition worldwide during the past few decades resulting in significant decreases in coral cover and abundance. Traditional monitoring metrics such as percent coral cover and species richness have not provided an avenue to address the processes that contribute to these changes. Knowledge of population dynamics of corals is required to address questions concerning the sustainability of coral reefs. Colony density and size structure provide information on fundamental demographic rate processes (colony recruitment, growth, mortality, and survivorship) as well as the net outcome of these processes. To address coral population structure and recruitment in the Florida Keys, adult (colonies >4 cm in diameter) and juvenile (colonies < 4 cm diameter) abundance were estimated using a two-stage stratified random sampling survey design. Primary sample units (sites) were allocated among thirteen reef-types (habitat strata) within the Florida Keys reef tract (survey domain). Design features included strategic sampling that produced relatively precise population estimates and the ability to statistically compare multiple sites within and among benthic habitats over relatively broad spatial scales. From 1999-2006, surveys of coral colonies were conducted at sites which spanned the range of habitats along Florida Keys reef tract through the Dry Tortugas. Quantitative analyses addressed coral population structure in three categories: descriptive and species size analysis, coral-habitat regression analysis, and habitat use analysis. These results help to discern the influence of habitat type and location on demographic processes that regulate coral population size structure and facilitate inferences concerning the consequences of the current coral population distributions in the Florida Keys.

## 10-35

**Partial Mortality Of Caribbean Corals: Modes, Trends, And Consequences**

**Jessica GILNER*[1]**, Robert VAN WOESIK[2]

[1]Biological Sciences, Florida Institute of Technology, Melbourne Beach, FL, [2]Biological Sciences, Florida Institute of Technology, Melbourne, FL

Partial mortality leads to changes in life-history strategies and energetics, which can jeopardize colony fitness and survival. Increases in partial mortality of coral colonies are arguably the primary mechanism of declines in coral cover in the Caribbean. In 2005, an intense coral bleaching event was recorded on reefs at Puerto-Morelos, Mexico. We applied a hierarchical sampling design, using randomly selected 75 x 25 m stations as our effective sampling units nested within five sites spaced 1-2 km apart. Re-randomized 50 x 1 m belt transects were used to sample partial morality of coral colonies during and after the bleaching event. In 2006, three 4 x 4 m permanent quadrats were established at each station to track colony changes through time. In 2005, bleaching was recorded on 88% of surveyed colonies. Using the re-randomized sampling, there was an increase in the frequency of partial mortality from September 2005 to August 2007 in some species, while other species were less affected. The permanent quadrats detected different trends because of the manner in which corals undergo partial mortality. For example, *Diploria strigosa* and *Agaricia agaricites* are more likely to die at peripheral edges, while other species, such as *Porites astreoides* and *Siderastrea siderea* undergo patchy mortality within the colony. The former mortality process is more difficult to detect with one-off surveys, but are detectable when plots are examined over time; both processes lead to changes in size-frequency distributions. Partial–mortality trends do not appear to depend on reproductive strategies but rather the degree of colony integrity. Some species appear more vulnerable at the colony periphery, while others loose integration and are vulnerable throughout. While species-specific partial mortality serves as a reliable indicator of coral stress, there are clearly two different modes, and both are useful proxies of population dynamics.

## 10-36

**Spatial Aggregation Promotes Species Coexistence Of Reef-Building Corals**

**Joshua IDJADI*[1]**, Ronald KARLSON[1]

[1]Biological Sciences, University of Delaware, Newark, DE

Scleractinian coral species with varying competitive abilities often occur in communities where shared resources are limited. Despite this, these communities can be very diverse, without dominance by the best competitors. We experimentally tested the role of spatial heterogeneity, specifically the spatial arrangement of competitors, in promoting species coexistence among corals. Using a strong competitor (*Porites rus*) and a weaker one (*P. lobata*) we addressed the hypothesis that when corals are intraspecifically aggregated, coexistence is increased. When these corals were placed into artificial competitive neighborhoods, weaker competitors grew at almost twice the rate when they were grown in aggregated versus non-aggregated patterns. Further experimental work suggested that aggregation is most important when there is no refuge from competition for weaker competitors. The results of these experiments were extrapolated to larger spatial and temporal scales by a discrete space model. The persistence of weaker competitors was increased substantially when the beneficial effect of aggregation was applied to this model system. This research adds to evidence from other work in plant systems that spatial arrangement can promote species coexistence in competitive, resource limited communities.

## 10-37

**Fish Demography in The Large**

**Richard VANCE*[1]**, Mark STEELE[2], Graham FORRESTER[3]

[1]Ecology & Evolutionary Biology, UCLA, Los Angeles, CA, [2]Biology, California State University Northridge, Northridge, CA, [3]Natural Resources, University of Rhode Island, Kingston, RI

Effective management of commercial coral reef fish metapopulations will require creation of marine protected areas. Informed design of MPA's must employ demographic rate functions that drive fish metapopulation dynamics. Unfortunately, practical constraints usually force measurement of demographic rates on small portions of individual reefs, a spatial scale far too small to apply directly to metapopulations. Using these measurements therefore requires some way of "expanding" them to the spatial scale of entire large coral reefs.

This talk will describe a practical scaling-up procedure. We will show, for the bridled goby *Coryphopterus glaucofraenum* (a convenient non-commercially fished species) how a whole-reef density-dependent death rate function can be constructed from an empirically measured death rate function that applies at the local scale. The procedure employs a computer simulation model that follows the fates of individual gobies in all 2m x 2m cells of a large reef. The reef habitat varies spatially both in its local density of crevices that provide refuge from predators to goby adults and in the substrate's attractiveness to goby settlers. From simulated cell-level demographic data is calculated a whole-reef per capita death rate, and this rate is then statistically fitted to a function of whole-reef goby and refuge densities using maximum likelihood methods.

Density dependence at the whole-reef scale is highly statistically significant and can be described by a function whose form resembles that of the local-scale function. However, reef spatial heterogeneity forces some adjustment in parameters. Indeed, density dependence at the whole-reef scale actually proves stronger than at the local scale. We shall display how scaling up the death rate function is influenced by variability in local refuge density and in local settler attraction, by the correlation of these reef attributes, and by the spatial scale on which this habitat heterogeneity occurs.

## 10-38

**Large-Scale Experiment Reveals Effects Of Habitat Structure On Coral Reef Fish Assemblages**

**Mark STEELE*[1]**, Graham FORRESTER[2], Jameal SAMHOURI[3], Clare WORMALD[2]

[1]Department of Biology, California State University Northridge, Northridge, CA, [2]Department of Natural Resources Science, University of Rhode Island, Kingston, RI, [3]Northwest Fisheries Science Center, NOAA Fisheries, Seattle, WA

The structure of coral reef fish assemblages is usually strongly correlated with attributes of reef structure. Experimental studies on small patch reefs have improved our understanding of how certain attributes of reef structure (e.g., shelter hole size) influence these assemblages, but it is not clear if these results from small-scale experiments extrapolate to larger spatial and temporal scales. We manipulated the abundance of rubble habitat to evaluate how this shelter-providing habitat affected the structure of coral reef fish assemblages at large scales. We added several tons of limestone rubble and conch shells to one half of each of 5 large (3,000-15,000 $m^2$), isolated reefs near Lee Stocking Island, Bahamas. We tracked changes in the reef fish assemblage with underwater visual censuses over 4 years. On rubble addition halves of reefs, several species of small fishes (damselfishes, wrasses, and gobies) became more abundant, whereas several similar species in the same families were unaffected. Small-scale habitat associations and results of previous small-scale habitat manipulations generally did a good job of predicting which species would be affected by the habitat manipulation and which were not. Larger species (e.g., snappers, grouper, and squirrelfishes) were unaffected by the manipulation, presumably because they are not dependent on small crevices for shelter and their abundance is not influenced by the abundance of smaller potential prey species that increased as a result of the rubble addition. There was no strong evidence that any species was negatively affected by the habitat manipulation. Thus, our results indicate that assemblage structure can by altered by large-scale habitat manipulations, which increase the abundance of some habitat-dependent species, without unintended negative effects on other species.

## 10-39

**Extrapolating From Small-Scale Experiments: Predation And Refuge-Shortage in Coral Reef Fishes**

**Graham FORRESTER*[1]**, Mark STEELE[2], Jameal SAMHOURI[3], Richard VANCE[4]

[1]University of Rhode Island, Kingston, RI, [2]Biology, California State University Northridge, Northridge, CA, [3]NOAA Fisheries, Seattle, WA, [4]University of California Los Angeles, Los Angeles, CA

Although field experiments allow rigorous tests of ecological hypotheses, they are usually limited to small spatial scales. We often want to know if their findings extrapolate to larger scales, especially when seeking to apply their results to conservation and management. Experiments on small coral reef fishes (bridled gobies) occupying small habitat patches reveal that locally density-dependent mortality is inflicted by predators. As prey become crowded, they suffer a progressively increasing shortage of structural refuges. Consequently, goby mortality at small-scales is well described by a model in which vulnerability is proportional to the ratio of gobies to refuges. A manipulation of refuge abundance on entire reefs, which are the size of small marine reserves and approach the scale at which some reef fisheries operate, suggests that a similar interaction occurs at this much larger spatial scale. This result is in accord with a scaling model which indicates that the effects of refuge shortage on entire reefs can be extrapolated from the model describing goby vulnerability as proportional to the ratio of fish to refuges. In simple terms, the biological interactions causing density dependence scale up. Careful extrapolation from small-scale experiments identifying species-interactions may thus be possible, and so should improve our ability to predict the outcomes of alternate management strategies for coral reef fishes.

## 10-40

**Musical chairs: competition for unguarded refuges and density-dependent mortality**

**Jameal SAMHOURI*[1,2]**, Richard VANCE[3], Graham FORRESTER[4], Mark STEELE[5]

[1]Northwest Fisheries Science Center, NOAA Fisheries, Seattle, WA, [2]Department of Ecology and Evolutionary Biology, UC Los Angeles, Los Angeles, [3]Department of Ecology and Evolutionary Biology, UC Los Angeles, Los Angeles, CA, [4]Department of Natural Resources Science, University of Rhode Island, Kiingston, RI, [5]Department of Biology, California State University Northridge, Northridge, CA

Predation is widely recognized as a dominant structuring force in marine populations and communities. As a result, refuges that reduce predation risk can be an important limiting resource in prey populations, ultimately mediating the occurrence and strength of density-dependent mortality. On coral reefs, many fishes retreat to unguarded structural refuges, such as crevices under coral or other hard substrate, only in response to a predator strike. This behavior leads to a type of competition for refuges that resembles conceptually the childhood game of musical chairs: prey scramble to find a safe place to hide when threatened or attacked, and only when refuges are abundant relative to the number of retreating prey is it likely that individuals will successfully evade predation. We introduce a new mathematical function to describe the relationship between structural refuges, population density, and per capita mortality in bridled gobies (*Coryphopterus glaucofraenum*) under this form of competition. In this model, we assume that the proximate cause of all goby deaths is predation, a fixed fraction of individuals do not respond to predator strikes by retreating to structural refuges, and the remaining individuals are capable of seeking shelter in a fixed number of unguarded refuges when threatened or attacked. Therefore, the likelihood of an individual dying during a predation event is either constant and density-independent or directly proportional to refuge availability, and these two components of mortality are not additive. In comparison to conventional density-dependent mortality functions, our musical chairs function provides a much improved fit to available empirical data for bridled gobies. We suggest that the musical chairs function may have broad applicability to other coral reef fishes, and more generally, for species in which refuges from predation are a limiting resource but territorial refuge-guarding does not occur.

## 10-41

**Substrate Effects On Reef Fish Distribution**

**Karen NEELY*[1]**

[1]Ecology, Duke University, Beaufort, NC

Western Atlantic coral reefs host up to 750 species of fish. It has been hypothesized that substrate characteristics control the abundance and distribution of these fish, but this has traditionally been examined at a community level. I conducted a correlational study in Curacao, Netherlands Antilles, that addressed fish abundances at the level of species and age class. I also experimentally tested habitat preferences in two ways. Choice experiments on adults of common species determined the influence of live coral and rugosity in an isolated environment, while habitat preferences of adults and juveniles in a multi-species environment were tested using *in situ* artificial reefs that differed in live coral cover. As a whole, these studies showed rugosity to greatly affect total abundance and diversity, while live coral cover had a slight effect on these community parameters. However, this small effect of live coral masks large differences at the species and age class level. For coral cover and other measures of substrate, both positive and negative selections were seen among species, but these preferences did not follow a readily identifiable taxonomic or niche classification. Algae-feeding species within the genus *Stegastes*, for example, showed both positive and negative preferences for live coral. Ontogenetic changes in habitat preferences were also documented. These results suggest that changes in live coral cover on a reef would affect fish communities in ways not observable using the standard community measures of fish distribution.

## 10-42

**Competitive Displacement Vs. Habitat Structure: The Selection Agents That Shape Microhabitat Recognition Of A Damselfish Over Time**

**Mati HALPERIN*[1]**, Yehuda BENAYAHU[1]

[1]Department of Zoology, The George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel

The three-spot dascyllus, *Dascyllus trimaculatus* Rüppell, has generally been described as recruiting to sea-anemones. However, in a preliminary survey in Eilat, northern Red Sea, we recorded *D. trimaculatus* individuals mainly in branching coral colonies. Intrigued by the lack of *D. trimaculatus* juveniles in their typical microhabitat, we studied the fish abundance and distribution there through a survey of types of microhabitat and their structural features, in addition to a fish census, aimed at developing and experimentally testing a hypothesis regarding microhabitat preferences. We addressed the question of whether the distribution of *D. trimaculatus* is regulated by the presence of competitor fish species through mechanisms of displacement, or whether it is microhabitat-dependent, taking into account specific microhabitat recognition by damselfish at their various life stages. A distinct pattern of distribution of corals and damselfish was revealed, in which the marine lab site constituted the major habitat for *D. marginatus* while the jetty site hosted *D. trimaculatus.* We also found that it is the abundance of *Pocillopora* coral microhabitats that determines the population distribution of *D. trimaculatus* in Eilat. Consequently, it is suggested that the abundance and distribution of both *Dascyllus* species may follow the general pattern of the competition model, emphasizing their apparent need for specific microhabitats. In addition to the competitive displacement, which excludes *D. trimaculatus* individuals from their congeners' microhabitat (i.e. *Stylophora* colonies), and determines the population distribution at the microhabitat level, we also suggest that the specific recognition of a microhabitat by juvenile *D. trimaculatus* may play a major role in determining the distribution of its population at the macrohabitat level. The demographics of *Dascyllus* fish in Eilat may reflect a unique situation in which the selection forces of microhabitat recognition by *D. trimaculatus* have undergone alteration over time.

## 10-43

**Fish Grazers As Gatekeepers Of The Species Composition Of Coral Reefs**

**Paul YOSHIOKA*[1]**

[1]Marine Sciences, University of Puerto Rico, Mayaguez, Lajas, Puerto Rico

In this report I propose that intermediate-sized (about 15 cm long) fish mesograzers play a critical role in determining the species composition of sessile coral reef communities. Fish mesograzers include parrotfishes (Scaridae), wrasses (Labridae) and surgeonfish (Acanthuridae) that feed on small prey. I describe these fish as gatekeepers in the sense that they control the entry of small (newly recruited) prey individuals into coral reefs. In contrast, keystone grazers control the 'post entry' abundances of larger sized prey. The gatekeeper scenario is based on several well-recognized features of coral reef ecology: (1) Fish grazing has major impacts on overall abundances of benthic organisms; (2) Artificial substrates in tropical open coast habitats are often colonized by fouling communities characterized by species such as the octocoral Carijoa (Telesto) riisei, the sponge Tedania ignis, the tunicate Ascidea nigra and the anemone Aiptasia tagetes; and (3) Many prey species in coral reefs enjoy a refuge in size from grazers due to structural/chemical defenses. Differences between keystone and gatekeeper effects probably arise from features (2) and (3) because many fouling (and typical coral reef) species are vulnerable to gatekeepers when small and inconspicuous, but enjoy a refuge in size from keystone species when large. Due to these size-specific effects, assemblages of prey species controlled by gatekeepers and keystone predators will differ to some degree. Escape from gatekeeper grazing will also have indirect effects on community structure because of interactions (e.g., competition) among prey populations. From a more general perspective, both the gatekeeper and keystone concepts emphasize species-specific effects on prey populations. In addition, the gatekeeper scenario posits that the size of prey individuals also plays a key role in the ecological structure of coral reef communities.

## 10-44

**Coral Morphology Modulates The Benefits Of Resident Fishes To Coral Growth?**

**Andrew BROOKS*[1]**, Sally HOLBROOK[2], Russell SCHMITT[2], Hannah STEWART[3]

[1]Marine Science Institute, University of California, Santa Barbara, Santa Barbara, CA, [2]Department of Ecology, Evolution and Marine Biology, University of California, Santa Barbara, Santa Barbara, CA, [3]Friday Harbor Labs, University of Washington, Friday Harbor, WA

Hermatypic corals are functional mixotrophs that rely on water flow for the delivery of dissolved nutrients and prey. As the external morphology of individual colonies affects the rate of water flow through the colony, coral morphology may exert a strong influence on the flux of materials within the interior spaces of the colony itself. We explored the relationships between local water flow, abundance of resident fishes, external coral morphology and coral growth rates for a common species of branching coral, *Pocillopora eydouxi*, in lagoons of Moorea, French Polynesia. Colonies of *P. eydouxi* provide structural habitat and refuge space for a variety of reef fishes. In turn, these fishes may augment nutrient supply to their host coral while sheltering through the natural excretion of ammonia. To measure coral growth rates, we outplanted small coral nubbins into colonies of *P. eydouxi*. Mesh cages were used to exclude resident fishes from half of these colonies. Flow rates within host corals were measured using fluorescent dye and external morphology was quantified using digital photographs. Our experiments revealed that colonies of *P. eydouxi* containing resident fishes grew substantially faster than neighbors that did not. Coral growth rates were significantly correlated with within colony concentrations of ammonia. Our estimates of water flow within coral colonies indicated that this flow varied considerably among experimental colonies experiencing the same general flow regime, suggesting that coral morphology may modulate the effects of resident fishes on coral growth rates by influencing the overall flux of nutrients within a coral colony.

## 10-45

**Interactions Among Inhabitants Of Branching Coral: Multiple Predator Or Competitor Effects?**

**Russell SCHMITT*[1]**, Sally HOLBROOK[1], Andrew BROOKS[2], Jennifer LAPE[1]

[1]Ecology, Evolution & Marine Biology, University of California Santa Barbara, Santa Barbara, CA, [2]Marine Science Institute, University of California Santa Barbara, Santa Barbara, CA

The ability to forecast change in coral reef communities requires sufficient understanding of how multiple factors operate together, yet the complexity of real systems often is simplified by lumping species into such functional groups as predators or competitors. Oversimplification can obscure important influences on the strength of interactions, such as non-additive effects of multiple predators (MPEs) on shared prey that can either reduce or enhance their mortality risk. In French Polynesia, we explored interactions involving two putative predators (arc-eye hawkfish *Paracirrhites arcatus*, red-spotted coral crab *Trapezia rufopunctata*) and several damselfishes (*Dascyllus flavicaudus*, *D. aruanus*, *Chromis viridis*). Field and laboratory observations revealed that both hawkfish and coral crabs were capable of capturing and consuming recently settled damselfish. Because these species all use the branches of the coral *Pocillopora eydouxi* as shelter from 'external' predators, the hawkfish, coral crabs and damselfishes also may be competitors for enemy-free space. A survey suggested that the density of damselfish on *P. eydouxi* was reduced in the presence of either an arc-eye hawkfish or red-spotted coral crab. A field experiment confirmed that both hawkfish and coral crabs reduced survivorship of recently settled damselfish, and that their combined per capita effects were additive. Additivity occurred because the strongest effect of these species on damselfish was from competition for enemy-free space that increased their vulnerability to external predators; only 25% of damselfish mortality attributable to hawkfish resulted from consumption by hawkfish, while none of the mortality caused by crabs resulted from predation by crabs. Hence, in this case, there were no emergent effects of multiple predators. These results underscore the need to understand the particular mechanisms by which species exert their influence on others.

## 10-46

**Indirect Effects On Coral Dynamics From Interactions Between Resident Fishes**

**Sally HOLBROOK*[1]**, Russell SCHMITT[1], Andrew BROOKS[2]

[1]Ecology, Evolution and Marine Biology, UCSB, Santa Barbara, CA, [2]Marine Science Institute, UCSB, Santa Barbara, CA

Mortality rates of coral often scale inversely with colony size, and hence factors that enhance the growth of smaller, more vulnerable size classes can be important to the dynamics of coral populations. In a field experiment, we found that branching coral in the genus *Pocillopora* grew a third faster when a colony was occupied by a group of damselfishes; the amount of growth enhancement varied positively with the number (biomass) of resident damselfish. We undertook field studies to determine what influences the occurrence of damselfish groups on *Pocillopora* in Moorea, French Polynesia. Field surveys revealed three distinct fish occupancy patterns that were related to coral size: (1) no coral <40 cm in circumference was occupied, (2) intermediate-sized corals (40–75 cm) hosted either a group of damselfish or a single arc-eye hawkfish (*Paracirrhites arcatus*, a predator of small damselfish), and (3) >80% of large corals (>75 cm circumference) hosted a group of damselfish, more than half of which also had co-occurring hawkfish. Field experiments and observations revealed that arc-eye hawkfish could prevent the establishment of a damselfish group on intermediate-sized corals by suppressing recruitment of young damselfish (reducing settlement rates, increasing early mortality rates). By contrast, hawkfish could not stop groups of damselfish from colonizing larger corals because they could not prevent immigration of older (larger) damselfish and they appeared less efficient at reducing larval recruitment in large corals. Thus the growth - and perhaps survival - rates of intermediate-sized *Pocillopora* can be influenced substantially by a small piscivore. These results indicate that biotic interactions among species of fish that use corals as habitat can have substantial but non-obvious indirect effects on the dynamics of corals.

## 10-47

**Recruitment And Population Dynamics Of A Coral-Reef Fish: A Large-Scale Long-Term Field Experiment**

**Mark HIXON*[1]**, Todd ANDERSON[2], Kevin BUCH[3], Darren JOHNSON[4], Christopher STALLINGS[5]

[1]Department of Zoology, Oregon State University, Corvallis, OR, [2]San Diego State University, San Diego, CA, [3]Texas A&M University at Galveston, Galveston, TX, [4]Oregon State University, Corvallis, OR, [5]Florida State University, St Teresa, FL

The relationship between the input of newly settled recruits and post-settlement demographic rates in populations of coral-reef fishes is complex, and has thus been controversial. To examine this relationship at the spatial scale of entire local populations and the temporal scale of entire generations, we conducted an 8-year field experiment in the Bahamas. First, from 1998 to 2002, we monitored demographic rates (recruitment, survival, growth, and egg production) in four populations of the bicolor damselfish (*Stegastes partitus*). During this 4-year baseline period, two "near sites" adjacent to the Exuma Sound source of larvae exhibited relatively high recruitment rates and largely density-dependent dynamics. In contrast, two "far sites" located some 20 km from the Sound on the Great Bahamas Bank exhibited low recruitment and density-independent dynamics, in accordance with the "recruitment limitation" hypothesis. Second, during four consecutive recruitment seasons (2002-2005), we reduced recruitment 10-fold at one near site by removing new recruits as they settled, and bolstered recruitment 10-fold at one far site by transplanting new recruits. We continued demographic monitoring at all four sites into 2006. Examining all 8 years, population dynamics remained mostly density-dependent (compensatory) at the near sites, yet became inversely density-dependent (depensatory) at the far sites. The cause of depensation appears to have been a combination of relatively low habitat complexity and high physical (including hurricane) disturbance at the far sites, such that new recruits suffered higher mortality rates at lower densities. We conclude that a combination of factors, rather than larval supply alone, determines the level and kind of dependence on population density exhibited by demographic rates.

## 10-48

**Habitat Competes For Fish Larvae: Increased Fish Production Despite Settlement Redirection**

**Adrian STIER*[1]**, Craig OSENBERG[2]

[1]Zoology, University of Florida, Gainesville, FL, [2]University of Florida, Gainesville, FL

Declines in the quality and quantify of coral reefs can decrease the abundance and diversity of the organisms that dependent on the reef habitat. As a result, coral reef restoration (e.g., via deployment of artificial reefs or coral fragments) has been proposed to reverse long-term degradation. The effect of new habitat remains unclear, primarily because added habitat may simply redistribute individuals, rather than increasing the regional size of a population. This uncertainty has led to the "attraction-production" controversy. Redirection alone does not increase production; it just redistributes it. However, if fish compete, then redistribution of larvae can enhance regional populations by lowering densities on existing reefs and thereby reducing the effect of density on post-settlement survival. Settlement redirection has never been previously tested in a field experiment. Thus, we designed a field experiment to quantify the degree to which new habitat increases settlement (or redirects it). Addition of new habitat increased total settlement, but decreased density. However the effect on settlement was much less than expected based on the increase in reef habitat: habitat increased 6-fold, but settlement increased less then two-fold. Thus, settlers are redirected to new habitat, but total settlement increases, and local density decreases. Based on the observed strength of density-dependence in these systems, we demonstrate how habitat addition should lead to a reduction in density, an increase in regional density, and a significant increase in fish production by ameliorating negative effects of density.

## 10-49

**Interactive Effects Of Competition And Microhabitat On Juvenile Survival in A Coral Reef Fish**

**Mary BONIN*[1,2]**, Glenn ALMANY[1,2], Maya SRINIVASAN[2], Geoffrey JONES[1,2]

[1]ARC Centre of Excellence for Coral Reef Studies, Townsville, Australia, [2]Marine and Tropical Biology, James Cook University, Townsville, Australia

Microhabitat type and competition for preferred microhabitats can influence patterns of abundance and mortality in coral reef fish communities, however the relative influence and interaction between these two factors is not well understood. In Kimbe Bay, Papua New Guinea, we used surveys to quantify microhabitat use in two live-coral specialist damselfishes (Pomacentridae), *Chrysiptera parasema* and *Dascyllus melanurus*. We then used a patch reef experiment to test how intra- and interspecific competition interacts with two types of microhabitat to influence survival of juvenile *C. parasema*. Surveys demonstrated that *C. parasema* and *D. melanurus* utilize similar coral microhabitats; 72% of *C. parasema* and 85% of *D. melanurus* used corymbose and bottlebrush growth forms of *Acropora*. One microhabitat type, *Pocillopora* spp. coral, was used by *D. melanurus* but not *C. parasema*. The patch reef experiment revealed that microhabitat type had the strongest influence on survival of *C. parasema*. In the absence of interspecific competitors, approximately 90% of *C. parasema* survived for 5 days after transplantation to bottlebrush *Acropora* compared to only 30% survival on *Pocillopora*. In both microhabitats, interspecific competition with *D. melanurus*, but not intraspecific competition, decreased survival of *C. parasema*. The interspecific effect of *D. melanurus* was greater in the more structurally-complex microhabitat; on *Acropora* reefs, interspecific competition resulted in a 34% decrease in *C. parasema* survival compared to 19% on *Pocillopora* reefs. This study demonstrates that interspecific competition and microhabitat type can interact to influence survival in coral reef fishes, though whether and how these factors influence survival will depend on the behavioural attributes and strength of habitat associations among potential competitors.

## 10-50

**Differential Effect Of Early Post-Settlement Processes On The Abundance Of Two Concurrently Settling Coral Reef Fishes**

**Henri VALLES*[1]**, Donald KRAMER[1], Wayne HUNTE[2]

[1]Biology, McGill University, Montreal, QC, Canada, [2]Biology, University of the West Indies, Cave Hill, Barbados

To examine the magnitude, spatial variability and causes of early density-independent (DI) and density-dependent (DD) post-settlement losses in coral reef fishes, we monitored density of *Sparisoma* (Scaridae) and *Stegastes partitus* (Pomacentridae) on three reefs in Barbados (West Indies) for 3-3.5 months following a period of high recruitment and fitted the data to a modified Beverton-Holt model. To assess whether surveys missed early DD mortality, we compared recruitment on reefs to that on standard monitoring units (SMURFs) that excluded predators. Recruitment was >11x (*Sparisoma*) and >3x (*S. partitus*) greater than the initial number of large juveniles/ adults. Mortality was very high (*Sparisoma* 97%; *S. partitus* 91%), indicating that post-settlement processes were more important than settlement in determining local density. Mortality did not vary significantly across sites. After 3-3.5 months, *Sparisoma* densities were similar to those before recruitment. *S. partitus* densities increased, but increases did not match among-site differences in recruitment, indicating that post-settlement processes differed spatially. DI effects did not vary significantly between taxa or sites. DD effects were one order of magnitude higher for *Sparisoma* than for *S. partitus*, possibly due to lower availability of refuge microhabitat for *Sparisoma*. DD effects varied significantly across sites for *S. partitus*, but not *Sparisoma*, perhaps because of lower precision in density estimates for *Sparisoma*. Among-site differences in DD effects for *S. partitus* were associated with differences in recruitment rates and substrate. Predator density was similar across sites. Recruit density on the reefs mirrored captures in SMURFs, indicating that surveys did not miss important DD predation. Our findings suggest that substrate influences rates of DD mortality and therefore local population dynamics, but with markedly different strength for different taxa.

## 10-51

**Living in a Washing Machine: Differing Capacities to Capture Prey Under Divergent Velocity/Turbulence Conditions Reflect Microhabitat Differences of Two Chaenopsid Blennies**

**Raymond CLARKE*[1]**, Christopher FINELLI[2], Edward BUSKEY[3]

[1]Department of Biology, Sarah Lawrence College, Bronxville, NY, [2]Department of Biology and Marine Biology, University of North Carolina Wilmington, Wilmington, NC, [3]The University of Texas at Austin Marine Science Institute, Port Aransas, TX

Wave-generated oscillating water flow on coral reefs creates a challenge for the fishes that live there, but it also creates opportunities. Roughhead blennies (*Acanthemblemaria aspera*) and spinyhead blennies (*A. spinosa*) live in holes in dead coral skeletons from which they make rapid forays to capture passing prey, primarily copepods. On coral reefs throughout the Caribbean, spinyheads occupy locations in tall corals while roughheads reside close to the reef surface. Spinyheads have metabolic rates 1.5 times higher than those of roughheads. Our study involves (1) measuring water speeds and flow patterns both generally and within blenny feeding volumes, (2) videotaping blennies feeding in the field and (3) studying blenny feeding patterns and success in flumes. The flume studies include wild-caught calanoids (*Acartia tonsa*) as prey and water flow regimes that replicate those measured in the field. Spinyheads experience greater velocity and turbulence and possess a more fixed attack pattern, focusing primarily on planktonic prey whereas roughheads feed primarily on benthic prey but periodically shift to planktonic prey under low flow conditions. Spinyheads attack at greater distances and at greater rates under all conditions. Both species attack more frequently during the slack stage of the wave cycle, but spinyheads attack over a greater proportion of the wave cycle than do roughheads. Spinyheads also have greater capture success than roughheads under fast smooth flow and all turbulent water conditions. These data reveal in some detail the ways in which these blennies are adapted to different microhabitats thus facilitating coexistence in the same reef zones.

## 10-52

**Micropredator Gnathiid Isopods Reduce Larval Damselfish Persistence By Affecting Performance**

**Alexandra GRUTTER*[1]**, Angela CREAN[1], Lynda M CURTIS[1], Armand M KURIS[2], Robert R WARNER[2], Mark I MCCORMICK[3]

[1]School of Integrative Biology, The University of Queesland, St. Lucia Queesland, Australia, [2]Ecology, Evolution, and Marine Biology, Univeristy of California Santa Barbara, Santa Barbara, CA, [3]ARC Centre of Excellence for Coral Reef Studies and School of Marine and Tropical Biology, James Cook University, Townsville Queensland, Australia

Traditional hypothesis for the pelagic phase of demersal coral reef fishes are not strongly supported by the data. An alternative hypothesis is that they migrate to the pelagic environment to disrupt or avoid transmission of infectious agents. On the Great Barrier Reef, gnathiid isopods (mobile micropredators) are one of the most common ectoparasites of fish. Gnathiid effects on small fishes were used as a model for the consequences of keeping larvae on the reef. Nothing is known of how gnathiids affect the performance and survival of juveniles in the wild. We therefore tested the effect of gnathiids on the swimming performance, oxygen consumption, and survival of the common damselfish *Pomacentrus amboinensis* in nature. Of juvenile fish sampled at dawn and during the day, 3.5% and 0% had a gnathiid respectively, however, this difference was not significant. In the laboratory, most gnathiids (79%) remained attached to juvenile fish for up to 6 h and all fish survived exposure to the gnathiids. When tested in pairs in a double-laned swim chamber, settlement-stage fish that had previously been fed on by a gnathiid ceased swimming first in 77% of the trials. They also had a 14% lower critical swimming speed compared to fish not exposed to a gnathiid. Previously parasitized settlement-stage fish had a 32% higher oxygen consumption rate than did unexposed fish. When tagged settlement-stage fish were placed in pairs on dead coral patches in the wild and monitored, the previously parasitized fish disappeared from the reef first in 67% of the trials. Our analysis indicates that gnathiid isopods significantly decrease the performance of young *P. amboinensis*. This may affect their survival and successful establishment on the reef. Micropredation by gnathiids may therefore contribute to selection pressure for a pelagic stage.

## 10-53

**Does Behaviour Mediate The Costs And Benefits Of Fast Growth? An Example in A Marine Fish, *pomacentrus Amboinensis***

Corinna VON KUERTHY[1], **Mark MEEKAN*[2]**, Mark MCCORMICK[3]

[1]University of Kiel, Kiel, Germany, [2]Darwin Office, Australian Institute of Marine Science, Brinkin, Australia, [3]School Marine and Tropical Biology, James Cook University, Townsville, Australia

Body size is a central determinant of survival, fecundity and competitive ability. Fast growth, resulting in large body size, can be beneficial so we might expect that individuals that are capable of maximising growth to attain the greatest body size will be favoured by selection. However, in the field, maximal growth is found only rarely. It has been suggested that trade-offs between the costs and benefits of growth are mediated by behaviour, whereby rapid growth is associated with greater predation mortality due to increased foraging effort. Here, test this hypothesis by examining the behaviour, growth and survivorship of a common reef fish, *Pomacentrus amboinensis* at Lizard Island on the Great Barrier Reef (GBR) during the first month of settlement on the reef. We collected young fish using light traps settled them onto small artificial reefs where their behaviour and survivorship was monitored for 24 hrs. One month later individuals of the same cohort were collected from shallow reefs and distributed on the same artificial reefs. Their behaviour and survivorship was monitored for 6 d. Size-at-age and growth rates of surviving fish in both experiments were reconstructed using the records stored within the otoliths or earbones of the juvenile fish. At settlement young fish suffered high mortality that preferentially removed larger, faster-growing individuals. However, we could not find any evidence that the foraging behaviour of these larger fish contributed to this pattern of selective mortality. In contrast, one month after settlement the same cohort of fish underwent negative size selective mortality where the smallest, slower-growing fish were preferentially removed by predators. Larger fish spent more time foraging and were more aggressive than smaller individuals. These results are discussed in the context of current views of the role of behaviour in mediating patterns of selective mortality in prey species.

## 10-54

**Microhabitat Specialisation, Recruitment And Coral Decline: Population Responses in Two Coral Reef Fish Families**

**Maya SRINIVASAN*[1]**, Geoffrey JONES[1], Mark MCCORMICK[1]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia

Many marine species are undergoing long-term changes in abundance in response to habitat degradation. While recruitment is known to be a primary driver of the temporal and spatial dynamics of coral reef fish populations, its role in determining responses to habitat change is poorly understood. Here we examined microhabitat use of recently settled reef fishes in Kimbe Bay (PNG), focussing on family-level patterns for the two most common reef-associated taxa, the damselfishes (Pomacentridae) and wrasses (Labridae). We also investigated the influence of microhabitat specialisation at settlement on temporal patterns in adult abundance following a decline in coral cover. The majority of species were strongly associated with a narrow range of microhabitats. Both live branching corals (particularly Acropora and Pocillopora spp.) and dead substrata were preferred recruitment microhabitats for different species. A decline in coral cover between 1997 and 2002 resulted in population declines of 75% of the common reef fish species. Wrasses exhibited the greatest range of responses, including increases, declines and stable populations, while the majority of damselfish species declined. The magnitude and direction of the long-term change in fish abundance was inversely correlated with the degree of association between recruits and live branching corals. For a given level of live coral dependence, the magnitude of decline was greater among the damselfishes than the wrasses. This may be explained by a comparison of recruit-adult relationships among species and between the two families, which established that a given average density of recruits resulted in greater average densities of adult damselfishes, compared with wrasses. The family-level differences between damselfish and wrasses may reflect fundamental differences in their life history traits, reliance on living corals and the carrying capacities of the habitat.

## 10-55

**Is Bigger Really Better? Investigating The Size Selectivity Of Predation On Newly Settled Coral Reef Fishes**

**Thomas HOLMES*[1,2]**, Mark MCCORMICK[1,2]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [2]Australian Research Council Centre of Excellence for Coral Reef Studies, Townsville, Australia

Recent evidence suggests that the early post-settlement period of coral reef fishes may be critical in determining the size and structure of adult fish populations. Predation by small site associated predators has been shown to be responsible for a majority of mortality during this period, and the relative body size of predator and prey is generally regarded as one of the most important characteristics influencing the outcome of such events. This study investigated the size selectivity of four predator species known to be responsible for a majority of predation on early post-settlement reef fishes at Lizard Island, northern Great Barrier Reef, Australia. Additionally, it examined how size selectivity changed with predator ontogeny. Using aquarium based predator trials, selectivity was examined for both the size range of prey at the time of settlement, and for the size range over the early juvenile period immediately following settlement. The intensity and direction of size-selection was found to differ greatly between the predator species. During the 'settlement stage' trials, distinctive preferences towards either large or small prey size classes were observed for some predator species, whilst others were more 'generalist' in their prey choice. During 'early juvenile' trials all predator species generally chose smaller size classes, although the intensity of this selection varied. Selectivity was not found to differ with changing predator body size. This research shows that larger size at the time of settlement does not necessarily convey a survival advantage during predatory interactions. However, larger size does become a clear advantage as an individual passes into the early juvenile stage. These selective patterns are thought to be driven by a combination of prey behaviour, and species specific predator behaviours, predation modes and gape size.

## 10-56

**Carry-Over Effects – The Importance Of A Good Start**

**Mark MCCORMICK*[1]**, Monica GAGLIANO[1]

[1]Marine and Tropical Biology, James Cook University, Townsville, Australia

Complex life cycles are common in marine organisms and success at each life stage depends upon individuals exhibiting the best series of performance traits to meet the challenges of their current environment. High performance in one stage does not guarantee success in another. Despite the potential for conflicting selective forces on sequential life stages, recent evidence emphasizes the importance of interconnections between survival traits among life stages. This presentation reviews recent studies of carry-over effects for marine fishes and emphasizes the overwhelming importance of previous growth history in biasing later survival and reproductive success. Research also stresses the importance of non-genetic maternal effects in affecting offspring success.

## 10-57

**A Comparison Of Rates And Structure Of Social Foraging Interactions in Coral Reef Fishes**

Kimberly BARBER[1], **Peter AUSTER*[1]**

[1]University of Connecticut, Groton, CT

We compared the rates and structure of social foraging groups at reef sites in the Gulf of California, off Bonaire in the Caribbean Sea, and on the Great Barrier Reef. Data were collected on number and composition of social foraging groups and background community composition. While on a regional scale species richness varied (i.e., Coral Sea > Caribbean > Gulf of California), comparisons of local community diversity and diversity of species participating in social foraging groups were not statistically different. Approximately 50% of species in local communities participated in social foraging. Sixteen to 30% of species participated in single species groups while 31%-46% of species participated in mixed species groups. Most groups, whether single or mixed-species, were composed of 2-9 individuals. Rates of social foraging varied with a mean of approximately 7 bouts per survey at Gulf of California and Caribbean sites, while only 4 bouts per survey were observed at Coral Sea sites. Interaction strengths between social foragers were "mapped" using cluster analysis and similarity levels were indicative of the consistency of such interactions. Mixed-species foraging groups observed at Gulf of California and Caribbean sites had highly mixed trophic guild composition while those at Coral Sea sites were composed primarily of species within single trophic guilds. Our results demonstrate the extent of social foraging interactions across a wide geographic range and infer a level of importance yet to be defined for the role such positive species interactions play in mediating local community structure and diversity.

## 10-58

**Short-term effects of the invasive Indo-Pacific lionfish (*Pterois volitans/miles* complex) on Bahamian coral-reef fish abundance and diversity**

**Mark A. ALBINS*[1]**

[1]Department of Zoology, Oregon State University, Corvallis, OR

Caribbean coral-reef communities have been substantially degraded over the last several centuries by numerous natural and anthropogenic disturbances. These communities now face a new threat: the invasive Indo-Pacific lionfish. Lionfish are voracious predators with defensive venomous spines. Using oversized, ornate pectoral fins, they herd and ambush small reef fishes and crustaceans, a novel strategy in the invaded system. Since 2005, we have observed increasing densities of lionfish at multiple study sites within Exuma Sound, Bahamas. During the summer of 2007, we initiated a combination of observational and experimental investigations to determine the effects of this invasive predator on native coral-reef fish communities. We observed a high rate of lionfish recruitment (*ca.*16 fish ha-1day-1) to a matrix of artificial (concrete-block) and translocated (live-coral) patch reefs over the summer recruitment period. Stomach-content analysis in combination with aquarium feeding observations confirmed that lionfish prey on a wide variety of native animals, including bony fishes and crustaceans, and that lionfish are capable of consuming large numbers of prey, as well as large prey relative to their body size. We ran a controlled experiment (lionfish present *vs*. absent) using a matrix of artificial and translocated patch reefs to examine the effects of lionfish on the survival of small reef-fishes. Reefs were censused at one-week intervals for a period of five weeks during the height of the summer recruitment season. Although lionfish affected the abundance of species differentially, the mean abundance and species diversity of small reef-fishes (<5 cm TL) was significantly reduced on lionfish reefs relative to control reefs over the experimental period. We conclude that invasive lionfish have substantial negative effects on the local abundance and species diversity of small, native, coral-reef fishes over short time scales.

## 10-59

**Mutualism, Aggregation And Predation Result in Behaviorally-Mediated Indirect Interactions On A Coral Reef**

**Thomas ADAM*[1]**

[1]Ecology, Evolution and Marine Biology, University of California, Santa Barbara, Santa Barbara, CA

Indirect interactions (eg., trophic cascades) are ubiquitous on coral reefs and can be transmitted through changes in behavior as well as changes in density. Here, I explore possible behaviorally-mediated indirect interactions resulting from a common mutualism on coral reefs where cleaner fish are visited by client fish for the removal of ectoparasites. Because client fishes include predators and herbivores that can alter the demographic rates of reef residents, cleaners are likely to have indirect effects on these residents by attracting and concentrating clients that may browse or graze nearby when visiting cleaner stations. I present results from field observations and experiments conducted in Moorea, French Polynesia, demonstrating that bluestreak cleaner wrasse (*Labroides dimidiatus*) are attracting corallivorous butterflyfishes (Chaetodontidae) to cleaner stations, and by doing so have a negative indirect effect on the growth rate of a common branching coral (*Porites rus*). In addition, herbivorous surgeonfishes (Acanthuridae) aggregate near cleaner stations, and consequently more algae are grazed in these areas. However, unlike butterflyfish, the greater abundance of surgeonfish at cleaner stations appears to result largely from overlapping habitat preferences between surgeonfish and cleaners. Thus, while cleaners are indirectly responsible for decreased growth rates of *Porites rus* at cleaner stations, morphological characteristics of coral colonies, rather than cleaners, result in an indirect effect on algae. These results highlight the potential for cleaners (and coral colonies) to create spatial heterogeneity in predation pressure and emphasize the need to incorporate knowledge about reef fish behavior into our understanding of community processes on coral reefs.

## 10-60

**Partitioning of coral defense by exosymbiotic crustaceans**

**Seabird MCKEON*[1]**, Adrian STIER[2], Shelby BOYER[3]

[1]Florida Museum of Natural History/Deparment of Zoology, University of Florida, Gainesville, FL, [2]Zoology, University of Florida, Gainesville, FL, [3]Moss Landing Marine Laboratories, Moss Landing, CA

Much of early ecological research focused on the role of negative interactions among organisms (e.g. competition and predation); more recently ecologists have become aware of the importance of positive interactions such as facilitation and mutualism. As diverse ecosystems, coral reefs serve as models for understanding the complexities of symbiosis; mutualisms in this system have previously been oversimplified and viewed as interactions between pairs of species, instead of guild-guild interactions. Studies of the obligate crustacean exosymbionts of the branching corals Pocillopora have previously identified these symbionts as mutualists, identifying their defensive and sediment-clearing capabilities on a species level, but ignoring the interactions among resident crustaceans. This type of simplified approach is present in many systems and has hindered our understanding of the importance of mutualism in many systems including the coral reef environment. Here we experimented on the role of the exosymbiotic crustacean guild, quantifying the defensive efficacy of both crab (Trapezia sereni), and shrimp symbionts (Alpheus lottini) in response to a common corallivorous seastar predator (Culcita novaeguineae). Our trials tested the effectiveness of these crustaceans both independently and in combination in a series of choice, no-choice, and behavioral experiments. The presence of any of the symbionts (T.serenei, A.lottini or both) consistently lowered the frequency of attack, but only the presence of both exosymbionts significantly reduced the amount of coral consumed by a corallivorous seastar. Defense of the coral host by both the shrimp and the crab increased coral survivorship - a result likely to have far reaching effects on the demography of host Pocillopora. These results demonstrate that the benefits provided to the host by the guild of crustacean exosymbionts are additive in nature- and provide more effective protection than one species alone.

## 10-61

**Sediment Removal By Crabs Maintains Health Of Young Corals**

**Hannah L. STEWART*[1]**, Nichole N. PRICE[2], Sally J. HOLBROOK[2], Russell J. SCHMITT[2], Andrew J. BROOKS[3]

[1]Friday Harbor Labs, University of Washington, Friday Harbor, WA, [2]Ecology, Evolution and Marine Biology, University of California, Santa Barbara, Santa Barbara, CA, [3]Coastal Research Center, Marine Science Institute, University of California, Santa Barbara, Santa Barbara, CA

Increasing threats to tropical reefs from long-term climate change and human land use render it critical to understand how stony corals, the foundational species of reef ecosystems, respond to such perturbations. Corals form habitat for other species, so it is necessary to understand the influence of associated organisms in mediating responses to perturbation. We show the importance of an association with trapeziid crabs (genus *Tetralia*) in reducing adverse effects of sediments deposited on coral for small (<12cm diameter) and juvenile (<3cm diameter) branching corals. In field experiments, mortality rates of both sizes of corals were significantly lowered by the presence of crabs. All outplanted corals with crabs survived whereas 45 - 80% of small corals without crabs died within a month, and 80% of juvenile corals were dead after 1 year. For surviving corals that lacked crabs, growth was slower and tissue bleaching and sediment load were higher. Laboratory experiments revealed that corals with crabs shed substantially more of the sediments deposited on coral surfaces, but also that crabs were most effective at removing grain sizes that were most damaging to coral tissues. The proportion of juvenile corals with crabs increased as a function of coral volume and branch number, indicating that certain morphological criteria must be met before a crab will associate with a coral, and that the presence of a crab in turn results in increased volume and growth of host corals. Field surveys indicated crab-coral associations are ubiquitous (>90% of corals harbor crabs) and this work shows they are important to the early life stages of corals, particularly in areas of high sediment and low flow. The mechanism underlying this symbiotic relationship has not been recognized previously, and its role in maintaining coral health is likely to become even more critical as reefs worldwide experience increasing sedimentation.

## 10-62

**Direct, Species-Specific Impacts Of Sea Urchins On Live Corals**

**Wendy COVER*[1]**, Donald POTTS[1]

[1]Ecology and Evolutionary Biology, University of California, Santa Cruz, Santa Cruz, CA

Interactions between species can shape major processes and influence community structure on coral reefs. Sea urchins and corals are usually thought to interact through indirect processes, mediated either through herbivory on macroalgae or excavations beneath corals. Although bioerosional capabilities of urchins on dead carbonate substrates are well documented, direct impacts of urchins on live coral tissue are rarely reported. We investigated the potential for direct urchin predation on live coral, and whether such interactions vary by species of urchin and coral. We conducted experiments in the backreef of Midway Atoll (NW Hawaiian Islands) during 2006-2007 using three coral species (*Pocillopora ligulata*, *Montipora* c.f *turgescens*, and *Porites lobata*) and two urchin species (*Echinometra mathaei* and *Heterocentrotus mammillatus*), both with broad Indo-Pacific distributions. We epoxied coral fragments of each species inside channels created by bioerosional activities of the two urchin species. In half the plots we removed urchins, and in the other half they remained; we found impacts on corals in plots with urchins present that varied by urchin and coral species. Most fragments of all coral species placed in plots with *E. mathaei* present were grazed down increasingly over a period of several weeks, often resulting in a complete removal of coral tissue and skeleton. Fragments of *M*. c.f. *turgescens* were grazed down more quickly than those of *P. lobata*. Fragments in plots with *E. mathaei* removed and fragments in all *H. mammillatus* plots were unaffected over the course of the experiment. The influence of E. mathaei is spatially patchy, limited mainly to their bioeroded channels. We conclude that E. mathaei can exert a clear direct negative impact on live corals, and the rate and relative impact can vary by coral species, with implications for coral recruitment and community structure.

## 10-63

**Context-Dependency Of Growth And Predator Deterrence Of Caribbean Coral Reef Sponges**

**Janie WULFF*[1]**

[1]Department of Biological Science, Florida State University, Tallahassee, FL

Sponges play key roles on coral reefs, including filtering the water column, gluing live corals to the reef frame, protecting exposed carbonate skeletons from excavating organisms, and facilitating regeneration of damaged reefs. Concerns that these roles could be lost due to declines in sponges, or, conversely, that sponges could overgrow reef surfaces with detrimental effect, impel understanding of factors that control sponge distribution and abundance. Relative importance of top down versus bottom up trophic factors was evaluated by comparing size changes of 12 common species of Caribbean coral reef sponges in three linked habitats that differ in spongivore abundance and taxa and in water column productivity. Small pieces were cut from parent sponges and protected in cages until cut edges healed. Sponge pieces of the same size and genotype were attached to stable solid substrata inside cages and next to, but outside of, cages on the reef and in the seagrass, and on PVC pipes suspended among mangrove roots. Growth and survival were monitored at intervals for 1-3 years. On the coral reef, growth and survival were indistinguishable for sponges inside and outside of cages, but in the seagrass most species did not survive outside of cages. Growth and survival of the reef sponges were highest among the mangrove prop roots.

## 10-64

**How Hydrodynamics And Corallivory Interact To Influence The Performance Of Juvenile Corals**

**Hunter LENIHAN*[1]**, Jim HENCH[2], Alice ALLDREDGE[3]

[1]Bren School of Environmental Science and Management, UC Santa Barbara, Santa Barbara, CA, [2]Environmental Fluids Laboratory, Stanford University, Pall Alto, CA, [3]Dept. of Ecology, Evolution, and Marine Biology, UC Santa Barbara, Santa Barbara, CA

Decades of research indicate that natural catastrophes have a major influence on coral reef community dynamics. Examining ecological processes that regulate reef recovery following major disturbances provides a means of testing whether and how reef communities are changing through time and space. Data suggests that reef composition in some areas of the IndoPacific and elsewhere is changing through the relative loss of acroporid and gain of pocilloporid corals. Whether such change is due to species replacement or represents a stage within the recovery process is unclear. We tested whether the individual performance of acoporid and pocilloporid coral colonies in Moorea, FP varied in response to chronic, low-level disturbances, and whether differences in the relative performance of two taxa help explain population and community dynamics. Using population surveys, demographic studies, and manipulative experiments, we found that growth and survival of juvenile *Acropora* spp. and *Pocillopora* spp. varied with habitat structure, hydrodynamic conditions (current speed, turbulence, sedimentation, and food delivery rates), corallivory by fishes, and their interaction. Results a multi-year demographic study indicated that coral recruitment is relatively high for both taxa, but that the growth and survival of juvenile colonies varies greatly with substrate type, hydrodynamics, and the abundance of corallivores (puffer-, butterfly-, and parrot fishes). Results from manipulative experiments indicate that corallivory has strong influence on juvenile growth and survival; that predation intensity is tightly controlled by turbulence, and thus seasonal variation in physical forcing; and that coral growth, in the absence of corallivory, is regulated in large part by the flux of zooplankton. Overall, rates of predation on *Acropora* and *Pocillopora* were similar, but had a greater negative effect on *Acorpora*. Variation in the response of the two taxa to abiotic and biotic stressors help explain present-day patterns of community composition, and are used to predict future change.

## 10-65

**Plasticity of the Corallivorous gastropod *Coralliophila abbreviata*: Implications for Imperiled Caribbean Coral**

**Lyza JOHNSTON*[1]**, Iliana BAUMS[2], Margaret MILLER[3]

[1]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [2]Department of Biology, The Pennsylvania State University, University Park, PA, [3]Southeast Fisheries Science Center, NOAA, Miami, FL

*Coralliophila abbreviata* is a corallivorous gastropod that lives and feeds on several species of scleractinian coral in the tropical Western Atlantic and the Caribbean. Throughout the region, gastropod populations found on branching acroporid corals display different morphological, behavioral, and life-history characteristics than those found on massive and plating corals, prompting hypotheses about host-associated genetic differentiation within *C. abbreviata*. Although damage to massive and plating corals appears minimal, these gastropods cause substantial and chronic mortality of *Acropora palmata* and *Acropora cervicornis*, two species recently listed as Threatened under the U.S. Endangered Species Act. Under the premise of one plastic species of *C. abbreviata*, massive and plating corals may serve as reservoir hosts, producing a continuous supply of predators even as acroporid populations continue to dwindle. The species status and population dynamics of *C. abbreviata* thus have important conservation and management implications for Caribbean coral reefs. To address this issue, we used mitochondrial and microsatellite markers to assess the genetic structure of *C. abbreviata* populations from two coral host taxa (*A. palmata* and *Montastraea* spp.) and three locations spanning the species range (Florida Keys, Navassa Is., and St. Vincent and the Grenadines). We found no significant genetic structure between hosts or among geographic locations, indicating that *C. abbreviata* is one plastic species with unrestricted gene flow throughout the range sampled. Based on these results, it seems pertinent that strategies be implemented to mitigate the impact of *C. abbreviata* on vulnerable acroporid coral populations.

## 10-66

**Strong Interactions From Hidden Species: Vermetid Snails Have Large Deleterious Effects On Corals**

**Craig OSENBERG*[1]**, Jeffrey SHIMA[2], Adrian STIER[1]

[1]Department of Zoology, University of Florida, Gainesville, FL, [2]School of Biological Sciences, Victoria University Wellington, Wellington, New Zealand

The dynamics and restoration of coral reefs is of critical concern given their ecological importance and the deleterious impacts caused by disease and anthropogenic activities. Previous research has demonstrated important potential effects of nutrients, algae, disease, and disturbance, but may have overlooked other key factors. Vermetid gastropods, which are sessile and feed via an extensive mucus net, are poorly studied members of the coral reef community, yet also may interact strongly with corals. We examined the possible effects of vermetids on coral growth and survival in a field study in a lagoon of Moorea, French Polynesia. Vermetids were either left at ambient densities or removed from small (~3m2) patch reefs. Coral nubbins were collected, weighed (using the buoyant mass technique), and outplanted to these patch reefs. Growth was assessed after ~7 weeks and survival after ~8 months. Eight experiments were conducted using four different species of coral (*Pocillopora*, *Montipora*, *Porites lobata*, and *Porites rus*). Growth and survival were both greater offshore than inshore, although effects of vermetids were similar in both regions. Effects of vermetids were strongly deleterious but varied among coral taxa. Vermetids reduced the growth of coral by as much as 90% (*Pocillopora*) and by as little as 30% (*Montipora*). Survival was reduced from >98% in the "removals" to 79% (*P. rus*), 70% (*P. lobata*), and 45% (*Pocillopora*). These large short-term effects can have dramatic consequences for coral regeneration and dynamics. We projected changes in coral community composition resulting from observed effects of vermetids and found that the effects rival those documented from other factors.

## 10-67

**Cultivation Mutualisms Between Territorial Damselfish And Algae in The Indo-West Pacific**

**Hiroki HATA*[1]**

[1]Graduate School of Science, Kyoto University, Sakyo, Kyoto, Japan

This research aims to understand the origin and evolution of cultivation mutualisms on coral reefs in the Indo-West Pacific. Territorial damselfishes defend territories individually against intruding herbivores and manage algal farms on which they exclusively feed in the territories. We revealed that some territorial damselfish farm species-specific *Polysiphonia* algae in Okinawa, Japan. Molecular genetics enabled us to detect four cryptic species of *Polysiphonia* algae, each of which were collected from territories of four different damselfish species. Notably, one *Polysiphonia* algal species dominated the farms of a damselfish *Stegastes nigricans* and was found nowhere else. *S. nigricans* feeds on this highly digestible alga as a staple food, whereas *Polysiphonia* sp. is exclusively protected and grown by the damselfish. In this way, the two species rely on each other; this situation is described as an obligate cultivation mutualism.

I studied damselfish territories in the Indo-West Pacific (Mauritius, Kenya, Egypt, Maldives, Thailand, Malaysia, and Australia) and revealed that the general pattern of species-specificity between *Stegastes* damselfishes and *Polysiphonia* algae was relatively stable throughout the Indo-West Pacific, but the dependency on the specific partner varied remarkably. *Polysiphonia* sp. 1, which is dominant in algal farms of *S. nigricans* in Okinawa, was also found in territories of the same fish species in Mauritius, Egypt, and Australia. However, *Polysiphonia* sp. 1 did not always dominate the farms in those areas, and therefore the fish did not always depend on the alga as a staple food. In addition, a new sibling *Polysiphonia* species was found. The farms of *S. nigricans* in Kenya, Maldives, and a part of Mauritius were inhabited by other *Polysiphonia* species, instead of *Polysiphonia* sp.1. These results imply that the cultivation mutualisms between damselfish and *Polysiphonia* algae have coevolved under geographic selection mosaics with host shifts across regions.

## 10-68

**Effects Of Farmerfish On Coral Community Structure**

**Jada-Simone WHITE*[1]**

[1]Department of Zoology, University of Florida, Gainesville, FL

Complex ecological interactions, coupled with abiotic processes, underlie the structure of diverse communities. In Moorea, French Polynesia, an abundant algal-farming fish, the dusky farmerfish *Stegastes nigricans*, alters the coral reef community by farming algal turf and exerting resource control through territorial defense. These behaviors affect coral indirectly by modifying their interactions with two guilds of community members: 1) increased interactions with farmed algal turf; and 2) decreased interactions with mobile grazers and predators due to reduced reef access. Small scale experiments involving farmerfish and / or turf removals indicated dominant massive *Porites* were more vulnerable to competition with turf than branching *Acropora, Pocillopora,* or encrusting *Montipora.* In contrast, delicate branching corals were more vulnerable to predation by mobile corallivores and grow and survive better in the presence of *S. nigricans* defense. I assessed these indirect effects in a demographic context using a combination of recruitment tiles and size specific population monitoring in the presence and removal of *S. nigricans.* Experimental parameter estimates were tested by comparing projected size distributions with spatially explicit size distributions of corals in the presence and absence of this abundant farmerfish. The disturbance history has played a pivotal role in the types of community changes observed. While *S. nigricans* usually colonizes *Acropora* thickets, a series of disturbances on the north shore virtually eliminated these habitats and farmerfish subsequently colonized disturbance tolerant, but turf sensitive, abundant massive *Porites*. The relative resistance to competition with turf allowed recovering, disturbance sensitive, species to utilize the dead portions of massive coral. This increase in substrate availability, when coupled with lower predation rates, has led to enhanced recovery of rare and branching corals within territories relative to outside.

## 10-69

**Ecological Processes in *halimeda Kanaloana* Meadows in Hawaii From 10 To 90 M Depths**

**Heather SPALDING*[1]**

[1]Botany Department, University of Hawaii at Manoa, Honolulu, HI

Hawaii's coral reef ecosystem includes expansive *Halimeda kanaloana* meadows, forming a continuous assemblage over soft sediments to 90 m. These meadows form habitat for cryptic organisms, and are a hunting ground for large, predatory fish. We used technical diving, ROV surveys, and submersibles to describe spatial and temporal variation in distribution, abundance, demography, and growth of *Halimeda kanaloana*, and to determine the role of herbivory, competition, and recruitment in structuring these meadows across a depth gradient. Sexual reproduction occurred intermittently throughout the year; 0.02 – 0.76% of the population was reproductive at any given time. Fragmentation and clonal propagation allowed large portions of the meadow to recover from wave induced burial and sand scour. Clearing experiments showed *Halimeda* could quickly regrow from the intact holdfast, but was slow (> 20 months) to recolonize areas cleared of both holdfast and thallus. Individuals were long-lived (> 27 months), but fluctuated greatly in segment number and height over time, suggesting plant size is not an appropriate age indicator. Densities peaked at 20 m (342 ± 13 SE individuals per m2), but varied seasonally and between locations at similar depths. *Halimeda* growth was rapid (9.8% ± 1.4% SE new growth per plant per week) and generally decreased with increasing depth. Herbivores (*e.g.*, *Tripneustes gratilla*) did not appear to significantly influence *Halimeda* densities. Episodic blooms of green algae (*e.g.*, *Caulerpa filicoides*, *Cladophora sericea*) and cyanobacteria (*Lyngbya majuscula*) overgrew *Halimeda*, and most likely competed for light and nutrients with increasing depths. The perennial nature, rapid growth rates, and asexual reproduction of *Halimeda kanaloana* appear to contribute toward the success and persistence of this species in Hawaii. Disturbance removing entire individuals over a large area, e.g. repeated cruise ship anchoring, would require years for recovery.

## 10-70

**Space Competition Between *acropora* Coral And Algae -Different Reaction Of Coral To Two Types Of Algae With Different Growth Form**

**Reiko TAMAI*[1]**, Kazuhiko SAKAI[1]

[1]Tropical Biosphere Research Center Sesoko Station, University of the Ryukyus, Okinawa, Japan

Dominance of reef-building corals on coral reefs is achieved by herbivory and oligotrophic sea water which restricts algal blooms. Since algae are superior space competitor to corals, reduced herbivory and increased nutrient may result in phase shift from dominance by corals to dominance by algae. Although some previous studies reported interplay among herbivory, algae and corals, studies that focused on the genus *Acropora*, which is dominant in coral communities of Indo-Western Pacific, are limited. We examined the effect of herbivory on algal biomass, and the effect of algae on survival and growth of *Acropora tenuis* by conducting field experiments at Iriomote Island, where human population density is low and land development is localized.

We set up grazer-exclusion cages and transplanted small (≈2 cm in length) coral fragments of *A. tenuis* inside and outside the cages. Algal biomass, and survival and growth of the coral fragments were monthly monitored.

Herbivorous fishes were excluded effectively by the cages, and algal biomass was significantly higher inside than outside the cages. Although growth rate of the fragments was significantly lower inside the cages as predicted, the growth rate changed drastically after algal species composition changed inside the cages at the middle of the experimental period. Before seasonal change, turf algae dominated inside the cages and the fragments could not enlarge the attachment area on substrata. Frondose algae increased after disappearance of turf algae in autumn, and the fragments grew rapidly afterward.

We conclude that the effects of algae on survival and growth of small corals may be variable depending not only on algal biomass but also on their growth form.

## 11-1

**Sex Change In Fungiid Corals**

**Yossi LOYA*[1]**, Kazuhiko SAKAI[2]

[1]Zoology, Tel Aviv University, Tel Aviv, Israel, [2]Sesoko Station, University of the Ryukyus, Okinawa, Sesoko, Motobu-Cho, Japan

Sex change in animals has been the subject of a variety of theoretical and empirical evolutionary studies. The direction of sex change in animals has been reported occurring mainly from M to F (males to females; protandry) and visa versa (protogyny) and in some cases as bidirectional. Our knowledge of the various modes of sexual reproduction in scleractinian corals has increased greatly during the last two decades, but is far from encompassing the wide plasticity of reproductive strategies exhibited by this group. Here we report on novel observations of sex change in two coral species, where tagged individuals have been monitored during 3 years in the field and experimental aquaria at Sesoko, Okinawa: Fungia repanda (exhibiting protandry), and Ctenactis echinata, revealing novel bidirectional mode of sex change: (M-F-M and F-M-F). Our study exemplifies the view that models that can be applied on the scale of individuals may provide important insights to the factors underlying the evolution of sex change in animals.

## 11-2

**Behavioural Endocrinology Of Bi-Directional Sex Change in Coral-Dwelling Gobies**

**Frederieke KROON*[1]**, Philip MUNDAY[2], David WESTCOTT[1], Luke GARDNER[3], Abigail ELIZUR[4,5]

[1]CSIRO Sustainable Ecosystems, Atherton, Australia, [2]James Cook University, School of Marine and Tropical Biology, Townsville, Australia, [3]Queensland Department of Primary Industries & Fisheries, Woorim, Bribie Island, Australia, [4]University of the Sunshine Coast, School of Science and Education, Maroochydore DC, Australia, [5]Queensland Department of Primary Industries & Fisheries, Woorim, Australia

The discovery of bi-directional sex change (i.e. the ability to change sex repeatedly in both directions) in various fish species provides a unique opportunity to study the endocrine mechanisms underlying female and male sex differentiation. We examined a potential causal relationship between behaviour, endocrine pathways, and natural sex change in coral-dwelling gobies of the genus *Gobiodon*. These species generally live in heterosexual pairs and natural sex change occurs as a result of changes in social conditions. If adult sex change in coral-dwelling gobies is a result of changes in behavioural interactions perceived by an individual fish, then we predict the following:

that in heterosexual pairs males are behaviourally dominant;

that in heterosexual pairs cortisol levels are higher in females than in males;

that in heterosexual pairs aromatase expression is higher in females than in males;

that in heterosexual pairs estradiol levels are higher in females than in males;

that an increase in cortisol levels results in protandrous sex change, and a decrease in cortisol levels results in protogynous sex change.

To test these predictions, we observed behavioural interactions in existing heterosexual pairs in the laboratory, and conducted field experiments under natural social conditions. The results suggest that, in coral dwelling gobies, behavioural interactions mediates sex change in each direction via the aromatase pathway.

## 11-3

**Light Sensing And The Coordination Of Coral Broadcast Spawning Behavior**

Dan HILTON[1], **Peter VIZE*[2]**

[1]Biological Sciences, University of Calgary, Calgary, AB, Canada, [2]Biological Sceinces, University of Calgary, Calgary, AB, Canada

While lunar cycles establish the day of spawning in corals, sunlight driven systems control the hour and minute of spawning. The two lines of evidence supporting this contention are: 1. coral spawning times change from year to year corresponding to changes in sunset time 2. artificially changing sunset time results in a corresponding change to spawn time. This later point also indicates that the solar control is not an entrained circadian system or it would not respond in this manner. Our research is exploring the cellular pathways by which solar light regulates spawning behavior through a combination of proteomics and candidate pathway analysis. We are mapping coral protein phosphorylation oscillations in response to different levels of illumination. As most light transduction systems result in changes in such patterns this approach will identify phosphoprotein signatures that can be used as markers of signal perception. Such signatures can then be used to test the role of different signaling pathways in the response to light, to compare responses in species with different spawning times, to measure the importance of zooxanthellae in the response etc. A second approach is identifying coral orthologs of genes involved in regulating either circadian cycles or light responses. These candidates are then tested for responsiveness to lunar and solar light at both the transcriptional and post-transcriptional level. Through a combination of these two approaches we hope to map the pathways by which lunar and solar light independently regulate coral spawning behavior. We are particularly interested in how these two different systems intersect to select the exact moment of gamete release and how changes in the dynamics of the molecular sensing systems generates distinct species-specific spawning windows.

## 11-4

**Light-Responsive Cryptochromes From A Simple Multicellular Animal, The Coral Acropora Millepora**

**Oren LEVY*[1]**, Lior APPELBAUM[2], William LEGGAT[3], Yoav GOTHILF[4], David HAYWARD[5], David MILLER[6], Ove HOEGH-GULDBERG[7]

[1]Department of Environmental Sciences, The Weizmann Institute of Science, Rehovot, Israel, [2]Center For Narcolepsy, Stanford University, Palo Alto, CA, [3]Biochemistry and Molecular Biology, James Cook University, Townsville, Australia, [4]Department of Neurobiochemistry, Tel Aviv University, Tel Aviv, Israel, [5]Molecular Genetics and Evolution Group, Australian National University, Canberra ACT, Australia, [6]Comparative Genomics Centre, James Cook University, Townsville, Australia, [7]Centre for Marine Studies, The University of Queensland, Brisbane, Australia

Hundreds of species of reef-building corals spawn synchronously over a few nights each year, and moonlight regulates this spawning event. However, the molecular elements underpinning the detection of moonlight remain unknown. Here we report the presence of an ancient family of blue-light–sensing photoreceptors, cryptochromes, in the reef-building coral Acropora millepora. In addition to being cryptochrome genes from one of the earliest-diverging eumetazoan phyla, cry1 and cry2 were expressed preferentially in light. Consistent with potential roles in the synchronization of fundamentally important behaviors such as mass spawning, cry2 expression increased on full moon nights versus new moon nights. Our results demonstrate phylogenetically broad roles of these ancient circadian clock–related molecules in the animal kingdom.

## 11-5

**Evidence For Opsin-Regulated Long-Wavelength Photosensitivity in Coral Larvae**

**Benjamin MASON*[1]**, Matthew BEARD[2], Margaret MILLER[3], Jonathan COHEN[4], Valery SHESTOPALOV[5], Vladlen SLEPAK[6]

[1]RSMAS, University of Miami, Miami, FL, [2]Biological Sciences, Florida State University, Tallahassee, FL, [3]NOAA - Southeast Fisheries Science Center, Miami, FL, [4]Marine Science, Eckerd College, St. Petersburg, FL, [5]BascomPalmer Eye Institute, McKnight Vision Center, Leonard M. Miller School of Medicine, University of Miami, Miami, FL, [6]Molecular and Cellular Pharmacology, Leonard M. Miller School of Medicine, University of Miami, Miami, FL

Research has demonstrated that light influences the swimming behavior and settlement of coral larvae, yet a physiological and molecular basis for photosensitivity has not been described in corals. Here we provide evidence for long-wavelength photosensitivity in several species of scleractinian coral larvae and demonstrate the presence of an opsin–like protein, localized in solitary, sensory epithelial cells. Settlement experiments with *Porites astreoides* and *Acropora palmata* demonstrated that these larvae are attracted to and preferentially settle on red substrates. Larvae settled and metamorphosed on red fluorescent plastic substrate but not on plastic substrates of other colors. Preference for red was not observed when larvae were maintained in the dark, suggesting that phototaxis, rather than a chemical cue, was responsible for the observed preference. Electrophysiology (electroretinographic traces) confirmed sensitivity to long-wavelength light in larvae of *P. astreoides*. Immunoblots, using a rabbit polyclonal antibody directed against squid opsin, indicated the presence of a ~50 kDa, opsin-like protein in larvae of *A. palmata*, and *Diploria strigosa*. Immunofluorescence and confocal imaging of sectioned larvae demonstrated this opsin-like protein is localized in solitary, ciliary epithelial cells in *P. astreoides*, *D. strigosa*, *Montastraea faveolata,* and *Favia fragum*. Protein blasts of *M. faveolata* larval contig ESTs with *Nematostella vectensis* and squid opsin sequences, revealed the expression of two 7-transmembrane receptors with significant similarity (2e^-9 to 2e^-18) to the query sequences. Efforts to determine the remaining sequence and confirm the identity of these proteins are currently in progress.

## 11-6

**Bleaching Has No Short-term Effect on Reproduction in the Scleractinian Coral *Montipora capitata***

**Evelyn COX*[1]**

[1]University of Hawaii West Oahu, Pearl City, HI

Bleaching is generally expected to produce detrimental impacts on coral reproduction. This study compared the fecundity of bleached and unbleached colonies of the Hawaiian coral *Montipora capitata*. It was hypothesized that bleaching would have no effect on reproduction because previous studies have shown that *Montipora capitata* can increase heterotrophic feeding following bleaching. Reproductive parameters, total reproductive output (bundles released ml-1 coral colony), number of eggs bundle-1, and egg size, measured in the summer of 2005 did not differ between colonies that bleached or did not bleach during 2004. These data were collected following a single bleaching event and cannot be used to predict the outcome should bleaching episodes become more frequent or severe.

## 11-7

**Reproduction in The Coral Reef Herbivore Scarus Ferrugineus (Scaridae): Its Timing And Seasonality**

**Yohannes AFEWORKI*[1,2]**, John VIDELER[2], Henrich BRUGGEMANN[3]

[1]Applied Marine Science, College of Marine Science, Massawa, Eritrea, [2]Marine Biology, University of Groningen, Haren, Netherlands, [3]Laboratoire ECOMAR, Université de La Réunion, La Réunion, France

Reproductive behavior of the rusty parrotfish *Scarus ferrugineus* was studied in a fringing reef in the Southern Red Sea (Eritrea). Observations on territory holding Terminal Phase Males (TTP) were conducted to record the following parameters: the location of the territory, timing and duration of territory holding, territory size, size of the TTP, number of Initial Phase females (IP) and non-territorial Terminal Phase males (TP) arriving at the territory, frequency of spawning and streaking. The mating system of *S.ferrugineus* is lek-based where large TTPs occupy a temporary breeding territory in the deep fore reef (6 – 10 m depth). Territory holding and spawning occurred daily year-round. But the timing was different for the cold (November – April) and warm (May – October). During the warm months (July – September) breeding territories were kept at around high tide time. The timing of spawning shifted with the peak high-tide-time as it progressed through the consecutive days. Only when the day high tide occurred after 3:00 pm the fish switched to the early hours of the morning just after the night high tide. Duration of the breeding ranged between 1 – 3.5 hours with the longest periods occurring during the morning. In the colder months (December – March) territory holding invariably took place during the morning hours between 7:30 and 11:00 irrespective of the period of the tide. Intensity of reproductive behavior was highest during the cold months. During that period 70 % of females that were striped had hydrated eggs compared to 40 % during the warm months. A tradeoff between reproduction and growth is evident in the cold months as reflected in the low body condition of all the social categories. This tradeoff appears to be caused by lost feeding opportunities while spawning, high energetic costs of spawning and territory keeping and low primary production during that period.

## 11-8

**Patterns of Egg Predation at Reef Fish Spawning Aggregation Sites and the Role of Target Egg Predators**

**Matthew FRASER*[1]**, Mark MCCORMICK[1]

[1]Marine and Tropical Biology, James Cook University, Townsville, Australia

Predator-prey interactions at reef fish spawning aggregations are poorly understood yet form the foundation of hypotheses explaining spawning site selection and temporal patterns of spawning aggregations. The current study examined egg predation by reef based obligate and facultative planktivores at reef fish spawning aggregation sites at Kimbe Bay, Papua New Guinea. The objective of this study was to quantify egg predation levels among spawning aggregation sites and among three reef fish species, and examine characteristics of both the spawners and spawning sites in order to explain the patterns of egg predation. Spawning activity was monitored daily at seven spawning aggregation sites across three reefs over a two month period. During each spawning event the number of spawning rushes released, the number of rushes preyed upon and the species of egg predators that fed on each rush. Attributes of each spawning aggregation site measured were density of egg predators during a spawning event and substratum topographic complexity. Egg predation was greatest for the surgeonfish, *Ctenochaetus striatus*, and differed significantly among sites. Levels of egg predation for *C. striatus* correlated significantly with egg predator density while egg predation levels for the parrotfish, *Chlorurus bleekeri*, and wrasse, *Thalassoma hardwicke*, did not. Similarly, levels of egg predation for *C. striatus* correlated significantly with substrate topographic complexity while egg predation levels for *C. bleekeri* and *T. hardwicke* did not. This study shows the immediate predation of eggs by target egg predators is an important source of mortality and directly influences the number of propagules being effectively liberated from spawning sites used by *C. striatus*. The differences in the levels of egg predation between spawning species suggests that the intensity of target egg predation may not be an important determinant in the choice of spawning aggregation sites.

## 11-9

**Reproductive Pattern Of The Polychaete Sabellastarte Spectabilis in Hawaii.**

**David R. BYBEE*[1]**, Julie H. BAILEY-BROCK[2], Clyde S. TAMARU[3]

[1]Department of Biology, Brigham Young University-Hawaii, Laie, HI, [2]Department of Zoology, University of Hawaii, Honolulu, HI, [3]Sea Grant College Program, University of Hawaii, Honolulu, HI

The objective of this study was to determine the timing of reproduction in the Sabellid polychaete *Sabellastarte spectabilis* (Grube 1878) and to correlate reproductive activity with water temperature and day length. Worms were collected at approximately monthly intervals from Jan. 2002 to Dec. 2003 from intertidal and subtidal reefs in Kaneohe Bay, Hawaii, USA (21° N, 157 ° W). Reproductive activity was investigated qualitatively using histological techniques and quantitatively with induction of spawning trials. Worms were characterized into four discrete reproductive stages based on histological evidence: 1) No evidence of reproductive activity in the coelom 2) Only coelomocytes present in the coelom 3) Some gametes present in the coelom and 4) Coelom densely packed with gametes. Stage 4 worms were present over an extended period of time (females, March-December and males, March-November) indicating a potentially broad reproductive season. No correlation between day length and maturation stages in *S. spectabilis* was detected. However, there was a correlation between water temperature and % frequency of Stage 4 worms. Maturation appeared to coincide with water temperatures of 24 to 25 ºC (March – September) after which there was a reduction in the % frequency of stage 4 individuals. Induction of spawning trials conducted between May – January showed the month of October with a significantly higher percent success than any other month investigated. According to all available information (e. g., natural spawning in water tables, histological data, induction of spawning trials, correlation of maturation stages with observed changes in average monthly water temperature.), there is an apparent peak in reproductive activity (spawning) within a broad maturational season, which may be influenced by water temperature.

**The Effects Of Temperature And Light On The Gametogenesis And Spawning Of Four Sea Urchin And Five Sea Cucumber Species On Coral Reefs in Kenya And La Reunion**

**Nyawira MUTHIGA*[1]**, Chantal CONAND[2], Joan KAWAKA[3], Sophie KOHLER[4]

[1]Marine Program, Wildlife Conservation Society, Bronx, NY, [2]Laboratoire de biologie marine, Université de La Réunion, Saint Denis, France, [3]Wildlife Conservation Society, Mombasa, Kenya, [4]University de La Reunion, Saint Denis, France

This paper reviews studies of the reproductive cycles of 4 species of sea urchins (*Echinometra mathaei, Diadema savignyi, D. setosum, Tripneustes gratilla*) and 5 species of sea cucumbers (*Actinopyga echinites, Holothuria atra, H. leucospilota, H. scabra* and *Stichopus chloronatus*). Measurements of gonad index and macro and microscopic observations of gonads were used to evaluate changes during gametogenesis in individuals collected on Kenyan and Reunion reefs. The effects of temperature, light and lunar period were also assessed. *Echinometra mathaei*, *H. arenacava*, *H. leucospilota* in Kenya and *H. atra* in Reunion showed an annual pattern while *A. echinites*, *H. leucospilota* and *S. chloronatus* in Reunion and *H. scabra* in Kenya showed a biannual pattern of reproduction. A particularly pronounced seasonal pattern occurred in *E. mathaei*, *H. arenacava* and *H. leucospilota* on Kenyan reefs where gametogenesis started in July when temperatures and light were at their lowest and spawning peaked between March-April just after peak levels of temperature and light. These species showed higher correlations between light and gonad index than between temperature and gonad index indicating that light had a stronger influence than temperature on the onset of gametogenesis on these species on the Kenyan coast. In the species without pronounced annual reproductive patterns, gonad indices were high during one (*D. setosum*, *D. savignyi, T. gratilla* in Kenya) or two (*A. echinites*, *H. leucospilota* and *S. chloronatus* in Reunion and *H. scabra* in Kenya) periods of 1 - 2 and up to 6 months but the reproductive season often coincided with periods of high temperature and light. Only three of the sea urchin species (*D. savignyi*, *D. setosum* and *T. gratilla*) showed lunar periodicity.

## 11-11

**Gametogenic and reproductive cycles of a sea anemone that provides essential habitat for anemonefish**

**Anna SCOTT*[1,2]**, Peter HARRISON[3]

[1]Coral Reef Research Centre, Southern Cross University, Lismore, Australia, Coffs Harbour, Australia, [2]National Marine Science Centre, Coffs Harbour, Australia, Coffs Harbour, Australia, [3]Coral Reef Research Centre, Southern Cross University, Lismore, Australia, Lismore, Australia

Sea anemones that host obligate symbiotic anemonefish are ecologically important throughout many reefs of the Indo-Pacific. Despite their importance there is very little information available on their sexual reproductive biology. This study aimed to address this lack of knowledge by determining the gametogenic cycles of the sea anemone, *Entacmaea quadricolor*. Gonad samples were taken in the field using a specially developed biopsy sampling technique from January 2003 to February 2005 at North Solitary Island, Solitary Islands Marine Park, Australia. On each sampling occasion, 15 to 20 individuals were sampled, with the depth, colour and pedal disc diameter of each anemone being recorded. Samples were fixed and histological sections were prepared to determine the state of reproductive activity for each individual. All oocytes sectioned through the nucleus were measured and assigned to size classes of 150 µm. Males were classified into one of five stages based on assessment of spermary maturity. Spawning was inferred by the disappearance of the largest size class of oocytes in the females, and the disappearance of mature spermaries and the appearance of the ruptured or spawned mesenteries in the males. *E. quadricolor* had separate sexes at the study location, with female anemones being significantly more abundant than male anemones. Female anemones displayed asynchronous oocyte development, both within and among individuals, whereas male anemones showed a single cycle of spermary growth, development and spawning. Six spawnings, which occurred between January and April, were inferred over the study period. On all but one occasion both female and male anemones were inferred to have spawned during the same period. Due to ease of interpretation, the developmental pattern of the spermaries may therefore provide a better indicator of spawning times in this species.

## 11-12

**Mass Coral Spawning Events At Reunion Island (21°s) From 1991 To 2007**

**Mireille M.M. GUILLAUME*[1,2]**, Maurice PARMANTIER[2], J. Henrich BRUGGEMANN[2]

[1]Milieux et Peuplements Aquatiques, UMR 5178 CNRS-UPMC-MNHN, Muséum National d'Histoire Naturelle, Paris, France, [2]ECOMAR, Université de la Réunion, Saint-Denis, Reunion

The occurrence of mass coral spawning has been checked intermittently at Reunion Island since 1985. In 1991, M. Parmantier discovered the timing of mass spawning in A. muricata and surveyed one coral patch annually until 2003. While correlation to full moon was confirmed, the month and exact timing varied between years.

The objectives of the present study are to inventory the species involved and analyze the timing of mass spawning in relation to environmental parameters susceptible to trigger these events. Mass spawning events were surveyed from 2004 to 2007 on three coral reefs (Saint-Gilles, la Saline and Saint-Leu) during the four nights following full moon in August to December, involving each night ~20 observers from the University of Reunion. Temperature was recorded in situ at each reef, while solar insolation is available by Météo France. Few species contributed to mass spawning on the shallow reef flats, the dominant species Acropora muricata, both ecomorphs of A. digitifera, A. vaughani and sometimes A. gemmifera. The long-term spawning record (1991-2007) of A. muricata is analyzed with environmental data. Mass spawning occurred when SST was the lowest, in October or November, once in September. Coral spawning was clearly related to the lunar cycle, occurring from the 1st to the 4th day after full moon, 1 to 2.5 hours after the night-time low tide, but not later than midnight. Gamete release coincides with the incoming flow by night, following the tidal wave that sweeps the West coast of Reunion Island from South to North. Synchrony is high between reef flats, but A. muricata at one site at la Saline, may be one month in advance. Corals on outer reef slopes spawn together with those on reef flats, but not yearly.

## 11-13

**Biannual Multi-Specific Coral Spawning On North-West Australian Reefs**

**Natalie ROSSER*[1]**, James GILMOUR[2], Andrew BAIRD[3]

[1]RPS, Perth, Australia, [2]Australian Institute of Marine Science, Perth, Australia, [3]ARC Centre of Excellence for Coral Reef Studies, Townsville, Australia

Observations of multi-specific synchronous coral spawning periods in Australia have lead to the recent realisation that on the west coast of Australia there is a primary multi-specific spawning in the austral autumn (March/April), and on some northern reefs, a secondary multi-specific spawning in spring (October). Here we present data of species participating in the secondary spring spawning from three locations in north Western Australia: the Bonaparte Archipelago (Kimberley), Scott Reef and the Dampier Archipelago, indicating that the spring spawning occurs across a wide latitudinal range. In all three locations all species that spawned in spring also spawned in autumn. However some species that spawned in spring in one location did not necessarily spawn in spring in another, e.g. A. hyacinthus spawned in spring at Scott Reef, but not at Dampier. Other species spawned in spring at all three locations e.g. A. humilis and yet others never spawned in spring at any location e.g. A. millepora. These results suggest that there is a physiological element driving a species ability to be able to spawn during both spring and autumn, as some species consistently spawned in both seasons while others consistently did not. Furthermore, that some species spawned in both seasons in one location but not in another, would also suggest that it may be a combination of both physiology and environmental conditions that allows a species to spawn in both seasons, and that these environmental parameters are highly localised.

## 11-14

**Sexual Reproduction Of Hermatypic Corals Along The Mexican Pacific Coast**

**Eugenio CARPIZO-ITUARTE*[1]**, Hector REYES-BONILLA[2], Amilcar CUPUL MAGAÑA[3], Andrés LÓPEZ-PÉREZ[4], Pedro MEDINA-ROSAS[3], Hector Efraïn CHÁVEZ-ROMO[1], Paola RODRÍGUEZ-TRONCOSO[1], Verónica VIZCAINO-OCHOA[1], Miriam MORA-PÉREZ[2], Gerardo LEYTE-MORALES[4], Luis E. CALDERÓN-AGUILERA[5], Guillermina CHI-BARRAGÁN[1], Olivia TAPIA-VÁZQUEZ[6]

[1]Oc. Biológica, Isnt. Inv. Ocean. UABC, Ensenada, B.C., Mexico, [2]Biología Marina, Universidad Autónoma de Baja California Sur, La Paz, Mexico, [3]Ciencias Médicas y Biológicas, Universitario de la Costa, Univ. De Guadalajara, Pto. Vallarta, Mexico, [4]Instituto de Recursos, Universidad del Mar, Pto Angel, Mexico, [5]Ecología, Centro de Investigación Científica y Educación Superior de Ensenada, Ensenada, Mexico, [6]Comité Estatal de Sanidad Acuícola e Inocuidad de Baja California, Ensenada, Mexico

In contrast to the equatorial eastern Pacific (EEP), where the sexual reproductive activities of several zooxanthellate coral species have been described, only recently have similar studies been initiated in the Mexican Pacific (MP) region. During the last eight years, the reproductive patterns of three of the most common MP species have been investigated: *Pocillopora damicornis*, *Porites panamensis* and *Pavona gigantea*. The study areas range from La Paz, Baja California Sur (24o 19' 02" N; 110o 19' 57" O) to Bahia de Banderas, Jalisco-Nayarit (20o 42' 03" N; 105o 33' 52" O), and along the Huatulco coast, Oaxaca (15o 44' 40" N; 96o 07' 35" O). Initial surveys have shown the three species produce mature gametes, and that seasonality, frequency and extent of the reproductive period are highly influenced by local oceanographic conditions (upwelling centers, thermocline shoaling, marked seasonal temperature variation). Compared to extended reproductive activity in Panama, Costa Rica and Ecuador in the EEP, the same species in the MP exhibit a higher degree of seasonality. Continuing studies of the three species in different areas, and other less abundant species, will allow a more critical comparison of the reproductive activities of corals along the entire latitudinal range of the eastern Pacific. Regional comparisons of asexual reproduction and recruitment are also planned to better understand the relative importance of these life history traits in relation to MP coral community dynamics. We are hopeful these studies will provide information that can be used to promote better management and conservation strategies for the preservation of coral communities and reefs along the MP coast.

## 11-15

**Reproduction of Reef Corals from the Southwestern Atlantic (Brazil)**

**Débora PIRES*[1]**, Clovis CASTRO[1]

[1]Departamento de Invertebrados, Museu Nacional/Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Brazil has the only true coral reefs known in the South Atlantic, with most builder corals endemic. Based on histological data, we investigated sexual patterns, mode and seasonal patterns of reproduction, and spawning periods of 10 scleractinians (five endemic: Mussismilia braziliensis, M. harttii, M. hispida, Favia gravida, and Siderastrea stellata; and five also occurring in the Caribbean: Scolymia wellsi, Porites astreoides, Madracis decactis, Agaricia humilis, and Montastraea cavernosa). Our results indicated that half of the species are brooders and half are spawners. Two species are gonochoric. In Brazil, the release of gametes/planula occurs in different times of the year. A few simultaneous spawning days of M. hispida and M. harttii were observed in Porto Seguro (16ºS). Histological data from Abrolhos specimens (18ºS) suggested that M. hispida can present simultaneous spawning with M. braziliensis in this area. More studies are necessary to understand the variation in time of spawning of M. hispida in different areas. Mussismilia spp. are hermaphroditic and present at least two consecutive monthly periods of spawning a year, dictated by the new moon. Most of the brooder corals present several annual periods of planula release. Favia gravida and Agaricia humilis release planula monthly, while Scolymia wellsi and Porites astreoides release only in some consecutive months of the year. Siderastrea stellata has a period of planula release restricted to the summer, and in Madracis decactis it happens in the beginning of the autumn. Mussismilia harttii presents synchronic spawning in different places (08ºS, 16ºS, 18ºS). There is assynchrony in the spawning period of S. stellata and M. hispida, when populations of Búzios (23ºS) and other places are compared. Upwelling events, that happen in Búzios during the summer, may be influencing the gametogenesis of these species.

## 11-16

**Planulation Near Dawn Results in Increased Survivability Of *favia Fragum***

**Gretchen GOODBODY-GRINGLEY*[1,2]**

[1]Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, [2]Bermuda Institute of Ocean Sciences, St. George's, Bermuda

Numerous studies have addressed annual timing of planulation in scleractinians, documenting a tightly synchronized process that coincides with lunar periodicity. In contrast, diel variation has received little attention yet may have important implications for post-metamorphic success. In summer 2007, I examined hourly release of planulae by *Favia fragum* in Bermuda. Planulation occurred throughout the night with a significant peak between 4 and 5 am. Release near dawn may be advantageous for *F. fragum* as a means of maximizing time for utilization of light cues in larval behavior and increasing availability of symbiont-derived photosynthetic products. Such benefits to pre-dawn release may be manifested in life history traits such as competency, settlement, mortality and growth. To compare competency and metamorphic success of larvae released at night versus pre-dawn, planulae were collected over two-hour intervals, from 10 pm to 12 am (night) and 4 to 6 am (pre-dawn), in July and August 2007. Percent larvae competent for settlement was significantly higher for those released pre-dawn than those released at night. Despite the 6-hour difference in release time, settlement in both groups coincided with daylight hours, suggesting that environmental factors govern this process. Additionally, percent metamorphic success was significantly higher for larvae released pre-dawn. Following settlement, terra-cotta tiles with new spat were placed on an inshore patch reef and monitored for growth and mortality over the succeeding 40 days. Growth rates for pre-dawn planulae were initially significantly higher than night released planulae, however this difference did not persist over time. Benefits accrued to larvae released near dawn, compared to those released 6 hours earlier, may be explained by a combination of increased energy reserves provided through immediate exposure of photoautotrophic symbionts to light, coupled with decreased total respiration from time of planulation to settlement.

## 11-17

**The Annual Timing Of Coral Spawning: A Role For Rainfall?**

**Judith MENDES*[1,2]**

[1]Department of Life Sciences, University of the West Indies, Kingston, Jamaica, [2]Bellairs Research Insititute of McGill University, St James, Barbados

Sea surface temperature (and the solar insulation responsible for temperature) is the most frequently cited trigger for the annual timing of coral spawning. We conducted a meta-analysis of spawning time at 42 sites worldwide in relation to sea surface temperature and rainfall. The data on temperature, rainfall and spawning time were examined by log-linear analysis. The log-linear model of best fit included al 2-way interactions (temperature x rainfall, spawning x temperature, and spawning x rainfall; chi-squared = 41.06, df = 39, p = 0.38). The chi-squared test is not significant indicating that the values predicted by the model are not significantly different from the observed values. One can thus conclude that the model is sufficient to explain the time of spawning. Tests of partial association show that the magnitude of the temperature effect was greater than that for rainfall, however, on its own, temperature was insufficient to explain the time of spawning. Only when the interaction between rainfall and spawning was incorporated in the model could the time of spawning be adequately explained. According to our model, temperature and rainfall have opposite effects on the time of spawning with the likelihood of spawning increasing with increasing temperature and decreasing with increasing rainfall. Two possible roles underlying the contribution of rainfall to spawning time are, firstly, that spawning during period of low rainfall reduces the risk of catastrophic reproductive failure caused by gametes coming into contact with rain diluted surface water. Secondly, spawning prior to the peak of heavy rainfall, may also increase the food available for newly-settled, azooxanthellate coral polyps and the chance of such polyps acquiring zooxanthellae. A similar association of spawning to heavy rainfall (typhoons) has recently been described for the abalone *Haliotis diversicolor* (Onitsuka et al, 2007)

## 11-18

**Global Patterns And Environmental Controls Of Sexual Reproduction in Scleractinian Reef Corals**

**Peter HARRISON*[1]**

[1]Coral Reef Research Centre, School of Environmental Science and Management, Southern Cross University, Lismore, NSW, Australia

Research on sexual reproductive patterns of scleractinian reef corals continues to expand rapidly, providing important insights into proximate environmental controls and evolutionary constraints on coral reproductive success. An updated global review of scleractinian coral reproductive patterns confirms that hermaphroditic broadcast spawning remains the dominant pattern among scleractinian corals studied to date, with fewer gonochoric broadcast spawning or brooding species known. In a few species, mixed patterns of sex allocation and both brooding and broadcast spawning occur. Sea temperature and light in various forms are key environmental factors that interact to control reproductive cycles, lunar periodicity and spawning periods in reef corals. These proximate cues also strongly influence breeding periods and reproductive synchrony among coral species, with mass spawning (involving many species) or multispecific spawning (with fewer species) prevalent on many tropical and subtropical reefs. Protracted breeding periods and less synchronous reproduction are evident among reef corals on some equatorial reefs. A new model is developed that integrates thermal and light energy optima as primary determinants of coral reproductive patterns, with suboptimal conditions resulting in impaired reproduction and reduced reproductive success. Sea temperature also significantly influences coral larval development, competency and settlement success, with more rapid larval attachment and increased likelihood of localised settlement, but lower post-settlement survival, under elevated temperature. This has very important implications for reef connectivity and gene flow among coral populations in a rapidly warming global climate, and the future viability of some isolated reef systems.

## 11-19

**Solar Insolation Drives Reproductive Schedules Of Reef Corals: A Long Road in The Search For Proximate And Ultimate Cues**

**Robert VAN WOESIK*[1]**

[1]Biological Sciences, Florida Institute of Technology, Melbourne, FL

Coral populations depend on the formation of sex cells (gametes) for survival and adjustment to climatic shifts. Since adaptation involves differential-reproductive rates of individuals in populations, it is critical to understand global reproductive schedules of corals. This study tested the hypothesis that annual rising Sea Surface Temperatures (SSTs) and solar insolation are related to gamete maturation and synchronous gamete release in the Atlantic and Indo-Pacific Oceans. Reproductive schedules of corals were positively related to solar insolation cycles, and SSTs were poor predictors of coral spawning schedules. Near the equator coral spawning coincided with the equinoxes, showing two annual events. While proximate cues may explain how spawning synchronicity develops, there is a need to identify ultimate cues to ask why questions, including: 1) Why do such patterns exist? and 2) What is the long-term advantage (or adaptive significance) of such synchronized patterns? There is a strong positive relationship between the derivative of solar insolation and mean-wind speed, suggesting that rates of solar insolation change are strong predictors of mean-wind speed. This infers that corals appear to synchronize mass spawning during seasonally calm periods; which clearly agrees with recent genetic evidence of local dispersal and high local retention. Synchronization during calm periods would have rapidly evolved through selection outside the seasonally calm periods, because gametes and larvae would have been lost from the local species pool. Therefore, while solar insolation may be the proximate cue, the strong evolutionary filter (the ultimate cue) may have been the calm periods when insolation was not changing rapidly, which in turn facilitated local larval retention. This research demonstrates that solar insolation strongly influences coral reproductive schedules worldwide, and synchronization enhances time-varying differences in reproductive output and fitness because it occurs at times of low regional wind speeds that facilitate high local larval retention.

## 11-20

**Predicting patterns of coral spawning at multiple scales**

**Andrew BAIRD*[1]**, James GUEST[2]

[1]ARC CoE Reef Studies, James Cook University, Townsville, Australia, [2]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom

Early theoretical work predicted that the reproductive season of widespread organisms should be more extended near the equator than at high latitudes because conditions favourable for gametogenesis persist year round. Similarly, it was believed that synchrony among both populations and species would be lower at the equator because there are fewer good cues in the tropics where annual fluctuations in environmental variables are lower. Here, we present data from numerous locations within the Indo-Pacific which indicates that multi-specific synchronous spawning is a characteristic feature of all Acropora assemblages and further, at large scales, spawning episodes are highly predictable. In the central Indo-Pacific, for example, the majority of reproductive output is concentrated in brief periods following full moons at the beginning and end of the monsoon. Above approximately 28-30 degrees latitude, and possibly at some sites in the cental Pacific, this pattern breaks down and the spawning episode is progressively one month later in the season for every 2-400 km further from the equator. At smaller scales the patterns are far less predictable. For example, in the central GBR peak spawning times within sub-populations of a single species can vary dramatically over very small scales. In conclusion, while large scale patterns in coral spawning seasonality may be relatively predictable, detailed studies at the local scale are required to determine precisely when a given sub-population will spawn.

## 11-21

**Spatial Patterns Of Reproductive Synchrony By Four Genera Of Tropical Green Seaweed Across A Latitudinal Gradient in The Caribbean.**

**Kenneth CLIFTON*[1]**

[1]Biology, Lewis and Clark College, Portland, OR

Spatial and temporal patterns of reproductive effort are an especially significant feature of fertilization success for virtually all broadcast spawning organisms. While most research efforts on this topic have focused on varying temporal scales of reproductive synchrony (i.e., diel, lunar, and seasonal scales), patterns of reproductive synchrony on varying spatial scales (i.e. from meters to hundreds of kilometers) are less well studied. Simultaneous investigations of sexual reproduction by tropical green seaweeds (e.g., *Caulerpa, Halimeda, Penicillus, Udotea*) across a latitudinal gradient in the Caribbean (Panama, U.S. Virgin Islands, Florida) reveal patterns of reproductive synchrony on different spatial scales. Within a region, spatial synchrony often extends beyond local populations (meters to tens of meters) to at least scales of tens of kilometers, however, such synchrony is not maintained across larger (hundreds of kilometer) spatial scales. Relative synchrony within and between genera is maintained across this larger latitudinal gradient, however. Reproductive seasonality also shows an interaction with latitude for these seaweeds, with shorter, temporally delayed seasons of reproductive activity occurring at higher latitudes.

## 11-22

**Genetic, Spatial And Temporal Patterns Of Spawning in The Caribbean Montastraea Annularis Species Complex**

**Don LEVITAN*[1]**, Nancy KNOWLTON[2]

[1]Biological Science, Florida State University, Tallahassee, FL, [2]Department of Invertebrate Zoology, Smithsonian Institution, Washington, DC

Members of the *Montastraea annularis* species complex all spawn on the same few evenings each year. *Montastraea franksi* spawns approximately 100 minutes after sunset and *M. faveolata* and *M. annularis* overlap in spawning approximately 200 minutes after sunset. These latter two species have incompatible gametes, whereas *M.franksi* and *M. annularis* gametes are compatible when corals are manipulated to spawn simultaneously. Here we investigate patterns and consequences in spawning times within a species. What factors influence spawning times and what are the consequences of spawning early or late within a conspecific spawning event? We have mapped and genotyped over 350 individual corals on a reef off of Bocas del Toro, Panama. These tagged corals have been monitored for spawning over the past six years. The results indicate that (1) putative clone-mates produced via fragmentation have more similar spawn times than unrelated genotypes, (2) corals in deeper water tend to spawn earlier, and (3) there is a genotype by depth interaction in spawning times (clone-mates have significant differences in the way they respond to depth in spawn time). In addition although the species tends to spawn over a period of approximately 40 minutes, (4) individuals corals tend to spawn within a few minutes of when they spawned in previous years; individuals have a high degree of fidelity to a particular spawn time. Overall these results suggest a large genetic component to precise spawn times. Data on reproductive success of corals that spawn at different times indicate that (5) corals spawning during the mid-point of the event have higher reproductive success compared to individuals spawning at the tails of the event. The genetic control over spawning time coupled with the fitness consequences of variation in spawning times provide the evolutionary mechanism by which reproductive synchrony is achieved.

## 11-23

**Correlated Evolution Of Life-History Traits in Scleractinian Corals**

**Alexander KERR*[1,2]**, Andrew BAIRD[2], Terry HUGHES[2]

[1]Marine Laboratory, University of Guam, Mangilao, Guam, [2]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

The population and quantitative genetic aspects of life-history traits receive considerable theoretical and empirical attention, yet far less is known about the macroevolutionary relationships among such characters, particularly in a phylogenetic context. In this study, we examine the evolution of two important life-history features, sexuality and reproductive mode, on a composite or "supertree" phylogeny of 242 species of scleractinian corals in order to address the following questions: (1) How rapidly do reproductive traits evolve? (2) Are the evolutionary rates of reproductive characters correlated? (3) How does trait evolution generate large-scale taxonomic patterns in reproductive traits? Both maximum likelihood-based model selection and maximum-parsimony mapping of state transitions done over a sample of optimal trees to incorporate phylogenetic uncertainty indicate that the evolution of sexuality (gonochorism versus hermaphroditism) and reproductive mode (brooding versus spawning) were unambiguously correlated across Scleractinia. Transition rates between states differed significantly and by as much as two orders of magnitude among, as well as within, characters. Reproductive mode evolves at twice the rate of sexuality, while the evolution of sexuality was heavily biased: Gonochorism is over 100 times more likely to be lost than gained and then only among brooders, such that gonochoric spawners seldom evolve hermaphroditism. Gonochoric spawners preferentially shift to brooding and then, or jointly, become hermaphroditic before reacquiring spawning to attain the dominant scleractinian reproductive condition. Thus, we conclude that large-scale taxonomic and phylogenetic patterns in a fundamental life-history character may be accentuated by correlated evolution with other life-history traits when coupled by state bias in at least one character. Further, phylogenetic and taxonomic patterns of joint character states can be generated through unanticipated and extended pathways of state change if traits are under intense natural selection.

## 11-24

**The Reproductive Biology Of Pacific Island Corals: Patterns And Permutations**

**Robert RICHMOND*[1]**

[1]Kewalo Marine Laboratory, University of Hawaii at Manoa, Honolulu, HI

Data and observations on reproductive characteristics are available for approximately 220 species of scleractinian corals world wide. Only 10 coral species have been identified as having year round production of gametes and larvae, and all of these are brooders. The remaining 200+ species have been identified as having limited periods of reproductive activity each year, from a few nights or days per year, to several periods over several months. Two decades of data on coral reproduction in the Pacific Islands of Hawaii and Micronesia have revealed annual, lunar and diel patterns in timing as well as reproductive responses to both natural and anthropogenic disturbances. Many of the mass spawning species including those in the genera *Acropora*, *Goniastrea*, *Favia*, *Porites* and *Leptoria* have distinct temporal patterns during the days or nights on which they spawn. Repeated sampling has demonstrated species will release gametes consistently at specific times of day, evening or night year after year. Variability in annual reproductive cycles has been found in response to climatic conditions and events. Recent research on the effects of multiple stressors on corals has found reproduction is affected by both exogenous and endogenous factors and that reproductive patterns can be interrupted or otherwise affected by pollution and other sources of stress. Reproduction and subsequent recruitment are the two processes responsible for the persistence of coral reefs, and as such, are important processes for addressing the future of these precious ecosystems in the face of mounting levels of anthropogenic disturbances including global climate change.

## 11-25

**Survival Of Brooding And Broadcasting Reef Corals Following Large-Scale Disturbances: Is There Any Hope For Broadcasting Species During Global Warming?**

**Peter GLYNN*[1]**, Susan COLLEY[2]

[1]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [2]PBS&J, Ft. Lauderdale, FL

This study examines the reproductive ecology of extant equatorial eastern Pacific (EEP) zooxanthellate scleractinian corals relative to projected global warming conditions. Reproductive characteristics (e.g. sexuality, fecundity, timing of spawning, seasonality, larval type, asexual propagation), colony morphology, growth, survivorship, and patterns of abundance and distribution of 12 recently studied species in Costa Rica, Panamá, and the Galápagos Islands are considered. All but one of these 12 EEP species are broadcast spawners. The broadcasting species, which make up 44% of the known zooxanthellate species occurring in the EEP (25 species), are numerically abundant, widely distributed, and the principal reef builders in this region. *Porites panamensis*, which broods and releases planulae, is a small nodular coral with a restricted distribution; it does not contribute importantly to contemporary reef building. The majority of the broadcasting species are highly fecund, active sexually during large parts of the year, with sexual recruits that appear to disperse relatively far to a variety of habitats. Asexual fragmentation is also common in broadcasting species compared with brooding species in the EEP region. We hypothesize that diverse habitats and varying environmental conditions (e.g., upwelling/nonupwelling centers, carbonate/basalt substrates, wet/dry seasons, high/low turbidity, high/low productivity, El Nino/La Nina activity) would increase the probability of survival of sexual recruits and the asexual fragments of broadcasting species. Such refuge populations could serve as sources of larvae or fragments to repopulate coral communities in disturbed areas. The EEP reef coral fauna, consisting dominantly of broadcasting species, may appear to be poised to resist extinction during global warming.

## 11-26

**To Eat or Not To Eat? Trophic Biology of Stylophora pistillata Larvae - A Stable Isotope Approach**

**Ada ALAMARU*[1,2]**, Ruth YAM[3], Aldo SHEMESH[3], Yossi LOYA[4]

[1]Department of Zoology, George S. Wise Faculty of Life Sciences, Tel-Aviv University, Eilat, Israel, [2]Interuniversity Institute for Marine Sciences of Eilat, Eilat, Israel, [3]Department of Environmental Sciences and Energy Research, Weizmann Institute of Sciences, Rehovot, Israel, [4]Department of Zoology, George S. Wise Faculty of Life Sciences, Tel-Aviv University, Tel-Aviv, Israel

Recruitment success of planktonic larvae to coral reefs is essential for the continued survival of these highly diverse ecosystems. Feeding strategies may affect recruitment success and potentially determine species distribution. The aim of this study was to ascertain the feeding strategies of *Stylophora pistillata* larvae (planulae) using stable isotopes, a powerful method utilized in dietary studies. Planulae and fragments of parental colonies were collected from 2m and 20m depth at the coral reef of Eilat, Israel (Gulf of Aqaba) during 2007. Carbon and Nitrogen stable isotope compositions and C/N ratios of planulae were compared with those of parental colonies. Results showed that δ13C of planulae was significantly lower than that of the parental colonies, but that C/N ratio was two times higher regardless of depth. Following lipid extraction, we found no significant difference in δ13C and in C/N values between planulae and parental colonies. Therefore, the differences in δ13C originate in the lipid content of the planulae and not from an isotopic fractionation during embryological development. In order to determine if released planulae feed heterotrophically, I conducted controlled feeding experiments using dissolved organic matter, phytoplankton and zooplankton comparing the isotopic ratios of planulae and the food sources. To evaluate the contribution of photosynthates translocated from the algal symbionts to the planulae, experiments were carried out under light and dark conditions. Despite the presence of an oral opening, the planulae did not feed. Moreover, following two weeks of "starvation" in the dark, planulae started utilizing their lipid reservoirs, indicating the importance of photosynthesis to the planulae. Our findings stress the importance of the physiological state of parental colonies in producing viable planulae, capable of going through metamorphosis and successful recruitment to coral reefs.

## 11-27

**Sexual Reproduction And Early Life History Of Acropora Reef Corals At Moorea, French Polynesia**

**Andrew CARROLL*[1,2]**, Peter HARRISON[3,4], Mehdi ADJEROUD[5,6]

[1]Coral Reef Research Centre, Southern Cross University, Lismore, Australia, Coffs Harbour, Australia, [2]National Marine Science Centre, Coffs Harbour, Australia, Coffs Harbour, Australia, Australia, [3]Coral Reef Research Centre, Southern Cross University, Lismore, Australia, Lismore, Australia, [4]National Marine Science Centre, Coffs Harbour, Australia, Coffs Harbour, Australia, [5]Ecole Pratique des Hautes Etudes, Perpignan, France, Perpignan, France, [6]Centres de Recherches Insulaires et Observatoire de l'Environnement, Moorea, French Polynesia, Papetoai, Moorea, French Polynesia, French Polynesia

This study provides the first detailed quantitative data on the sexual reproduction, larval development and settlement competency periods of broadcast spawning *Acropora* reef corals at Moorea, French Polynesia. From 2002 to 2004 the timing and mode of sexual reproduction for *Acropora* reef corals was examined at four sites on the outer reef slope and reef lagoon. To determine extent of spawning synchrony within and among species, colonies of *Acropora* spp. were tagged and repeatedly sampled, or collected for spawning in flow through outdoor aquaria, during September through November. Spawning was observed in aquaria and inferred in the field from the disappearance of mature gametes for 13 species of *Acropora*, between 6-9 nights after the full moon in September, October and November. Following spawning in November 2004, post fertilisation samples were taken from *A. nasuta*, *A. striata* and *A. lutkeni* to compare the morphological stages of embryo and larval development from early cleavage to ciliated planula larvae. Larval development and settlement competency periods were studied using *A. retusa* and *A. striata* planulae. Larval attachment onto settlement tiles occurred within 3-4 DAS (days after spawning) in both species. Peak periods of larval metamorphosis and permanent settlement occurred between 4-10 DAS for *A. retusa* and 5-10 DAS for *A. striata*. The early development and initial rapid attachment patterns of *A. retusa* and *A. striata* larvae indicate that some planulae may be retained close to their natal reef. However, the extended settlement competency periods observed in *A. striata* (31 DAS) and *A. retusa* (26 DAS) suggest that some planulae also have the potential for dispersal away from their natal reef before settling. This information is important for understanding and predicting the likely sources of larval supply to Moorea, and examining the potential likelihood of reef interconnectivity via larval dispersal in French Polynesia.

## 11-28

**Reproductive Biology, Embryogenesis And Larval Development Of The Gorgonian *calicogorgia Granulosa* (Gorgonacea: Plexauridae)**

**In-Young CHO*[1]**, Jun-Im SONG[1]

[1]Division of EcoScience, Ewha Womans University, Seoul, Korea, Republic of

The sexual reproduction and larval development of the gorgonian, *Calicogorgia granulosa* were examined in the southern most part of Korea Jejudo Island, Korea from August 2003 to March 2007. There are the unique soft coral communities with tropical and subtropical elements. *Calicogorgia granulosa* is a dominant species in the communities.

The reproductive mode, gametogenic cycle, fecundity and spawning time of reproduction on the species were assessed by using histological preparation and field surveys. Early developmental processes from gametes, embryos to planulae have been observed under the light and stereo microscopes.

*Calicogorgia granulosa* was found to be a gonochoric broadcaster. The ratio of females to males was 1.5 : 1. Gametes were found all year round. Gametogenesis took place three times a year and spawning of gametes occurred at new moon in March, August and November. Spawned eggs ranging from 650 to 750 μm in diameter were spherical and dark blue. Fertilized eggs developed into mature planulae over 4-6 days after spawning. The mature planulae were settled on substrata on 25 days post-spawning. Especially, they preferred to settle on the lower part of substrata. And the planulae developed into the primary polyps with 8 tentacles and oral part within 5 days after settlement. The survival rate of planulae was recorded approximately 30% in the laboratory.

## 11-29

**The Reproductive Biology And Recruitment Ecology Of Porites Bernardi**

**Jonathan MARTINEZ*[1]**, Robert RICHMOND[1], Jorg ANSON[2], Sean MCDUFF[3]

[1]Pacific Biomedical Research Center, University of Hawaii at Manoa, Honolulu, HI, [2]Kewalo Marine Laboratory, Honolulu, HI, [3]University of Hawaii at Manoa, Honolulu, HI

Porites cf. bernardi is a scleractinian coral described by Vaughn 1904. Its worldwide distribution remains uncertain although it has been reported from locations in Japan, Hawai'i & São Tomé e Principe. In Hawai'i, this coral inconspicuously grows in encrusting forms rarely larger than 10 cm2 in areas of high wave motion, inhabiting the subtidal zone to depths of 13m. No previous data are available describing the reproductive biology and larval ecology of this species.

P. bernardi is a brooding coral, which reproduces year-round. Colonies do not appear to be dependent on sperm from conspecifics for planulae production and release larvae most days of the year with peak planulation near the lunar third quarter. There is a positive relationship between adult size and reproductive output. A regression model predicts that adults larger than 0.7225 cm2 may be reproductively mature, and adults as small as 0.882 cm2 have been observed to planulate. The larvae of P. bernardi have not been observed to swim in the water column under laboratory conditions, but rather only crawl along the substrata along a single axis Larval recruitment occurred mainly in response to coralline algal chemical metabolites although modest recruitment has been observed in presence of bacterial biofilms. In bioassays, almost all of the larvae settled within 48 hrs of exposure to appropriate crustose coralline algae.

The availability of P. bernardi planulae throughout the year, and the larvae's responses to metamorphic inducers makes this a good model organism for studies of the effects of anthropogenic stressors such as pollution, elevated temperatures, acidification and sedimentation on coral reproduction and recruitment.

## 11-30

**A Review Of Sexual Reproduction in Octocorallia**

**Samuel KAHNG*[1]**, Yehuda BENAYAHU[2], Howard LASKER[3]

[1]College of Natural Science, Hawaii Pacific University, Kaneohe, HI, [2]Tel Aviv University, Tel Aviv, Israel, [3]University at Buffalo, Buffalo, NY

Since its initial discovery on Oahu in 1966, the azooxanthellate octocoral, *Carijoa riisei* (Duchassaing and Michelotti, 1860), has spread across the main Hawaiian Islands and proliferated in abundance. To help understand the substantial ecological success of *C. riisei* in Hawaii, its sexual reproduction was examined. *Carijoa riisei* is gonochoric with a male to female ratio of one. Gametogenesis is asynchronous, continuous, and does not exhibit seasonal or lunar periodicity. *Carijoa riisei* spawns negatively buoyant eggs which suggest external fertilization and possibly benthic larvae. Under favorable conditions, *C. riisei* exhibits high polyp fecundity. Asynchronous, continuous spawning of gametes is an unusual mode of reproduction which forgoes the advantages of concentrating gametes in space and time and requires dense aggregations of male and female colonies in close proximity to ensure fertilization success. Other life history traits such as fast growth, early age of sexual maturity, vegetative propagation, and superior competitive ability enable *C. riisei* to form dense, multi-colony aggregations thereby facilitating sexual reproduction. Provided *C. riisei* can achieve a critical density, this unusual sexual reproductive strategy probably enables it to exploit the ephemeral availability of space across time with a high and continuous production of larvae.

## 11-31

**Sexual Reproduction In The Soft Coral *Lobophytum* Sp. In Tung Ping Chau Marine Park, Hong Kong Sar, China**

**Chung Wing YEUNG*[1]**, Put ANG[1]

[1]Marine Science Laboratory, Department of Biology, The Chinese University of Hong Kong, Hong Kong, Hong Kong

The soft coral genus *Lobophytum* is a carpet-like encrusting coral and is commonly found in Hong Kong waters. The reproductive biology of *Lobophytum*, as well as that of other soft corals in Hong Kong has never been investigated. This study provides the first baseline information on the reproductive biology of soft corals in Hong Kong.

The sampling site in this experiment was Lung Lok Shui in Tung Ping Chau Marine Park. Three samples from five marked *Lobophytum* aggregations were collected monthly from 16 Aug 2006 to 7 Jul 2007. Histological sections of each sample were prepared and their gonadal development was observed under the microscope. All colonies in the same aggregation were assumed to come from the same mother colony, since *Lobophytum* was reported to undergo asexual reproduction and thus, its daughter colonies would remain in close proximity forming the aggregation.

From the histological analysis of the samples, all colonies bore only eggs. As *Lobophytum* was reported to be gonochoric, all the colonies sampled were therefore female. Male colonies may be missed during sampling. Oocytes from the samples measured increased in mean (±SD) diameter from 116.5±18.8 µm in Aug 2006 to 239.3±82.2 µm in Jun 2007, and dropped back to 93.0±23.2 µm in Jul 2007. This indicates that spawning of *Lobophytum* probably occurred in or before Jul 2007. The oocyte development appeared synchronized as shown in the simultaneous increase in their sizes. However, new oocytes likely developed before the release of the mature ones so that each cycle of development took more than one year to complete. Additional samples will be processed in order to confirm this initial observation.

## 11-32

**Reproductive Biology Of Temperate Soft Corals (Alyonacea: Nephtheidae) in Korean Waters**

**Sung-Jin HWANG*[1]**, Jun-Im SONG[1]

[1]Division of EcoScience, Ewha Womans University, Seoul, Korea, Republic of

There was little information about the reproductive biology of family Nephtheidae. This study were examined the reproductive diversity on three soft coral species from 2003 to 2007, and two of them were belonged to *genus Dendronephthya* and one was to *genus Scleronephthya*. They are all sympatric species in the Jejudo Island area (33° 22′ N, 126° 33′ E), and highly distributed on the horizontal and vertical rocky substrata from 3 to 50 m in depth. One species, *Dendronephthya castanea*, was a gonochoric internal brooder and two, *D. spinulosa* and *Scleronephthya gracillimum*, were gonochoric broadcasters. They showed annual reproductive cycles and similar patterns in gametogenesis. Gametes of them were matured as seawater temperatures increased, reflecting a seasonal correlation in reproductive cycle. While oocytes were observed at all times of the year, spermaries were found during a short period. *D. castanea* released lecithotrophic planulae from July to September, and *D. spinulosa* and *S. gracillimum* spawned gametes asynchronously from August to December and in August, respectively. The ratio of female to male was 2.5: 1 in an internal brooder (*D. castanea*) and 1.5: 1 in broadcasters (*D. spinulosa* and *S. gracillimum*), suggesting the correlation to mode of reproduction.

## 11-33

**Reproductive Cycle Of The Deep-Sea Coral, *drifa Glomerata* (Octocorallia: Alcyonacea), in The Nw Atlantic**

**ZHAO SUN*[1]**, JEAN-FRANÇOIS HAMEL[2], ANNIE MERCIER[1]

[1]Ocean Sciences Centre (OSC), Memorial University of Newfoundland, St John's, NL, Canada, [2]Society for the Exploration and Valuing of the Environment (SEVE), St John's, NL, Canada

This study of the mode and timing of reproduction in bathyal corals was undertaken in an effort to gather information on poorly understood deep-water species. Colonies of *Drifa glomerata* were collected between 103 and 334 m off Newfoundland (eastern Canada) from November 2004 to December 2007. They were frozen at -20˚C and studied using a mix of micro-dissection and histological procedures. The ratio of reproductively active colonies, with mature planulae, was >50% all year round, suggesting the capacity to release larvae throughout the year. Among the breeding colonies, the number of planulae within a single reproductive polyp varied from 1 to 8, with an average between 2 and 5. The number of reproductive polyps per colony varied from 2 to 1030 and was positively correlated with the size of the colony. Fecundity, expressed in planulae g-1, showed a seasonal trend with an increase between November and January and lower values in June-July of a given year. Inversely, the average size of oocytes or planulae decreased from November to January, and this trend was detectable in both polyps and branchlets. The average surface area of the oocytes or planulae was consistently greater in the polyps than in the branchlets across all dates and depths, indicating that the development pathway of planulae is from the coelenteron to the polyps. Based on these data, we believe the peak breeding season may be between November and February, when new planulae are produced and large mature larvae are released.

## 11-34

**The Influence Of Size, Morphology And Parental Conditions On Coral Reproductive Outputs**

**Jacqueline PADILLA-GAMINO*[1,2]**, Ruth GATES[3]

[1]Oceanography, University of Hawaii, Honolulu, HI, [2]Hawaii Institute of Marine Biology, Kaneohe, [3]Hawaii Institute of Marine Biology, Kaneohe, HI

Understanding factors that influence the reproductive biology of corals is fundamental to predicting the future of coral communities in the face of climate change and/or anthropogenic disturbances. While several studies have analyzed the size at which corals become sexually reproductive, few have focused on the reproductive ecology of corals belonging to larger size classes. This is due to the difficulty in transporting large colonies to aquaria for study and designing devices large enough to deploy over these colonies that allow gametes to be collected in the field. To better understand the relationships between size, morphology and reproductive capacity, this study examined *in situ* reproductive outputs (gametes) in three size classes and two morphologies of the hermaphrodite spawning coral *Montipora capitata* in Hawaii. Gametes were collected from plating and branching corals situated in two environments for each of three months in the summer of 2007. Regardless of morphology and environment, colonies spawned simultaneously and had similar egg sizes, number of eggs per bundle, endosymbiont densities and chlorophyll concentrations. There was a significant difference in the egg size and number of eggs per bundle for the different months sampled with egg size being negatively correlated with the number of eggs per bundle. Earlier in the reproductive season (June) there were a high number of small eggs per bundle as compared to later in the season (July and August) when there were a smaller number of large eggs per bundle. Current analyses are focused on comparing a suite of physiological traits in coral eggs and their parental colonies. These include endosymbiont identities and densities, chlorophyll, lipid and protein concentrations; and mycosporine-like amino acid profiles.

## 11-35

**Density And Size Of Aaptos Aaptos Sponge Gametes**

Mujizat KAWAROE[1], **Mujizat KAWAROE*[1]**

[1]Marine Science and Technology, Bogor Agricultural University, Bogor, Indonesia

The reproduction of the demospongia *Aaptos aaptos* in Pari Island (Jakarta Bay) was studied histologically during March 2007. One hundred and fifty thousand transplanted individuals sponges were sampled from northern and southern and examined with light microscopy for the presence of gametes. The species is ovoviviparous and no males were found, possibly owing to the very short period of spermatogenesis. The non mature oosit with high density were present at surrounding mesohyl layer. And the mature oosit with low density were moved to brood chamber. Sponges transplanted with fragmentation involved sexual reproduction on the prior development stage (177 days), meanwhile within 241 days, the sponge average size increased to 11,70 cm and 11,83 cm, reproduction activity have been increased. The present results demonstrated that oosit average size of *Aaptos aaptos* from transplanted and nature could be opposite with its density.

Key words : *Aaptos aaptos,* reproduction, gamete, transplanted, development,

## 12-1

**Past Frequencies Of Thermal Anomalies Determine Extent Of Coral Bleaching**

**Diane THOMPSON*[1]**, Robert VAN WOESIK[1]

[1]Biological Sciences, Florida Institute of Technology, Melbourne, FL

Coral bleaching events have increased in the past few decades due to an increase in the frequency, severity and spatial scale of anomalous sea-surface temperature (SST) events. These coral bleaching events are expected to become even more frequent as SSTs continue to rise. Yet, the frequency of past anomalous SSTs may influence coral acclimatization and adaptation. The objective of this study was to determine whether the frequency of anomalous SST events in the past influences the ability of corals to resist bleaching. We hypothesize that corals at sites that have experienced frequent anomalous SSTs over the last three centuries will be able to resist bleaching during contemporary regional thermal stress events. Wavelet analysis of coral stable oxygen isotope records was used to determine significant interannual and decadal variability at 17 reef locations. Interpolation was then used to determine the probability of interannual and decadal variability throughout the Pacific and Indian Oceans and the Red Sea. The difference between these probabilities was used as the predictive variable, as less bleaching is expected at sites with high-frequency variability (high interannual and low decadal). A global meta-analysis categorically defined bleaching severity at each site during the peak of the 1997-98 event as either: 1) no, 2) low, 3) medium or 4) high bleaching. We show that sites that experienced no or low bleaching had a significantly higher difference between the interannual and decadal modes. Therefore, corals at sites that had experienced frequent thermal anomalies in the past were more likely to resist bleaching during contemporary thermal events. Based on the frequency of past thermal events, reef corals in the Pacific Ocean may be more likely to resist bleaching during future climate change-associated anomalies compared with corals in the Indian Ocean and Red Sea.

## 12-2

**Corals in Hot Water: Physiological Responses Of *porites Lobata* in A Diurnally Fluctuation Environment**

**Daniel BARSHIS*[1,2]**, Jonathon STILLMAN[3], Ruth GATES[1], Robert TOONEN[1], Lance SMITH[4], Charles BIRKELAND[4]

[1]Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kaneohe, HI, [2]Department of Zoology, University of Hawaii at Manoa, Honolulu, [3]Romberg Tiburon Center for Environmental Studies, San Francisco State University, Tiburon, CA, [4]Department of Zoology, University of Hawaii at Manoa, Honolulu, HI

The Ofu back reef in the National Park of American Samoa hosts a wide variety of corals that withstand mean temperatures (up to 30oC) and daily fluctuations (3-4oC) greater than most coral reef habitats. Despite these known stressors, back reef corals appear healthy, exhibiting limited bleaching despite high levels of environmental fluctuation. We hypothesized that frequent exposure to the fluctuating environment of the Ofu back reef enhances the corals ability to cope with environmental stress. Samples from 4 source colonies of *Porites lobata* from the back reef and 4 colonies from the neighboring forereef were cross and back transplanted to each source location. Transplants were sampled every 24 hrs for 5 days following transplantation (n=40). Heat shock protein 70 (Hsp70), ubiquitin-conjugated proteins, manganese superoxide dismutase (MnSOD), and 4-Hydroxynonenal (4-HNE) protein levels were analyzed by Western blot for each sample. Ubiquitinated protein levels were higher in back reef source colonies for all transplants and all days ($p<0.001$). The high level of ubiquitin-conjugated proteins in the back reef corals could be indicative of more rapid protein turnover, enabling them to respond to the abrupt changes in their surrounding environment. Hsp70, MnSOD, and 4-HNE levels were higher in back reef source colonies ($p<0.01$), although not consistently for all days and sites. There were no differences among levels of any protein measured between cross and back transplants for back reef or forereef source colonies, suggesting that the corals are acclimatized or adapted to their native environments. Analyses of mitochondrial DNA (coral host), and nuclear rDNA (coral host and symbiont) revealed significant population differentiation between back reef and forereef hosts but not symbionts, providing additional evidence indicating a host adaptive response to the different environments.

## 12-3

**Responses Of Coral Hosts And Their Algal Symbionts To Thermal Heterogeneity**

**Hollie PUTNAM*[1]**, Peter EDMUNDS[1]

[1]Biology, California State University Northridge, Northridge, CA

The effects of high temperature on corals have been studied extensively, but little is known of the response to frequent thermal fluctuations common in shallow reef communities. In the lagoons of French Polynesia, daily oscillations of ~3-4ºC create a potentially challenging physical environment, yet coral communities in these habitats are extensive and largely healthy. Using *Pocillopora meandrina* and *Porites rus* as model systems, this study tested the effects of fluctuating temperatures on coral physiology. Initial experiments in 2006 exposed corals to both stable treatments (28ºC) and an oscillating treatment of a seasonal magnitude (~26ºC-32ºC), with the response assessed through changes in maximum quantum yield ($F_V/F_M$), and *Symbiodinium* density, which characterize the response of the symbiont. $F_V/F_M$ was depressed under oscillating treatment, in comparison to steady-state conditions, for both species. Building on these experiments, in 2007 microcosms with uniform artificial lighting and sophisticated aquarium controllers were used to produce steady treatments of 26ºC, 28ºC, 30ºC, and a daily oscillating treatment from 26ºC-30ºC. Coral response was measured as changes in both symbiont traits ($F_V/F_M$, chlorophyll-a content, and *Symbiodinium* density) and a whole organism trait (skeletal growth). MANOVA on these four response variables revealed a significant treatment effect on overall physiology, and univariate analyses determined this effect was driven primarily by large declines (17-45%) in *Symbiodinium* density in the oscillating treatment compared to the ambient treatments. Conversely, coral growth in the fluctuating treatment was not significantly different from all other treatments. Together, these results are interesting because they suggest under the maximum range of seasonal temperatures, as well as the greatest daily temperature range, that overall response of common coral species may be held relatively constant through compensatory changes in the symbiont physiology.

## 12-4

**Effect Of Physiological State On Regeneration in *porites Lutea* (Scleractinia) At Reunion Island**

**Vianney DENIS*[1]**, Joëlle RICHARD[1], Mireille MMM GUILLAUME[1,2], Henrich JH BRUGGEMANN[1]

[1]Laboratoire d'Ecologie Marine (ECOMAR), Université de la Réunion, St Denis, Reunion, [2]Milieux et peuplements aquatiques, UMR5178 CNRS/UPMC/MNHN BOME, Muséum National d'Histoire Naturelle (MNHN), Paris, France, Metropolitan

Colonial characteristics of corals allow them to withstand partial damage, resulting in areas of skeleton devoid of living tissue. Such lesions offering a settling substrate for competitors, regeneration is consequently fundamental for colony survival. However, the rate of regeneration is influenced by different environmental stressors which may alter the strategy of resource reallocation.

We combine, probably for the first time, monitoring of zooxanthellae physiological state and environmental parameters to evolution of lesion size with time. We characterize the regeneration process in *Porites lutea* at two sites with different environmental settings. The first site has higher mean temperature, higher temperature variation and lower flow rates compared to the more exposed, second site. Artificially induced lesions (30 mm², 3-4 mm deep) in 25 replicate colonies in each site were monitored from August-December 2007 (cold season) along with environmental parameters (temperature, solar radiation, hydrodynamics). Each lesion was photographed regularly and surfaces were measured using image analysis. Zooxanthellae physiological state was assessed prior to and during lesion regeneration using a Pulse Amplitude Modulated (PAM) fluorometer to estimate environmental stress on the colonies.

Regeneration was visible after three days following lesion induction. Regeneration rate initially increases, reaches a maximum after 10-20 days, then decreases exponentially. Overall, photosynthetic yield (Fv/Fm) and lesion regeneration rates do not differ significantly between the two sites, with maximum regeneration rates reaching 0.11 $cm^2\ day^{-1}$. However, in the high-temperature fluctuation site, regeneration rates track variations in photosynthetic yield. Contrastingly, photosynthetic yield and regeneration rates vary independently in the exposed site. These results suggest environmental control on regeneration capacity of coral colonies, possibly mediated by temperature dependent reduction of photosynthetic yield of the coral symbionts.

## 12-5

**The Contribution Of Heterotrophy To Recovery From Bleaching in A Cnidarian-Algal Symbiosis**

**Cameron JOHNSON*[1]**, Tamar GOULET[1]

[1]Biology, University of Mississippi, University, MS

When elevated sea-surface temperatures cause the decoupling of cnidarian-algal symbioses, leading to reductions in the densities of the host's autotrophic endosymbionts, some species of hosts will compensate by increasing heterotrophic feeding. In this study, we experimentally bleached the symbiotic sea anemone Aiptasia pallida, and then either starved (S) or fed (F) them during a 5 week period in order to see what effect heterotrophy may have on recovery rates. In each of three repeated factorial experiments (bleaching x feeding), half of the anemones were bleached (B) by elevating the temperatures from 25°C to 32°C for one week (week 0), while non-bleached anemones (NB) remained at 25°C. At the beginning of week 1, the bleached anemones were returned to their normal temperature (25°C), and both B and NB anemones were evenly divided among 2 additional treatments; starvation (SB and SNB), and fed (FB and FNB). Zooxanthella densities were monitored using photographic analysis of reflected spectra, which was calibrated with traditional bio-assays. Over the five week recovery period, zooxanthella densities had increased in the SNB, SB and FB treatments, while the zooxanthella densities in the FNB treatment remained constant. FB anemones had higher recovery rates than SB anemones (P=0.0044). Additionally, SNB anemones had significantly increased their zooxanthella densities (P=0.0331). These results suggest heterotrophy may play an important role in the reestablishment of endosymbiont populations after a bleaching event. Monitoring availability of plankton on a given reef may therefore be another important factor in determining reef recovery from a bleaching event.

## 12-6

**Bleaching Effects On Scleractinian Coral Reproduction And Lipids Stores On The Great Barrier Reef, Australia**

**Devin TU*[1]**, Selina WARD[1]

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia

This study investigated if bleaching reduced coral fecundity and lipids in the Great Barrier Reef. A secondary objective was to monitor the recovery rate of different coral species by using fecundity and percentage of lipid tissue in coral as a biological indicator. In addition, the study compared the severity of conditions in 1998 to the 2006 bleaching periods on the reef-flat, based on temperature and weather data. Many studies on coral bleaching focused on the 1998 bleaching event, which was considered the most severe event on the Great Barrier Reef (GBR) in that century (Hoegh-Guldberg 1999, NOAA 1998, ICRS 1998). Few have studied the effects of the 2006 bleaching event that took place in the southern Great Barrier Reef, Australia.

Results demonstrate bleaching may not always impact negatively on the physiology of *Acropora* corals. Because of high variability of samples, there were no obvious differences in fecundity between bleached and unbleached *Acropora aspera* and *Acropora millepore* colonies based on percentage of reproductive polyps, and egg size and egg number per polyps. We hypothesize that there were no significant differences in lipid content between bleached and healthy corals in several species, however complete results were not available at the time of this submission. Bleached corals may have recovered before reproductive development. Basic *in situ* data suggests that summer 2006 conditions had abnormally high SSTs and light, but were not as elevated as 1998 at Heron Island, Australia. Potentially, zooxanthellae loss in bleached coral was not significant enough to reduce reproduction and lipids in *Acropora* species. This suggests that 2006 bleaching event, unlike pervious events, did not have a major impact on corals. Future research anticipates examining changes in chlorophyll *a* and zooxanthellae densities to identify the relationship between the severity of bleaching and the physiological impact on corals.

## 12-8

**Thailand's Coral Reefs Show Resilience in The Face Of Repeated Natural Stressors**

Niphon PHONGSUWAN[1], Anchalee CHANKONG[2], Ronawon BOONPRAKOB[2], Chaimongkol YAMARUNPATTHANA[1], Sathika PAOKANTA[1], **Niphon PHONGSUWAN*[1]**

[1]Marine and Coastal Resources, Phuket Marine Biological Center, Phuket, Thailand, [2]Marine and Coastal Resources, Eastern Marine and Coastal Resources Research Center, Rayong, Thailand

Thailand's coral reefs in the Andaman Sea and Gulf of Thailand have been repeatedly affected by both man-made and natural stressors over the last 20 years and yet have demonstrated considerable resilience, in particular to natural perturbations. Natural stressors have included Acanthaster infestations on the Andaman Sea coast in the mid 1980s; monsoon storms in 1986; elevated sea water temperatures which led to extensive coral bleaching in 1991 and 1995 in the Andaman Sea and in 1998 in the Gulf of Thailand; sea-level depression in 1997-98 and the tsunami of 2004, both of which only affected reefs in the Andaman Sea. Repeated monitoring of reefs in the periods 1988-1989; 1995-1998, in 2002 and again during 2006-2007 has revealed remarkable recovery at sites affected by major bleaching in 1991 and 1995 with virtually no impacts of minor localised bleaching noted at some sites in 2003, 2005 and 2007. The tsunami of 2004 had a very limited effect on coral reefs of the Andaman Sea and where damage occurred recovery is well underway at several locations. Such resilience appears to be restricted to sites affected only by natural perturbations since many shallow reefs near the mainland, which are chronically affected by siltation from land development, show little recovery.

## 12-9

**Reefs, Resilience, And Refuges - Theoretical Considerations And Real-Life Examples**

**Bernhard RIEGL*[1]**, Samuel PURKIS[1]

[1]National Coral Reef Institute, Nova Southeastern University, Dania, FL

If global changes impact reefs relatively uniformly, reefs with viable population dynamics will be resilient but some, and maybe eventually all, corals may be forced into refuges. Resilience or refuge character can be rooted in a more clement environment, adaptation to a harsh environment, or readjustments of population (community) dynamics caused by modified mortality-, survival- and recruitment-characteristics among species. Since many "traditional reefal settings" (tropical reef crests and slopes) seem to be degrading, one may search for sustainable dynamics in different habitats such as upwelling areas, deep reefs, or non-reefs. While these habitats may harbor less species or individuals, their population dynamics may be more advantageous. Even if the environments appear less suitable and the communities depauperate, a positive net population growth identifies potential refuges. Also, pulse-instability within dominance hierarchies may promote, or be a sign of, resilience. Opportunistic species may be naturally prone to large swings in abundance and find refuge in meta-populations that allow easy expansion or restriction of range. These species may adapt to only temporarily dominate communities of more resilient species. Their adaptation to changed environments may be less likely, since their reaction to stress would be population restriction and relocation into other, presumably more favorable, habitats. Temporary local absence would be part of survival strategy. Thus monitoring and assessment programs that primarily focus on coral cover, and not the underlying dynamics, may misunderstand resilience or refuge value of a habitat – since the present abundances are variable and may be misleading. Stochasticity of timing and distribution of impacts may allow apparently rich, but increasingly maladapted communities to persist, and lead to false conclusions regarding the nature of resilience or refuge. The presently richest areas may not be those with highest survivability. We use examples from all oceans to illustrate our point.

## 12-10

**Tolerance, Refuge And Recovery Of Coral Communities To Thermal Bleaching**

**David SUGGETT*[1]**, David SMITH[1], Nat SPRING[2], Michelle ETIENNE[3]

[1]Biological Sciences, University of Essex, Colchester, United Kingdom, [2]Earthwatch Institute (Europe), Oxford, United Kingdom, [3]Seychelles Centre for Marine Research and Technology, Victoria, Seychelles

Long term viability of coral communities is dictated by their ability to withstand environmental change, such as periods of elevated temperature. Three "mechanisms" exist by which reefs may survive such change: (1) physiological tolerance, (2) geographical retreat (refuge), and (3) repopulation and growth (recovery) once ambient conditions return. Here we report these "mechanisms" in operation by corals and coral communities exposed to thermally-induced bleaching conditions in the Seychelles. During the 1998 El Niño event, sea surface temperatures (SSTs) around the Seychelles persisted above 32°C and more than 75% of all reefs bleached. Since then, SSTs have not exceeded 32°C potentially allowing reefs to recover unchecked from repeat exposure. We performed extensive surveys of the size frequency distribution of species-specific colonies and observed that certain species survived the 1998 event whilst other species did not but have rapidly recruited into the system post 1998. Laboratory experiments confirmed that these different species-groups exhibited alternative physiological properties: Older established corals were most tolerant to periods of elevated temperature, as characterised by minor 'downregulation' of photosynthesis, and exhibited a greater metabolic potential for recovery (higher heterotrophy: autotrophy). Consequently, physiological properties of key coral species determined the current community structure post 1998. Turbid lagoons containing large colonies of susceptible species were identified, suggesting that these species survived 1998 by recruiting into 'sub-optimal' habitats and thus buffered against the elevated temperatures. Our results demonstrate that community structure analysis can be an important tool in identifying the ability of species to withstand environmental variability. Furthermore, that corals will survive climatic events and possible climate change by utilising various "mechanisms".

## 12-11

**Defining And Utilizing Indicators Of Reef Resilience in The Red Sea And Arabian Gulf**

**Ameer ABDULLA*[1]**, David OBURA[2]

[1]Marine Biodiversity and Conservation Science, IUCN Global Marine Program, malaga, Spain, [2]CORDIO, Mombasa, Kenya

Defining and utilizing reef resilience indicators in the Red Sea and Arabian Gulf

Red sea and Arabian Gulf coral reefs are characterized by high endemism and a naturally high tolerance to extreme environmental conditions such as high salinity, turbidity, and temperatures. These characteristics may indicate particularly high resilience to impacts associated with Climate Change, a feature of global importance. Consequently, Red Sea and Arabian Gulf sites were surveyed for resilience characteristics in 2007 and 2008. Forty nine resilience factors were identified for the two seas and their relative importance are compared to similar studies and indices developed for the Indian Ocean and Indo-pacific. These factors were used to identify key ecological areas of high resilience that were undamaged by particularly high regional SSTs in 1998, 1999, and 2001 – 2003 and that are priority areas for conservation. An aggregate of these factors and their relative weighting may prove useful in identifying other global reef sites of particularly high resilience and conservation importance.

## 12-12

**Reef Resilience and Change 1998-2007, Alphonse Atoll, Seychelles**

**Annelise HAGAN*[1]**, Tom SPENCER[1]

[1]Cambridge Coastal Research Unit, Department of Geography, University of Cambridge, Cambridge, United Kingdom

Alphonse Atoll, southern Seychelles (7o01'S; 52o44'E), a small (11.28 km2) atoll with minimal anthropogenic influences, was severely impacted by the Indian Ocean warming event of 1997-1998. Quantitative measurements of benthic cover commenced at this location at the peak of the warming (April 1998), establishing bleaching impacts and allowing estimation of pre-bleaching cover characteristics. Underwater videography surveys of fixed transect lines were made in 2001/02, 2003, 2005 and 2007, providing quantitative information on the changing cover characteristics of 10 benthic classes. Immediately post-bleaching, the scleractinian community was dominated by few genera, particularly *Porites*, which survived the bleaching event, and *Pocillopora* and *Acropora*, which rapidly re-colonised bare surfaces, including dead coral skeletons. Lagoon corals and many shallow water corals, presumably acclimatised to warmer water conditions, were resilient to the 1998 thermal stress and may have seeded local coral recovery. In December 2006, wave fields associated with the passage of Cyclone Bondo resulted in transport of *Porites* colonies and large blocks of reef framework onto reef-flats, loss of post-bleaching coral recruits and increased macroalgal cover on the fore-reef slope. There is now a marked difference in reef health between the west and east fore-reef slope, despite a separation of only 2 km. This location provides one of the most detailed long-term (> 9 yrs) records of post-bleaching reef dynamics in the Western Indian Ocean. It demonstrates i) the interaction between, and subsequent recovery from, both physiological and physical disturbances and ii) varying resilience by atoll environment (fore-reef slope, reef crest, lagoon). Surveys 1998-2007 have shown changing relative proportions of scleractinian and macroalgal communities but no clear 'phase-shift' from a hard to a soft dominated reef community.

## 12-13

**The Effects Of Habitat On Coral Resistance And Resilience To Bleaching**

**Gabriel GRIMSDITCH*[1,2]**, Nassir AMIYO[3], Joseph KILONZO[4]

[1]IUCN Global Marine Programme, Mombasa, Kenya, [2]Cordio East Africa, Mombasa, Kenya, [3]Kenya Wildlife Service, Mombasa, Kenya, [4]Kenya Marine and Fisheries Research Institute, Mombasa, Kenya

This study examines the bleaching responses of scleractinian corals at four sites in Kenya (Kanamai, Vipingo, Mombasa Marine Park and Nyali) representing two distinct lagoon habitats (relatively shallow and relatively deep). Bleaching responses were monitored for the general coral community and zooxanthella densities and chlorophyll levels were monitored for target species (*Pocillopora damicornis*, *Porites lutea* and *Porites cylindrica*) during a non-bleaching year (2006) and a year of mild bleaching (2007). The objective of this study is to determine whether corals in different habitats display varying resistance and resilience to bleaching stress and to indicate which environmental characteristics are responsible for the variation in response. Considerable differences in bleaching responses between shallower and deeper lagoon sites were observed, with shallower sites Kanamai and Vipingo exhibiting much lower bleaching and paling incidence than deeper sites Nyali and Mombasa Marine Park. These shallower lagoons display much more fluctuating thermal and light environments than the deeper sites, with higher maximums, lower minimums, higher standard deviations and higher diel variation. These results suggest that corals in the shallower lagoons have acclimatized and/or adapted to the fluctuating environmental conditions they endure on a daily basis and have become more resistant to bleaching stress. Furthermore, in deeper sites that did exhibit significant bleaching (Mombasa Marine Park and Nyali), it was found that coral recovery occurred more quickly in the protected area compared to the non-protected area.

## 12-14

**Ocean Dynamics Drive Coral Reef Processes in The Andaman Sea**

**Claudio RICHTER*[1]**, Mélanie BON[1], Laura FILLINGER[1], Carin JANTZEN[1], Cornelia RODER[1], Gertraud SCHMIDT[1], Niphon PHONGSUWAN[2], Somkiat KHOKIATTIWONG[2]

[1]Center for Tropical Marine Ecology, Bremen, Germany, [2]Phuket Marine Biological Center, Phuket, Thailand

Coral reefs are rich benthic ecosystems thriving in nutrient-poor waters. A striking feature of the Andaman Sea is the exposure of offshore reefs to large amplitude internal waves. These solitary-like waves (or solitons) are generated by the ebb and flow of water across the shallow ridges of the Andaman-Nicobar island arc and propagate along the density discontinuity (pycnocline) between warm surface and colder deep waters pycnocline with speeds of ~2 m $s^{-1}$ and amplitudes of up to 80 m. Here, we show that the dissipation of the solitons' energy in shoaling water enhances pelagic-benthic coupling along the continental margin, due to turbulent mixing near the sea bed, entrainment of interstitial and subpycnocline nutrients, and formation of bores. These 'solibores' supply nutrients and plankton to the benthos of the Similan Islands. Lowered temperature, pH and light hamper, however, coral photosynthesis and calcification, and their resilience against macroalgal competitors and grazers, resulting in low or negative reef growth. The frequency and intensity of cold bores (with temperatures drops of up to 10°C within only minutes) may on the other hand increase the corals' resilience to thermal stress. The findings have important repercussions on the Similan reefs which have been impacted by earlier bleaching and recent Tsunami. Because solitons are ubiquitous in the Andaman Sea and elsewhere, they may be an important yet so far overlooked mechanism structuring benthic communities in tropical waters.

## 12-15

**Opposing Effects Of Water Quality On Coral Bleaching Resistance And Recovery**

**David OBURA*[1]**, Haji MACHANO[2], January NDAGALA[3], Monica ZAVAGLI[4]

[1]CORDIO East Africa, Mombasa, Kenya, [2]WWF Tanzania, Dar es Salaam, Tanzania, [3]Mafia Island Marine Park, Mafia Island, Tanzania, [4]Ramsar Secretariat, Gland, Switzerland

The Mafia-Rufiji-Kilwa system of coral reefs and islands in central Tanzania is influenced strongly by outflow from the Rufiji river, which forms the largest delta system in Tanzania. Within this area, the impact of coral bleaching and mortality in 1998 varied considerably among reefs, with estimated mortality of corals varying from 0 to 100%, from surveys and observations conducted in the subsequent 9 years from 1999 to 2007. A new assessment method that includes estimation of a broad scope of factors hypothesized to influence coral resistance and tolerance to bleaching, and reef recovery following mortality, was conducted in November-December 2007 on 15 reefs in the region, sampling coral communities in 10-12 and 3-5 m depth zones. Quantitative and semi-quantitative data were collected on benthic cover, coral community structure, coral population structure, coral condition, herbivorous fish community structure, and indicators of physical site properties including connectivity, cooling and flushing, shading and screening and acclimatization potential. The two major factors that affected coral community structure related to a) initial resistance to bleaching - reefs with highest indicators of mainland river influence showed the lowest evidence of mass mortality in 1998, with turbidity likely providing the greatest degree of protection from thermal stress; and b) recovery following mortality - a combination of factors that included clear water (least mainland influence), substrate robustness (maximize coral survival) and high larval supply. These factors act in direct opposition to one another: turbid waters maximized coral survival during thermal stress, but clear water maximizes coral recruitment and survival under normal conditions. Thus current status of reefs is a result of multiple interacting factors; these need to be considered in a holistic way in priority-setting for active management to minimize climate impacts to coral reefs.

## 12-16

**Two-Years Monitoring Of Water Flow Effects On Photosynthesis And Growth Of The Coral *acropora Digitifera***

**Takashi NAKAMURA*[1,2]**, Seitaro S. YAMAZAKI[1], Yeong Shyan YUEN[1], Hideo YAMASAKI[1]

[1]Faculty of Science, University of the Ryukyus, Okinawa, Japan, [2]Amakusa Mar Biol Lab, Kyushu University, Kumamoto, Japan

We conducted an outdoor aquarium experiment to clarify long-term influence of water flow on corals. Water motion has significant impacts on the physiology of corals; limitation in water-motion causes severe bleaching in the coral *Acropora digitifera* during a period with strong light and high water temperature. Although there are numbers of investigations that report the effects of water flow in short-term (hours to weeks) experiments, long-term effects especially on the interaction with seasonal change in weather are not fully understood. In this study we report effects of water flow on the coral *A. digitifera* in several water-flow conditions (flow/wave/limited-flow) over two-year period in Okinawa, southern Japan. We monitored algal photosynthesis *in hospite* of *A. digitifera* weekly with a Diving-PAM chlorophyll fluorometer. Colony growth was measured monthly by the underwater buoyant weight method. In subtropical southern Japan under the influence of monsoon climate, seasonal change in weather had strong impacts on the photophysiology of *A. digitifera*. *A. digitifera* was evenly stressed in spring as well as in summer. Notably, high photosynthetic efficiency was often recorded just after the period of rainy season. Throughout the entire experimental period, photosynthesis of *A. digitifera* in limited-flow condition showed lower activity level than that of in flow conditions. Less colony growth with the disappearance of axial polyps was also observed under limited-flow condition in contrasted with flow conditions. These adverse effects of limited-flow could be diminished by the subsequent exposure to flow. The results confirm that water-flow can keep photosynthesis as well as growth of *A. digitifera* in good conditions throughout the years. We suggest that water-flow is an important factor that should be taken into the consideration of coral reef conservation.

## 12-17

**Wave Effects On Coral Reefs**

Malcolm L. HERON[1], William J. SKIRVING[2], **Scott F. HERON*[3]**

[1]Marine Geophysical Laboratory, James Cook University, Townsville, Australia, [2]NOAA Coral Reef Watch, Silver Spring, MD, [3]NOAA Coral Reef Watch, Siver Spring, MD

The work aims to evaluate the extent to which wave mixing mitigates the phenomenon of coral bleaching on isolated reefs. The physical conditions which allow coral bleaching are high insolation, low currents and low winds. Under these conditions a stable warm layer can form at the surface of the ocean. In this work we argue that very low swell wave energy should be added to the list, not because of linear waves passing through, but because of wave breaking at the reef front. For most reefs which rise abruptly from a nearly flat seabed, linear wave theory is sufficiently accurate for estimating the amplitude of a swell wave as it propagates from open water to the encounter with the reef. At the reef front, the wave energy is redistributed into a reflected component, localized turbulent mixing, and a forward bore across the reef top and onto the reef flats beyond. Under almost all conditions the mixing at the reef front is sufficient to destroy any tendency for a stable warm surface layer to form. Therefore, corals on the exposed sides of a reef are less likely to suffer from bleaching during an event where the surface temperature is elevated elsewhere in the vicinity; unless the full water column is warmed. The bore water which overflows the reef front is well mixed and during a bleaching event carries the cooler mixed water across the reef and onto the flats nearby. The main outcome from this work is that we predict that corals on the exposed sides of a reef and those on the adjacent reef top will be protected from bleaching under any but the most severe thermal stress. Further work should discover whether these corals can act as brood stock for subsequent reef recovery.

## 12-18

**Coral Reefs Under The Impact Of Internal Waves, Similan Islands, Andaman Sea: Primary Production**

**Carin JANTZEN*[1]**, Cornelia RODER[1], Gertraud SCHMIDT[1], Christian WILD[2], Claudio RICHTER[1]

[1]Center for Tropical Marine Ecology (ZMT), Bremen, Germany, [2]Coral Reef Ecology Work Group (CORE), Center of Geobiology and Biodiversity Research, MÃ¼nchen, Germany

Internal waves induced significant small-scale differences in structure and dynamics of primary producers on the exposed W and sheltered E sides of Similan Islands, Andaman Sea: Living corals were less abundant on the W side of the islands (49-67 % of total hard substrate vs. 28-44 % on W sides), with a higher percentage of turf algae (W: 43-46 %; E: 12-19 %) and higher areal concentrations of chlorophyll *a* and pheophytin. Chamber incubations carried out at the same light intensities showed 30-40 % reduced levels of potential photosynthesis on the W sides, this applies for both, the hermatypic coral *Porites lutea* (mg O2 h-1 cm-1 of coral surface) and sediment-associated algae (mg O2 h-1 mg-1 of Chl *a*). *In-situ* rapid lightcurves measured with a submersible pulse amplitude modulated underwater fluorometer showed lower saturation light intensities along with higher Chl *a* content (mg cm-2of coral surface) in W Similan *P. lutea*, indicating an adaptation to lower light levels in turbid upwelling waters.

## 12-20

**Coral Reefs Under The Impact Of Internal Waves, Similan Islands, Andaman Sea: Heterotrophy**

**Cornelia RODER*[1]**, Carin JANTZEN[1], Gertraud SCHMIDT[1], Claudio RICHTER[1]

[1]Center for Tropical Marine Ecology, Bremen, Germany

Coral reefs of the exposed Western sides of the Similan Islands, an offshore island group in the Andaman Sea, experience strong swell during the SW monsoon and internal wave induced upwelling, increasing POM concentrations, turbidity and nutrient levels 3 to 4-fold relative to the sheltered E sides of the islands, Here, we test the effect of these internal bores on the autotrophic vs heterotrophic nutrition of corals.

Measurements on isotopic composition ($^{13}C$ and $^{15}N$) of zooxanthellae as well as coral host (*Porites lutea*, *Diploastrea heliopora*, *Pocillopora eydouxi*) tissue indicate that the corals of the W side of the islands are more heterotrophic than on the sheltered E sides, despite their close geographical distance (200 m), with plankton substituting the reduced measured photosynthetic activity on the W sides.

Shading experiments suppressing photosynthetic activity revealed a more effective maintenance of metabolic activity in all three species due to enhanced heterotrophy on the W side. Cross-transplantation experiments with *P. eydouxi* showed that corals from the W side, accustomed to the rough conditions there, show faster adaptability to changes and enhanced resilience to environmental disturbance. Measurements on fitness parameters such as RNA/DNA-ratios or protein concentrations further support these assumptions.

## 12-21

**Coral Recruitment in The Garden Of Good And Evil: Algae As A Driver Of Coral Reef Resilience**

**Robert STENECK*[1]**, Suzanne ARNOLD[1], Peter MUMBY[2], Valerie PAUL[3], Raphael RITSON-WILLIAMS[3]

[1]School of Marine Sciences, University of Maine, Walpole, ME, [2]Marine Spatial Ecology Laboratory, University of Exeter, Exeter, United Kingdom, [3]Smithsonian Institution, Fort Pierce, FL

Coral reefs are globally endangered ecosystems. Their resilience depends on the ecological success of reef corals. In recent decades, mortality rates of adult corals have increased due to bleaching and disease. Thus, the ability of reefs to recover depends on the successful recruitment of corals. We studied the factors driving the recruitment of Caribbean corals at multiple scales in space and time. Since 2003 we have studied eight regions (Bahamas, Bonaire, St. Croix, St. John, Mexico, Belize, Honduras, Guatemala) four to six reefs per region with replicated benthic community structure transects, fish surveys, bite rates, and coral settlement plates at multiple reefs per region. From this a clear pattern has emerged. Algal community structure regulates coral recruitment both positively, due to the presence of coralline algal species that facilitate coral settlement, and negatively, due to the presence of macroalgae and thick algal turfs that inhibit coral settlement and coralline algal species that kill newly settled corals (via smothering overgrowth, or the shedding of the coralline's surface cells). Increased algal biomass of turfs and macroalgae reduce larval settlement and post-settlement survival. Since different coralline algal species can affect coral recruitment both positively and negatively, we conducted laboratory studies to determine if settling corals are selective in settling on facilitating species and avoiding recruitment inhibiting species. We found that different coral species show different coralline-specific selectivity. For example, *Acropora palmata* metamorphoses and settles near the coralline *Hydrolithon boergesenii* whereas *A. cervicornis* settles onto *Titanoderma prototypum.* We suspect that settling corals can determine the right zone, microhabitat (e.g. subcryptic spaces) and ecological state (e.g. high vs. low algal biomass) based on the coralline flora they detect.

## 12-22

**Algal Effects On Coral Replenishment, And The Resilience Of Coral Reefs**

**Chico BIRRELL*[1]**, Laurence MCCOOK[2], Bette WILLIS[3], Guillermo DIAZ-PULIDO[4]

[1]Australian Institute of Marine Science, Perth, Australia, [2]Pew Fellow in Marine Conservation; ARC Centre of Excellence for Coral Reef Studies; GBRMPA, Townsville, Australia, [3]ARC Centre of Excellence for Coral Reef Studies; School of Biological Sciences JCU, Townsville, Australia, [4]Pew Program in Marine Conservation; ARC Centre of Excellence for Coral Reef Studies, Brisbane, Australia

The ecological resilience of coral reefs depends critically on the capacity of coral populations to re-establish in habitats dominated by macroalgae. Coral reefs globally are under rapidly increasing pressure from human activities, especially from climate change, with serious environmental, social and economic consequences. Coral mortality is usually followed by colonisation by benthic algae of various forms, so that algae dominate most degraded and disturbed reefs. The capacity of coral populations to re-establish in this algal-dominated environment will depend on direct and indirect impacts of the algae on the supply of coral larvae from remnant adults, on settlement of coral larvae and on the post-settlement survival and growth of juvenile corals. This talk summarises a recent review of this topic.

The effects of benthic algae on coral replenishment vary considerably but the thick mats or large seaweeds typical of degraded reefs have predominantly negative impacts. Some algae, mostly calcareous red algae, may enhance coral settlement on healthy reefs. Algal effects on coral replenishment include reduced fecundity and larval survival, pre-emption of space for settlement, abrasion or overgrowth of recruits, sloughing or dislodgement of recruits settled on crustose algae, and changes to habitat conditions. There is a serious lack of information about these effects, which are likely to cause bottlenecks in coral recovery and significantly reduce the resilience of coral reefs.

## 12-23

**Coral Reef Resilience To Chronic And Acute Disturbances: Lessons From 90 Years Of Monitoring in American Samoa**

**Alison GREEN*[1]**, Charles BIRKELAND[2], Douglas FENNER[3], Cheryl SQUAIR[4]

[1]The Nature Conservancy, Australia, Brisbane, Australia, [2]Hawaii Cooperative Fishery Research Unit, USGS, USA, Honolulu, HI, [3]Dept of Marine and Wildlife Resources, American Samoa, Pago Pago, American Samoa, [4]University of Hawaii, USA, Honolulu, American Samoa

In 1917, Alfred Mayor established a quantitative coral transect on the reef flat at Aua in Pago Pago Harbor, American Samoa. He recorded rich coral communities in distinct zones along the transect. In the 1950s-1980s, this area was seriously degraded by chronic pollution from two tuna canneries in the inner harbor and by coastal development. By the 1970s, coral communities had declined substantially, and there was a change in the relative abundance of coral genera and major changes in coral zonation. In 1992, a large pipe was installed to export wastewater from the tuna canneries to the harbor mouth. Since then, there has been a significant recovery of coral communities on the reef crest and outer reef flat where there is consolidated reef substratum (up to 30 m back from the reef crest). In contrast, recovery has been substantially slower behind the reef crest, where the substratum is primarily loose rubble. In particular, the *Acropora* zone recorded on the outer reef flat in 1917 (120-140m behind the reef crest) had disappeared completely by the 1990s. Recovery is now proceeding in this zone by the slow accumulation of *Acropora formosa* colonies that are large enough to become established on the loose substratum. This study demonstrates different rates of recovery after chronic disturbance due to the influence of substratum type. This is in contrast to the results of long term monitoring in Fagatele Bay National Marine Sanctuary west of the harbor (since the late 1970s), where reefs have been shown to recover from acute disturbances such as hurricanes within 10-15 years. Major differences in rates of recovery appear to be the result of different types of disturbance (acute vs chronic), and degree of substratum consolidation.

## 12-24

**What Is The Future For Extensive Areas Of Reef Impacted By Fish Blasting And Coral Bleaching And Now Dominated By Soft Corals? A Case Study From Malaysia.**

**Elizabeth WOOD*[1]**, Frances DIPPER[2]

[1]Marine Conservation Society, Hook, United Kingdom, [2]Marine Conservation Society, Ross-on -Wye, United Kingdom

Many reefs in the Tun Sakaran Marine Park, Sabah, East Malaysia have been damaged by fish blasting and to a lesser extent by coral bleaching and crown-of-thorns starfish. Coral communities that comprised a mixture of growth forms and included a greater proportion of massive or robust species are recovering better than those where the majority of corals were laminar and foliaceous. One particular problem is at clear-water sites where there were extensive stands of laminar Montipora on the reef rim and upper slope. Collapse of these colonies created rubble that typically became colonised by soft corals, particularly xeniids. The xeniids are acting as a barrier to recruitment of hard corals and provide no shelter or structural complexity, with the result that these areas are now largely devoid of fish. The implications of this changed ecology for biodiversity, reef growth and productivity are discussed.

## 12-25

**Stability Of Reef Framework And Post Settlement Mortality As The Structuring Factor For Recovery Of Malakal Bay Reef, Palau, Micronesia: 25 Years After A Severe COTS outbreak.**

Steven VICTOR[1], **Steven VICTOR*[1]**

[1]Research, Palau International Coral Reef Center, Koror, Palau

Corals in Malakal Bay reefs were devastated in the 1979 Crown of Thorns Starfish (COTS) outbreak. It has been almost 30 years since the outbreak and coral cover at the study sites have not come close to the cover before the outbreak. A question is asked: what factors may contribute to the slow recovery of these reefs: recruitment or post-settlement mortality? Two habitat types within the reef systems were monitored using coral transplants to determine if corals can survive in these environments and recruitment tiles to see if there are larvae coming into the system. The study revealed that coral survivorship is high in the fore reef areas compared to the reef channel slopes and that larvae is not a limiting factor to natural recovery. Stability of the reef framework, i.e unstable rubble substrate, and possibly high post settlement mortality, are the structuring factors that determine the recovery process in these reef systems and possibly so for similar habitats in other reef systems throughout Palau.

## 12-26

**Response And Adaptation To Climate Change Stress On Andros Island Reefs, Bahamas**

**Philip KRAMER*[1,2]**

[1]The Nature Conservancy, Sugarloaf key, FL, [2]Marine Geology and Geophysics, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami

The coral reefs along Andros Island, Bahamas provide an ideal setting to examine reef structural and functional response to climate change given that they have experienced minimal human and natural disturbances such as hurricanes over the past century. Here we show how key ecological processes of coral mortality, herbivory, and recruitment, and physical factors such as wave energy and temperature have influenced recovery from 1998 and 2005 bleaching events. Since 2002, twenty-nine fixed sites representing six coral reef types have been monitored using Atlantic and Gulf Rapid Reef Assessment (AGRRA) methodology every two years. This 6-year monitoring dataset has been augmented with baseline AGRRA data collected in 1997-98 and a historic dataset of in-situ temperature data and video and photographic monitoring data collected since the early 1970's. Extensive losses during the 1997-98 coral bleaching and disease event reduced coral cover on high relief fore reefs and reef crests from 34% down to 12%. Lingering diseases and additional temperature stress during 2005 further reduced stony coral cover below 10% on many fore reefs, with losses greatest in the Montastraea annularis complex. Coral recovery has been limited, observed mostly as regrowth of coral tissue remnants rather than direct recruitment. Even on shallow reef crests where high levels of herbivory and faster rates of coral growth occur, high predation and coral disease limit coral recruitment and recovery. Physical environmental factors correlate with observed spatial patterns of resistance to bleaching and disease events. Lagoonal patch reefs exposed to highly variable temperature and light conditions and patch reef located within inland tidal channels and associated blue holes showed minimal loss of stony corals compared to bank margin reefs. These results suggest that both functional and environmental factors account for the observed patterns in resistance and recovery.

## 12-27

**Interaction Between Fishing And Bleaching On Kenyan Coral Reefs Moderated By Disturbance History**

**Emily DARLING*[1]**, Tim MCCLANAHAN[2], Isabelle CÔTÉ[1]

[1]Simon Fraser University, Burnaby, BC, Canada, [2]Wildlife Conservation Society, Bronx, NY

Coral reef ecosystems are affected by many stressors. The possibility these stressors interact synergistically causes conservation concern, but such non-linear effects remain untested in nature. We examined the independent and interactive effects of two stressors, fishing and bleaching, on coral community structure using a 16-year time series of monitoring data from Kenyan reefs. While both fishing and a mass coral bleaching event in 1998 decreased hard coral cover, these stressors did not interact synergistically to accelerate coral decline. Instead, fishing and bleaching interacted antagonistically. Following 1998, hard coral cover on unfished reefs declined 74% (relative to pre-bleaching cover) compared to 48% on fished reefs. Multivariate community analyses suggest that the non-synergistic interaction between fishing and bleaching may be explained by changes in coral community structure associated with fishing history. Prior to 1998, unfished reefs had diverse coral assemblages (dominated by branching *Acropora* and plating *Montipora*) that were not resistant to the 1998 bleaching event. In contrast, fished reefs, composed primarily of massive and branching *Porites*, were both more resistant to and recovered more quickly from bleaching. Decades of fishing pressure thus appears to have favoured low-diversity disturbance-tolerant coral communities. By contrast, unfished reefs may be refugia for high-diversity disturbance-sensitive communities. We suggest that disturbance history, community susceptibility, and trade-offs between diversity and resilience can moderate interactions between multiple stressors and may be important factors determining resilience to future large-scale climate events.

## 12-28

**Great Barrier Reef Coral Communities: Resilient in the 1980s but Struggling in the 2000s**

**Terry DONE*[1]**, Lyndon DEVANTIER[2], Emre TURAK[2], Mary WAKEFORD[2], Abbi MCDONALD[2], Craig JOHNSON[3]

[1]Australian Institute of Marine Science, Townsville, Qld, Australia, [2]Australian Institute of Marine Science, Townsville, 4810, Qld, Australia, [3]University of Tasmania, Hobart, Australia

Coral communities were monitored using photography and video at 30 Great Barrier Reef study sites in the period 1980 – 2005. At Pandora Reef in the 1980s, regional elevation of land-based nutrients did not prevent spectacular recovery of coral cover and diversity following a sequence of environmental disturbances in the 1970s. There was high coral mortality in some habitats in the 1998 bleaching, and the standing dead corals were then flattened by a 2000 cyclone. Degree of impact and extent of recovery was related to marked differences around the reef in benthic species composition and relative abundance, notably fleshy algae, soft corals, poritids and acroporids. Relative paucity of larval derived recruits and viable fragments in 2005 suggests the strong coral population resilience of the 1980s will not be repeated in the short term, especially reflecting regional paucity in Acropora broodstock. At a small (32 m2) site at Lizard Island there were three acute disturbance events followed by good coral recovery and no tendency for phase-shift: 1982- a combination of coral bleaching and Crown-of-Thorns starfish; 1990 - cyclone waves and 1996 - Crown-of-Thorns starfish. However beyond 1996, observations and modeling using Johnson's Compete © Cellular Automaton model suggest the area may be subject to annual chronic background mortality. The apparent retardation of coral recovery may be exacerbated by projected reduced intervals between disturbances associated with global climate change. However hopefully recovery prospects will be improved as region-wide benefits of improved GBR-wide management introduced in 2004 take effect: i.e. an eightfold increase in the area of no take protected areas, and the initiation of actions to improved coastal water quality.

## 13-1

**Prioritizing Conservation Hotspots: Does Phylogeny Matter?**

**Christopher MEYER*[1]**

[1]Natural History Museum, Smithsonian Institution, Washington, DC

Most approaches to coral reef biodiversity use species richness as the metric for examining geographic patterns with the implicit assumption that all species are equal. However, some have argued various measures that incorporate evolutionary history, such as phylogenetic diversity or taxonomic distinctiveness, may be more appropriate metrics, especially when establishing conservation priorities. Most published comparisons that integrate phylogentic data into conservation planning are terrestrial and geographically restricted in scope. Using a taxonomically comprehensive phylogeny of cypraeid gastropods, a well-known, predominantly reef-associated group of snails, I examine the effects of incorporating phylogeny in prioritizing biogeographic hotspots for conservation importance. The global diversity profile of cowries is similar to most other major reef-associated groups, including corals and reef-fishes, and cowries have a range of life history attributes that make them a reasonable proxy for other reef-associated species. I compare three metrics of biodiversity: (1) richness, (2) phylogenetic diversity and (3) taxonomic distinctiveness across three phylogenetic scales: (A) genera, (B) species, and (C) ESUs (= DNA barcode lineages). This 3 x 3 approach indicates that some metrics or scales can act as effective surrogates for others in some instances. However, finer phylogenetic scales reveal the importance of inter and intra-basinal processes as engines of diversification and highlight their importance in both conservation efforts and establishing biodiversity survey focal regions.

## 13-2

**Identification And Conservation Of Evolutionary Processes in The Coral Triangle Biodiversity Hotspot.**

**Paul BARBER*[1]**

[1]Boston University Marine Program, Boston University, Boston, MA

The reefs of the Coral Triangle are the most diverse in the World. While the origins of pattern have long attracted the attention of evolutionary biologists, answering this question has largely been considered of purely academic interest. However, given the increasing threats facing the reefs of the Coral Triangle, it is becoming increasingly clear that understanding the processes generating high biodiversity in this region is critical for preserving this diversity, including the processes that create it. In this study we compare phylogeography and genetic connectivity of over 30 fish and invertebrate taxa that are codistsributed across the Coral Triangle, representing multiple reef functional groups ranging from corals to pelagic fish. Results indicate a broad array of evolutionary patterns in this shared physical environment. Some taxa exhibit the classic pattern of differentiation between Pacific and Indian Ocean populations, suggesting Pleistocene vicariance. Others show fine-scale genetic differentiation, suggesting a common history of regional geographic isolation. Still others show no genetic structure at all. Although patterns fell into these three basic classes, there were few commonalities among taxa with similar patterns of genetic structure. The unique responses of multiple taxa to a shared environment suggest a multiplicity of physical and ecological processes contributing to the evolution of high biodiversity in the Coral Triangle. While the commonalities seen among some taxa suggests some support for regional seascape conservation initiatives, the idiosyncrasies among taxa demonstrate the challenges facing marine managers in designing reserve systems that will effectively protect a broad array of biodiversity.

## 13-3

**Absence Of Geographic Barrier Across The Indo-Pacific Province For Coral Reef Fishes**

Serge PLANES[1,2], **Cécile FAUVELOT*[3]**, Vanessa MESSMER[1,4], Shital SWARUP[1], Matthieu LERAY[1], Jean-Luc TISON[1]

[1]UMR 5244 - Laboratoire Écosystèmes Aquatiques Tropicaux et Méditerranéens, CNRS - EPHE - UPVD, Perpignan, France, [2]UMS 2978 - CRIOBE, CNRS - EPHE, Moorea, French Polynesia, [3]UR 128 – CoRéUs, Institut de Recherche pour le Développement, Perpignan, France, [4]School of Marine and Tropical Biology, and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

With an area spanning half the world's tropical marine belt, from East Africa to western coast of Americas, the Indo-Pacific region is the largest biogeographic province. Within this province, coral reef species distributions varied greatly, with some species restricted to a single island while others are found throughout the province. In this context, the question related to the dynamic of spreading of species within such a large biogeographic province as always been a striking point. Recent phylogenetic studies on such topic remain too limited, and the results often conflicting to provide any consensus. In the perspective of providing a general view, it appears essential to compare the phylogeography of several taxa differing in life histories in order to reveal how geographic barriers may affect similarly evolutionary history of species. Here we investigate the phylogeographic patterns of seven coral reef fishes (i.e; *Acanthurus triostegus*, *Dascyllus aruanus*, *Forcipiger flavissimus*, *Lutjanus kasmira*, *Paracirrhites forsteri*, *Zanclus cornutus* and *Rhinecanthus aculeatus*) sampled among up to 29 locations throughout the Indo-Pacific with the objective of identifying common barriers to colonization and gene flow. Analyses based on sequences of the hypervariable region of the mitochondrial DNA Control Region (Dloop) revealed different phylogenetic patterns exhibited by the seven species. While some species showed marginal genetic isolation of remote islands, other showed clear phylogenetic signals. Nevertheless, all species did exhibit genetic footprint of exponential population growth. The pairwise mismatch distributions strongly differed among species revealing unique ancient demographic expansion signatures. The absence of common evolutionary histories is likely correlated with the high dispersal capabilities of coral reef fishes during their larval phase. Though recent works have emphasised local retention and small-scale self-recruitment at an ecological timescale, this does not prevent sporadic large-scale dispersal to spread molecular variants throughout the Indo-Pacific area on an evolutionary timescale.

## 13-4

**Population Structure Of The Three-Spot Damselfish, Dascyllus Trimaculatus Across Its Distribution Range**

**Matthieu LERAY*[1,2]**, Ricardo BELDADE[1], Serge PLANES[2], Sally HOLBROOK[3], Russell SCHMITT[3], Giacomo BERNARDI[1]

[1]Department of Ecology and Evolutionary Biology, University of California, Santa Cruz, Santa Cruz, CA, [2]EPHE - UMR CNRS 8046, Universite de Perpignan, Perpignan, France, [3]Ecology, Evolution & Marine Biology, University of California, Santa Barbara, Santa Barbara, CA

In previous studies, members of the three-spot damselfish species complex composed by four nominal species: Dascyllus albisella Gill, D. auripinnis Randall and Randall, D. strasburgi Klausewitz, and D. trimaculatus (Ruppell) were sampled from the Indian Ocean, the Pacific Rim (Japan to Wallis Island), French Polynesia, Hawaii, and Marquesas. Analyses of the control region of the mitochondrial DNA (D-loop) revealed five different clades: 3 of which correspond to the Pacific Rim (D. trimaculatus and D. auripinnis), Hawaii (D. albisella) and Marquesas (D. strasburgi) and the remaining two clades, Indian Ocean and French Polynesia (D. trimaculatus). We developed microsatellite primers to determine if clades uncovered by the mitochondrial analyses were consistent with nuclear data. Color morphs, species boundaries and incipient speciation in the three-spot damselfish complex are discussed.

## 13-5

**A Seascape Of Genes: A Complete Survey Of Coral Genetic Diversity On A Patch Reef in Kane'ohe Bay, Hawai'i**

**Kelvin GOROSPE*[1]**, Stephen KARL[2]

[1]University of Hawai'i at Manoa, Honolulu, HI, [2]The Hawai'i Institute of Marine Biology, Kane'ohe, HI

Genetic studies of corals have primarily focused on characterizing genetic differentiation on broad-geographic scales. These studies are important for informing management decisions regarding the prioritization and placement of marine protected areas. Genetic variation on the geographic scale of a single reef, however, has been largely overlooked. This has created a major gap in our understanding of coral population genetics as well as a missing link in our ability to efficiently manage these natural resources. By genotyping and mapping every single individual of *Pocillopora damicornis* on a patch reef in Kane'ohe Bay, Hawaii, this research will examine coral genetic variation on a micro-spatial scale. Eight microsatellite loci are being used to genotype approximately 3000 coral colonies. This will allow us to assess spatial patterns of genetic relatedness within a reef. Furthermore, temperature sensors deployed on a 4m grid throughout the reef are being used to characterize microhabitat variation. Thus, this research will be the first to fully characterize the genetic and environmental landscape of a reef. Correlating genetic, environmental, and spatial data lends insight into the processes that are driving variation on a small spatial scale. For example, what are the genetic resources of a single reef, and what role does genetic diversity at such a small spatial scale play in terms of reef resilience? Do genetically related colonies tend to cluster together or are they evenly distributed throughout the reef? How much does clonality (produced via fragmentation) versus recruitment of sexually-produced larvae contribute to coral abundance? Do coral phenotypic differences correlate more with genetic-relatedness or benthic microhabitat differences? Ultimately, by describing how genetic variation relates to coral survival and recruitment within a reef, this research will elucidate the connection between long-term evolutionary processes and contemporary conservation efforts.

## 13-6

**Kinship in The Orange-Fin Clownfish, Amphiprion Chrysopterus, From Moorea, French Polynesia**

**Ricardo BELDADE*[1]**, Serge PLANES[2], Sally HOLBROOK[3], Russell SCHMITT[3], Giacomo BERNARDI[1]

[1]Department of Ecology and Evolutionary Biology, University of California, Santa Cruz, Santa Cruz, CA, [2]EPHE - UMR CNRS 8046, Universite de Perpignan, Perpignan, France, [3]Ecology, Evolution & Marine Biology, University of California, Santa Barbara, Santa Barbara, CA

The orange-fin clownfish, Amphiprion chrysopterus, are diurnal planktivores that occupy the sea anemone Heteractis magnifica. They lay benthic eggs that hatch after 6 days, releasing pelagic larvae that settle to anemones after 8–12 days. Orange-fin clownfish generally live in pairs (an adult of each gender) and remain closely associated with the host anemone throughout their lives. In Moorea, French Polynesia, settlement of this species tends to be sporadic and at a very low level. We collected fin-clips from 151 individuals, mostly inside the lagoon, all around Moorea and used microsatellites to investigate kinship among individuals. Seven related specimens were found in the southeast quadrant of Moorea. All these specimens were collected inside the lagoon relatively far from any pass. Even though the geographical origin of this group of related individuals has not been established, the present findings point to the possibility of either self-recruitment of the orange fin clownfish in Moorea or the potential for related larvae to recruit in cohorts.

## 13-7

**Phylogeography Of The Ember Parrotfish (*scarus Rubroviolaceus*) Throughout The Indian And Pacific Oceans**

**John FITZPATRICK*[1]**, Catherine LIPPE[1], Dave CARLON[1]

[1]Zoology, University of Hawaii, Manoa, Honolulu, HI

Overfishing and pollution are affecting consumers on coral reefs and impacting ecosystem structure and function. To protect and conserve these valuable ecosystems, we need knowledge of reef connectivity and dispersal patterns to inform proper establishment and design of effective fisheries management tools, such as MPAs. In the tropical Pacific, many species of reef herbivores have long planktonic larval durations and enormous biogeographic ranges, yet patterns of the population structure are largely unknown. To determine how many populations (defined as interbreeding units) exist within the range of the ember parrotfish (*Scarus rubroviolaceus*) we sampled populations from Panama to Africa and genotyped over 300 individuals at 14 microsatellite loci. We used traditional measures of population structure and the population model STRUCTURE to determine how many populations are found within this species' range. This analysis found 4 populations defined by the following biogeographic regions: 1) Indian Ocean, 2) Central Pacific, 3) Hawaii, and 4) East Pacific. Further, pairwise comparisons revealed the largest *F*ST values between Hawaii and all other populations and the East Pacific and all other populations. The isolation of Hawaii and the East Pacific from all other populations are likely the result of unsuccessful dispersal over vast stretches of water that lie between favorable habitats. However, there is a high degree of dispersal in the larvae of these fish indicated by the panmixia found at smaller scales, e.g. within Hawaii and Samoa. Our results require confirmation with other key reef herbivores, but suggest management strategies should be built around population cohesiveness within at least four regions, and emphasize the uniqueness of Hawaii and the Eastern Pacific.

## 13-9

**A Restoration Genetics Guide For Coral Reef Conservation**

**Iliana BAUMS*[1]**

[1]Biology, The Pennsylvania State University, University Park, PA

World-wide degradation of coral reef communities has prompted a surge in restoration efforts and created an urgent need for restoration genetic guidelines. The major question restoration efforts face is over what distance from the source wild and/or captive bred propagules may be moved without causing a loss of fitness in the restored population. Evolutionary processes in reef corals may resemble those observed in long-lived plant and recommendations developed for plant restoration are modified here for reef conservation. Proposed causes for loss of fitness as a result of restoration efforts include founder effects, genetic swamping, inbreeding and/or outbreeding depression. Direct evidence for any of these processes is scarce in reef corals due to a lack of model species that allow for testing over multiple generations and the separation of the relative contributions of algal symbionts and their coral hosts to the overall performance of the coral colony. However, in controlled crosses presented here, certain colony pairings produce higher performing larvae then the control batch culture. These larvae do not yet contain zooxanthellae, implying that performance differences exist among coral genets. Clearly, further research is needed to study host-symbiont-environment interactions. Meanwhile, there is ample evidence for differentiated populations, inbreeding, asexual reproduction and the occurrence of ecotypes in corals, factors that influence the design of restoration projects. Contrary to published expectations, a review of the literature shows that inbreeding is as common in broadcast spawners as it is in brooders. The use of molecular tools may aid managers in the selection of appropriate propagule sources, guide spatial arrangement of transplants, and help in assessing the success of restoration projects by tracking the performance of transplants, thereby generating important data for future projects

## 13-10

### Local Interspecific Hybridization And Restricted Transpacific Gene Flow in Tropical Eastern Pacific *pocillopora*

**David J. COMBOSCH*[1,2]**, Hector M. GUZMAN[2], Helmut SCHUHMACHER[3], Steve V. VOLLMER[1,2]

[1]Biology, Northeastern University, Nahant, MA, [2]Smithsonian Tropical Research Institute, Balboa, Panama, [3]Biology and Geography, University Duisburg-Essen, Essen, Germany

Coral reefs in the Tropical Eastern Pacific (TEP) are among the most isolated in the world. This isolation has leaded to relatively low species diversity but high regional endemism. The dominant reef-building corals in the TEP are the *Pocillopora* corals, a ubiquitous Indo-Pacific genus commonly regarded as inferior reef-builder. In addition to being the dominant corals in the TEP, the Pocilloporids have undergone a reproductive shift from internal larvae brooding throughout most of their Indo-Pacific range to free gamete spawning in the TEP.

Using genetic data from the Internal Transcribed Spacer Regions (ITS) of the nuclear ribosomal DNA gene cluster, we show here that this apparent reproductive shift coincides with inter-specific hybridization among TEP *Pocillopora* species. We document a pattern of one-way gene flow into the main TEP reef builder *P. damicornis* from one or both of its TEP congeners –*P. eydouxi* and *P. elegans*. Strong population genetic differences within *P. damicornis* further indicate that transpacific gene flow between the Central and Eastern Pacific is rare ($\varphi ct = 0.419$). These results suggest that Eastern Pacific corals exist in relative isolation from their Central Pacific counterparts, interact with each other differently via hybridization, and thus must be protected for their evolutionary uniqueness.

## 14-2

**Oceanographic Coupling Across Multiple Trophic Levels Shapes Source-Sink Dynamics in Coral Reef Metacommunities**

Will WHITE[1], Jameal SAMHOURI[2], **Robert WARNER*[3]**

[1]Dept. of Wildlife, Fisheries, and Conservation Biology, University of California - Davis, Davis, CA, [2]Northwest Fisheries Science Center, NOAA Fisheries, Seattle, WA, [3]Dept. of Ecology, Evolution, and Marine Biology, University of California - Santa Barbara, Santa Barbara, CA

A central goal of most studies of marine population connectivity is to determine which subpopulations have the greatest value to the larger metapopulation. That is, where are the 'sources' that are most essential to population persistence? In a single-species context, this is a straightforward question, and theoretical models typically identify sites with high recruitment, especially high self-recruitment, as having the highest value. However, the oceanographic forces that shape the larval delivery of a given species are also likely to influence the recruitment of that species' predators, prey, and competitors. We present empirical evidence from the Virgin Islands and Bahamas that oceanographic forces produce spatial coupling between the recruitment of planktivorous fishes, the recruitment of their predators, and the productivity of their zooplankton prey. Both empirical and theoretical evidence suggests that this coupling causes planktivores at the highest recruitment sites to experience higher, more strongly density-dependent mortality (a consequence of higher predator densities). At the same time, planktivores at high recruitment sites demonstrate faster growth and higher fecundity (a consequence of higher zooplankton densities) than planktivores at low recruitment sites. Furthermore, the results of both analytical and simulation metapopulation models reveal that the relative strength of oceanographic coupling between the three trophic levels strongly determines whether a given reef acts as a source or sink. Consequently, we argue that the potential for such coupling should be incorporated into future models of coral reef metapopulation dynamics and considered in the design of marine protected areas.

## 14-3

**Coral Reef Conservation Planning With Connectivity**

**Maria BEGER*[1]**, Hugh POSSINGHAM[1]

[1]The Ecology Centre, The University of Queensland, St Lucia, Brisbane, Australia

There are biophysical linkages and interactions between coral reefs and adjacent realms, as well as connections among reefs themselves. Contemporary conservation planning and reserve design theory and practice is largely incapable to deal systematically (i.e. spatially explicit, repeatable, and mathematically sound) with connectivity. This talk explores two new frameworks of how connectivity can be incorporated into the systematic design of conservation area networks.

Firstly we present a classification scheme of cross-realm connections that provides a basis for conservation planning. This includes four broad types of interactions: a) narrow interfaces such as inter-tidal zones; b) broad interfaces such as estuaries; c) constrained connections such as corridors of native vegetation used by amphibian to move between natal ponds and adult habitat; and d) diffuse connections such as the movements of birds or sea turtles between breeding and feeding habitats. We then use this classification to describe a framework of technical approaches to conservation planning that promote the persistence of these types of processes, with formulations and case studies of implementation in decision support software.

Secondly, we present new methods of incorporating marine population connectivity into systematic conservation planning. We develop a framework of incorporating the spatial, temporal and species-specific variability of connectivity and present the newly developed capability of the decision support system MARXAN to incorporate connectivity, and demonstrate the improvement of potential reserve networks with connectivity above reserve systems without for a Great Barrier Reef case study.

## 14-4

**Tropical-Temperate Connectivity Of Expatriated Fishes: Backtracking Dispersal Along The East Coast Of Australia**

**Will FIGUEIRA*[1]**

[1]Department of Environmental Sciences, Univeristy of Technology, Sydney, Broadway, Australia

Juvenile coral reef fishes from the families Pomacentridae (Damselfish) and Chaetodontidae (Butterflyfish) are commonly found along the east coast of Australia as far south as the New South Wales - Victorian border (37°S) during the austral summer months, though they typically fail to survive the ensuing winter. Previous work has highlighted the role of the East Australian Current in the transport of the larvae of these species and indicated the possibility that while some of the Pomacentrid species may be sourced from year-round populations located well south of the Great Barrier Reef (GBR), the Chaetodontids more likely originate from the southern end of the GBR. In order to evaluate these hypotheses, potential larval pathways of collected individuals were back-calculated using an individually-based larval dispersal model. Dispersion was behaviourally influenced by larval swimming and orienting (contingent upon larval age) and forced in an advective-diffusive manner using modeled flow data from the Bluelink Ocean Forcasting System. Using estimated planktonic larval durations and date of settlement (from otolith analysis) of fish collected at sites all along the south coast from 2003 to the present, a mean dispersal pathway (MDP) and point of origin probability distribution (OPD) was estimated from 100 repeated simulations. MDPs and OPDs were compared between species and among species across sites and years to look for consistent patterns. The importance of larval behaviour parameters was also assessed. Variability in the structure of the EAC led to a large degree of complexity in the estimated dispersal patterns. There is general support for the supply of some of the Pomacentrid species from temperate sites but patterns for the Chaetodontids were less clear.

## 14-5

**A numerical study on larval dispersal in the Southeast Asia and West Pacific (SEA-WP) regions using a new Indo-Pacific Ocean Circulation Model**

**Aditya R. KARTADIKARIA*[1]**, Kazuo NADAOKA[1], Yasumasa MIYAZAWA[2], Nina YASUDA[1]

[1]Mechanical and Environmental Informatics, Tokyo Institute of Technology, Tokyo, Japan, [2]Frontier Research Center for Global Change, Japan Agency for Marine-Earth Science and Technology, Yokohama, Japan

The South East Asia and West Pacific (SEA-WP) region is a significant reservoir of the world's richest marine biodiversity. However, coral reef communities of this region are now severely threatened by numerous environmental factors. It is therefore of vital importance to reveal the reef-connectivity to effectively conserve and manage this region. Recent molecular ecological studies on genetic variations have shown that the gene flow patterns in this area are associated with a number of factors but are found mostly in discordance with the present overall schematics of the surface ocean current, although the knowledge on the ocean currents in this region is still limited. To provide more detailed and reliable information on the ocean currents in SEA-WP region and thereby to examine associated larval dispersal processes in the complicated topographic area having numerous islands, we have been developing a numerical simulation model based on a new Indo-Pacific Ocean Circulation model. In addition to the complicated topographic effect, the SEA-WP region may be influenced by atmospheric disturbances including monsoon and typhoon and the various through-flows across straits and passages with the Pacific and Indian Oceans. For properly simulating ocean currents in the SEA-WP region under these effects, the Indo-Pacific Ocean Circulation model is coupled with a regional atmospheric model. The model simulation results elucidate detailed characteristics of Indonesian Through Flow (ITF) and other through-flows at Luzon strait and North Australia-Pacific passage and their effects on larval dispersal processes.

## 14-6

**Modelling Coral Larval Dispersal Patterns Within The Singapore Straits**

**Ywee Chieh TAY*[1]**, Peter Alan TODD[1], Per Sand ROSSHAUG[2], Loke Ming CHOU[1]

[1]Department of Biological Sciences, National University of Singapore, Singapore, Singapore, [2]Environmental processes, DHI, Hørsholm, Denmark

Despite almost five decades of anthropogenic impacts, the reefs of Singapore's Southern Islands support a rich community of scleractinian corals (165 species in just 10km$^2$ of reef). Ongoing reef restoration efforts are important for reducing degradation rates of the remaining reefs, but natural recruitment processes remain poorly understood. Given the dynamism of the marine environment, broadcast spawners such as scleractinian corals display great potential for exchange of genetic material. Determining the connectivity among Singapore reefs is one of the fundamental steps in understanding the sustainability and viability of coral populations, and would contribute to more informed reef management decisions.

It is logistically challenging, however, to track the dispersal patterns of millions of microscopic larvae. Coral larval dispersion patterns were therefore predicted with a 2D-hydrodynamic flexible mesh (MIKE21 FM) model coupled with a Lagrangian particle-tracking module. Neutrally buoyant, passive particles representing the generally passive coral larvae were released from various coral source reefs in the Southern Islands during mass spawning events. Particles were also released from the northern coasts of some of the neighbouring Riau islands of Indonesia at predicted spawning times. Preliminary findings indicate that the coral reefs of the Southern Islands are mainly self- replenishing. Most of the input, however, comes from an eastern cluster of islands due to the seasonal net east-west current that runs through the Singapore Straits during this period. Such connectivity patterns can be used to predict which reefs are key sources of genetic material and thus suitable for conservation priorities.

## 14-7

**Larval Dispersal In Archipelagic Basins And Interconnecting Straits Using Particle-Tracking Models**

**Cesar VILLANOY*[1]**, Marites CANTO[2], Wilfredo CAMPOS[3]

[1]Marine Science Institute, University of the Philippines, Quezon City, Philippines, [2]Marine Science Institute, University of the Philippines, Quezon City`, Philippines, [3]OceanBio Laboratory, University of the Philippines in the Visayas, Iloilo, Philippines

Larval dispersal models have been used to investigate marine population connectivity in the Philippines. The unique archipelagic nature of the seas around the Philippines where semi-enclosed basins like the Sulu Sea and the Bohol Sea, interconnected with narrow straits and passages, may define scales of larval dispersal. Surface current velocities from global and regional models were used to drive particle-tracking larval dispersal models to gain insights on the role of interconnecting passages and semi-enclosed basins on dispersal patterns. The location of larval sources were based on coral reef habitat maps and the magnitude of larval sources scaled according to habitat characteristics, particularly reef fish biomass and percent live coral from field survey data. The virtual larvae contain simple behavior involving sensory and swimming capabilities. Survival rate of settled recruits is also scaled by a simple measure of fishing and environmental pressure. The results show that while hydrodynamics of straits and basins control dispersal, spatially varying magnitudes of the larval sources and survival of recruits are highly influenced by protection and degree of fishing pressure.

## 14-8

**A Preliminary Effort in Linking Connectivity Information And Coral Reef Fisheries Using A Simple Systems Model**

**Ma. Carmen ABLAN*[1]**

[1]Biology Department, De La Salle University Manila, Manila, Philippines

Connecting connectivity information to reef fisheries management is a major challenge. It requires the availability and integration of good information and a means of obtaining feedback from managers and resource users. The need in developing countries is especially urgent because management interventions to halt the decline and restore productivity of reef fisheries are increasingly becoming focused on local scales. As policies change, including connectivity in decision making becomes essential to the success of any intervention. This study presents initial work on constructing a simple systems model, using Stella 8.0. It integrates available information on recruitment, spillover and fishing of reef fish to determine fish stocks in three islands in the Bohol Sea. The effect of introducing estimates of connectivity to the model in predicting the availability of reef fish was explored in the model and compared to estimates without information on connectivity. Fish stocks over time in Balicasag, Apo and Sumilon Islands were first modeled in relation to recruitment, spillover from marine protected areas and fishing within each of these islands based on published information and data from interviews with fishers. Estimates of asymmetric migration among islands based on previous work using microsatellite markers on the sedentary damselfish *Dascyllus trimaculatus* and the further ranging *Pterocaesio pisang* was factored into the model. Values of fish stocks for each area were recalculated. When conservative estimates of connectivity based on *D. trimaculatu*s were used, fish stocks in Balicasag and Sumilon declined by 20% and 15% while those in Apo increased by 22%. Using connectivity estimates from *P.pisang*, decline of 18-33% in fish stock was predicted. Results show that different connectivity scenarios have different consequences for management and raise the question of whether we could actually produce a measure which can be useful.

## 14-9

**Segregation Of Queen Conch, Strombus Gigas, Populations From Mexico**

**Claire PARIS*[1]**, Dalila ALDANA ARANDA[2]

[1]Rosenstiel School of Marine and Atmospheric, Marine Biology and Fisheries, University of Miami, Miami, FL, [2]Recursos del Mar, CINVESTAV IPN Unidad Merida, Merida, Mexico

Despite active conservation measures, slow recovery of Queen conch (Strombus gigas) is a growing concern in the Caribbean. Although conventional expectations presume that S. gigas populations are largely connected, we present results of veliger larval drift and survival from the Yucatan peninsula in Mexico that suggest otherwise. Spatial patterns of observed and simulated larval stages during the reproductive season revealed isolation of the Alacranes Reef population on Campeche Bank (North Yucatan) from the Mexican Caribbean coast populations (East Yucatan). High levels of larval retention on Campeche Bank contrasted to the highly variable larval transport and survival along the Mexican Caribbean coast into the Yucatan Current, and eventually into the Loop Current, drive the degree of segregation. In addition, these populations do not mix downstream. In effect, the probability that S. gigas larvae originating from Alacranes Reef settle in Florida is insignificant, while a small fraction of larvae produced north of the Mexican Caribbean coast periodically reaches the Lower Florida Keys. Although this long-distance dispersal may not be sufficient to replenish the downstream populations, gene flow could prevent differentiation of the Florida Keys and Mexican Caribbean Queen conch populations. This study constitutes and essential step in understanding the structure of S. gigas populations and the needed actions for the recovery of individual populations in Mexico. Detailed larval dynamics (e.g. behavior, growth, mortality, settlement) and mapping of populations' networks at the regional and wider Caribbean scales will be an extension of this work.

## 14-10

**Does Vertical Migration Behavior Of Reef Fish Larvae Influence Their Transport?**

**Klaus HUEBERT*[1]**, Su SPONAUGLE[1], Robert COWEN[1]

[1]Division of Marine Biology and Fisheries, University of Miami / RSMAS, Miami, FL

The degree to which the population connectivity of coral reef organisms is influenced by the behavior of their dispersive larvae is controversial. One type of behavior that potentially affects larval transport is vertical migration between depths with different ambient currents. Our objective was to describe vertical migrations of pelagic coral reef fish larvae in the Straits of Florida, and estimate their influence on larval transport. Repeated time series of plankton net tows were conducted offshore of Miami using a Multiple Opening Closing Net and Environmental Sensing System (MOCNESS). The upper 100 m of the water column was sampled at 3 h intervals for a duration of 48 h, with different nets fishing at 0-25 m, 25-50 m, 50-75 m and 75-100 m. Simultaneously, a suite of environmental variables was recorded by the MOCNESS as well as a shipboard Acoustic Doppler Current Profiler (ADCP). Across several families of reef fishes, large larvae were distributed significantly deeper than small larvae, revealing downward vertical migration with ontogeny. Taking ambient light levels and visual net-avoidance behavior into account, vertical distributions of some families also varied significantly between day and night, revealing diel vertical migrations. The predominant long-shore component of the Florida Current was consistently greatest at the surface and decreased with depth, while the cross-shore current was an order of magnitude weaker and highly variable. The distribution of currents together with the observed patterns of vertical migration of larvae results in an overall reduction of larval horizontal advection speeds, with important consequences for population connectivity.

## 14-11

**Homing in Coral Reef Cardinalfish Contributes to Low Population Connectivity Among Reefs**

**Naomi GARDINER*[1]**, Geoff JONES[1]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

Recent studies have indicated greater levels of self-recruitment within coral reef fish populations, and less connectivity among populations than once appreciated. However, the ability of individuals to return to home reefs, and the spatial scales over which homing can occur are poorly understood. While cardinalfish are known to return home when displaced within lagoon environments, whether or not they can return home across open water, when displaced from one reef to another is unknown. This study employed displacement experiments to investigate the homing-ability of 5 common Indo-Pacific cardinalfish species (*Apogon fragilis*, *A. leptacanthus*, *Archamia zosterophora*, *Ostorhinchus artus* and *O. quinquelineatus*) in Kimbe Bay (PNG). Individuals were displaced ca. 500m from 'home' positions onto either the same reef or onto a neighboring reef (separated from the home site by open-water). Despite their small size (SL ca. 5-8cm) and limited swimming capabilities, all species were capable of returning to home coral heads, across open-water, within a single night. Homing capabilities from up to 5km away were also demonstrated. We argue that homing in these nocturnal foraging species contributes to the lack of connectivity among coral reefs.

## 14-12

**The Biology Of Acropora Palmata Larvae: Implications For Dispersal And Population Connectivity**

**Ainhoa LEON ZUBILLAGA*[1]**, Alina M. SZMANT[2,3]

[1]Biologia de Organismos, Universidad Simon Bolivar, Caracas, Venezuela, [2]Center for Marine Science, University of North Carolina Wilmington, Wilmington, NC, [3]Center for Marine Science, University of North Carolina Wilmington, Wilmington

The exchange of genetic material within and across coral populations will depend not just on physical factors (e.g. hydrography) but also on larval characteristics such as buoyancy, duration of development to competency and competency, swimming abilities, and other larval behaviors. A range of experimental procedures were used to determine these variables for the threatened species Acropora palmata. Eggs are buoyant upon release and rise to the ocean surface; embryos lost buoyancy over time as they developed into planulae ($F = 46.4$, $df = 9$; $p = 0.000$) presumably as they metabolized lipid stores. Embryos reached a swimming planula stage at ca. 60 h after fertilization, and gradually gained the ability to swim downwards; however, maximum swimming capabilities were not observed until 192 h after fertilization. There was no evidence of diel swimming patterns as was previously found for Montastraea faveolata. Larvae did not reach competency until they were at least 6 to 8 days old. These larval characteristics could lead to fairly extensive dispersal depending on local current conditions during the first week after spawning. There was a significant dependence ($x2 = 29.7$, $p<0.05$) between the number of A. palmata larvae that settled with the presence or absence of settlement substrate (field conditioned tiles). A. palmata larvae preferentially settled on tile sides ($12.1 \pm 6.5\%$) followed by tops ($5.3 \pm 4.2\%$) and bottoms ($1.2 \pm 1.5\%$) and these differences were statistically significant (KW: 67.9, $p<0.05$). Differences in community composition of growth on tiles surfaces were also significant ($x2 = 1801.7$, $p<0.05$). Bray-Curtis indexes indicated 56% dissimilarity between tops and bottoms, 43.5 % between sides and tops, and 47.8 between sides and bottoms. These results support previous studies that highlight the importance of substrate characteristics to larval settlement.

## 14-13

**Sensory Mechanisms Limiting Connectivity At Different Scales**

**Jelle ATEMA*[1]**, Gabriele GERLACH[2], Vanessa MILLER-SIMS[3], Michael KINGSFORD[4]

[1]Biology, Boston University, Boston, MA, [2]University of Oldenburg, Oldenburg, Germany, [3]University of Southern California, Los Angeles, CA, [4]James Cook University, Townsville, Australia

Evidence from different coral reef fish species shows that settling larvae prefer the odor of the reef where they were captured. Indirect evidence shows that this is most likely also their natal reef, where odor imprinting occurred at hatching as demonstrated in *Amphiprion* sp. imprinting on anemones. When settling, different species appear to use this odor information differently resulting in different connectivity scales.

The cardinal fish *O. doederleini* shows limited larval dispersal and strong homing. Genetic data show that it does not often survive to maturity in non-natal reefs even as close as a few km away. Behavioral experiments show that settlers from foreign reefs face severe conspecific competition, reflecting perhaps a limitation on settlement sites. Such post settlement competition would exert strong selection pressure for homing. In habituation tests they show persistent home odor preference. Other cardinal fishes behave similarly in odor choice tests. In contrast, the damsel fish *P. coelestis* can settle "abroad" and genetics shows it does so at a spatial scale of 20-100 km. This relaxes selection pressure for homing and facilitates the wider dispersal. Settlers still show evidence for imprinting on reef odor but their odor preference is less persistent. They may use their knowledge of home odor to later recognize *any* reef. This species settles on outer reef slopes where competition for settlement sites may be less severe. Finally, the damsel fish *A. polyacanthus* guards its larvae, which do not have a pelagic dispersal phase and do not show home odor preference in choice tests. Their behavior appears to allow for juvenile integration into adult habitat with very limited local dispersal.

In ocean environments it is important to understand the local hydrography and the spatial-temporal scale of mixing water masses, identifiable by the odor of their origin.

**Environmentally-Mediated Variation in Larval Traits And Linkages To Juvenile Survival in Two Reef Fishes**

**Su SPONAUGLE*[1]**, Tauna RANKIN[1], Kirsten GRORUD-COLVERT[2]

[1]Marine Biology & Fisheries, RSMAS/University of Miami, Miami, FL, [2]PISCO/COMPASS, Oregon State University, Corvallis, OR

Population connectivity of benthic marine organisms depends on larval transit through the ocean as well as successful settlement and survival of young recruits. Thus environmental and oceanographic processes have the potential to play a significant role in population connectivity through their influence on early life history traits such as larval and juvenile growth, pelagic larval duration (PLD), and size and condition at settlement. We examined these otolith-based traits in multiple monthly cohorts of two common coral reef fishes, the bluehead wrasse *Thalassoma bifasciatum* and bicolor damselfish *Stegastes partitus,* in the Florida Keys to evaluate the role of water temperature and larval traits on early juvenile survival. Seasonal variation in water temperature explained a significant proportion of the variation in early life history traits among cohorts of both species, with potential consequences for the amount of time larvae have to disperse to suitable settlement habitats. Within cohorts, comparison of the distribution of early life history traits among late-stage larvae, and new and older recruits demonstrated that recruit survivorship is non-random and influenced by PLD, larval size and condition at settlement, and early juvenile growth. Contrasting patterns between species in the distribution of traits of young survivors suggest that the two species experience conflicting constraints as recruits.

## 14-15

**Simulated Regional-Scale Genetic Structure of Caribbean and Southeast Asian Coral Reef Communities**

**Johnathan KOOL*[1]**, Claire PARIS[2], Robert COWEN[1]

[1]Marine Biology and Fisheries, RSMAS - University of Miami, Miami, FL, [2]Applied Marine Physics, RSMAS - University of Miami, Miami, FL

Recent advances in the development of coupled bio-oceanographic larval dispersal models have opened up new opportunities for evaluating large-scale population genetic structure in marine environments. Using this approach, it is possible to create transition matrices describing migration between different patch environments. Expected genetic structure (neutral or incorporating selection) may then be evaluated through projection using either classic matrix analysis or individual-based models. In this study, transition matrices based on larval dispersal patterns were generated and projected for two areas of interest: the Caribbean and the Coral Triangle Region of Southeast Asia (Philippines, Indonesia, Papua New Guinea). Preliminary results for the Caribbean indicate a strong east-west break (Gulf of Venezuela to Puerto Rico), which is consistent with previous field-based studies. Weaker clusters in other areas are also anticipated, as well as a cline through the Bahamas. Results for the Coral Triangle region are more complex due to current reversals, however the results suggest that if contemporary migration patterns are primarily responsible for creating genetic structure, then clusters in the Banda Sea region, in the vicinity of the Makassar Strait and the Celebes Sea, and along the eastern portion of Sulawesi should be evident. Although the results are specific to the set of life-history characteristics adopted in the simulations, they do appear to be robust, and provide a means of bridging the gap between observed marine population genetic patterns and bio-oceanographic processes.

## 14-16

**Modeling The Influence Of Genotypic Diversity On Coral Meta-Population Structure**

**Claire PARIS*[1]**, Iliana BAUMS[2]

[1]Applied Marine Physics, Rosenstiel School of Marine and Atmospheric Science, miami, FL, [2]Department of Biology, The Pennsylvania State University, University Park, PA

In sessile benthic invertebrates such as reef-building corals, fertilization is density dependent. Determining factors include the abundance, spatial distribution, and genetic makeup of those partners. Hence, the total number of larvae produced differs widely among populations in space and time. For instance, some hermaphroditic broadcast spawning corals reproduce mainly by asexual means (e.g. fragmentation) that can result in large monoclonal stands yet these species are self-incompatible. Such populations are unlikely to produce sexual offspring due to the lack of non-self mates. In turn, the genotypic (clonal) makeup of individual populations may influence the larger-scale meta-population structure. To test this hypothesis, we use estimates of clonal structure in several Acropora palmata populations in the Caribbean to scale the total larval output and simulate dispersal. Mortality rates and development times measured in the laboratory serve to parameterize the biophysical model. Sensitivity analyses of life history traits and scaled production on population connectivity networks are used to quantify the relative influence of the genetic makeup on the survivors in the meta-population.

## 14-17

**Reef Fishes As "Living Tracers Of Connectivity"**

**Patrick COLIN*[1]**

[1]Coral Reef Research Foundation, Koror, Palau

Comparisons of the distribution patterns of small reef fishes with limited larval dispersal to ocean current patterns, determined by satellite-tracked current drifters, provide an alternative method to biophysical modeling and genetic-based studies for assessing both connections and barriers within the tropical western North Atlantic (TWNA). The neon gobies (*Elacatinus*), the most speciose fish genus in the region, and other fish genera often have limited geographic distributions displaying similar distribution patterns among species. These patterns are the result of a natural connectivity experiment running since at least the last glacial low water and as such integrate the biological and physical aspects of connectivity over time. Oceanographic isolating mechanisms consistent with fish range limits have been identified and these modest zoogeographic barriers, combined with limits on fish larval dispersal, are responsible for the observed patterns of distribution. Consequently these fishes are indicators of connectivity and their zoogeography implies the TWNA is divisible into a series of enclave-like regions with limited genetic and ecological exchange among them. Even for reef fish species with longer maximum larval lives, the vast majority of larvae would recruit within their home enclaves and, as such, proposed enclaves provide an indication of ecological connectivity among nearly all reef fishes relevant to fisheries management and marine protected area design.

## 14-18

**Meso-Scale Hydrodynamic Features And The Structure Of Great Barrier Reef Fish Communities**

**Michael EMSLIE*[1]**, Alistair CHEAL[1], Angus THOMPSON[1], Hugh SWEATMAN[1], Severine CHOUKROUN[1], Julian CALEY[1]

[1]Long Term Monitoring, Australian Institute of Marine Science, Townsville, Australia

Coral reef communities are among the most diverse and threatened ecosystems on Earth leading to strident calls for urgent conservation measures, particularly the establishment of extensive networks of Marine Protected Areas. As well as protecting a range of species and habitats the reserves in a network should be linked by larval dispersal. The scale of connectivity in reef environments is uncertain. Recent findings suggest that self-recruitment is much more common than originally thought, but the balance between self-recruitment and long distance dispersal is unknown. Here we use long-term monitoring data from a significant section of Australia's Great Barrier Reef that integrates the effects of ecological processes on communities comprising more than 200 species of fishes over more than a decade. This revealed previously undescribed, strong meso-scale structure of GBR reef fish communities that were associated with major hydrodynamic features. We postulate that these oceanographic features provide temporally stable barriers to ecologically significant fish dispersal among seven major community types within 1200 kilometres of reef matrix. We also propose that self-recruitment can apply not only to local scales but also has a regional context defined by oceanographic features.

## 14-19

**Distribution, Abundance, And Genetics Of Corals Throughout The N. Gulf Of Mexico: The World's Largest Coral Settlement Experiment**

**Paul W. SAMMARCO*[1]**, Amy D. ATCHISON[1], Daniel A. BRAZEAU[2], Gregory S. BOLAND[3], Steven B. HARTLEY[4], Angela LIRETTE[1]

[1]Louisiana Universities Marine Consortium (LUMCON), Chauvin, LA, [2]Pharmaceutical Genetics Laboratory, University of Buffalo, Buffalo, NY, [3]Minerals Management Service, US Department of the Interior, New Orleans, LA, [4]National Wetlands Research Center, US Geological Survey, Lafayette, LA

Thousands of oil/gas platforms in the N. Gulf of Mexico (GOM) provide hard substratum where none existed prior to the Pleistocene. This has facilitated biogeographic extension of Caribbean reef fauna in the GOM. We quantified the distribution and abundance of scleractinian corals, hermatypic and ahermatypic, by surveying a total of 48 platforms around the Flower Garden Banks (FGB) and along four transects across the continental shelf: (T-I) Corpus Christi, TX, USA; (T-II) Lake Sabine, TX; (T-III) Terrebonne Bay, LA; and (T-IV) Mobile, AL. We also assessed genetic affinities between coral populations on the platforms and on the FGB to $\leq$ 37 m using AFLPs. The western limit for hermatypes was near the shelf edge in T-IV. The highest densities of hermatypes were at the shelf edge, ~175-225 km offshore, in T-II&III. Some hermatypes were found in T-IV - their eastern limit. Ahermatypes (*Tubastraea coccinea, Oculina diffusa*, *Phyllangia americana)* were absent inshore and in the north-central region. A GIS analysis of coral data, salinity, temperature, dis-O2, phosphate, and nitrate concentrations indicated that lower salinities and temperatures are the major factors forcing community structure. Hermatypic species diversity peaked near the FGB. Genetic analyses performed on *Madracis decactis* revealed high self-recognition and site fidelity in *M. decactis* in T-III&IV, with little recognition across the mouth of the Mississippi River. In *Tubastraea coccinea* (invasive species), cross-recognition was higher between platforms within a transect, but absent across the river mouth. The Mississippi River is an effective biogeographic barrier to dispersal. These brooders are highly effective at colonizing patchy habitats at this scale – moreso than the broadcasters *Diploria strigosa* and *Montastraea cavernosa* - rare or absent over most of the Gulf, indicating less effective dispersal capabilities.

## 14-20

**Genetic Connectivity Of Two Scleractinian Corals In Indonesia On Multiple Spatial Scales**

**Craig STARGER*[1,2]**, Paul BARBER[3], Mark ERDMANN[4], Andrew BAKER[5]

[1]Boston University Marine Program, Boston, MA, [2]Sackler Institute for Comparative Genomics, American Museum of Natural History, New York, [3]Department of Biology, Boston University, Boston University Marine Program, Boston, MA, [4]Indonesia Marine Program, Conservation International, Denpasar, Bali, Indonesia, [5]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

The Indonesian seas are home to some of the most biologically diverse marine ecosystems on Earth. They are also among the most threatened marine regions in the world. Studies focusing on genetic connectivity can shed light on the natural history of threatened populations while providing data that are useful to conservation managers. We have chosen the stony corals Pocillopora damicornis and Seriatopora hystrix to test hypotheses on barriers to larval dispersal. Microsatellite markers indicated that although coral populations are significantly differentiated across Indonesia, the level of genetic structure is much lower than that seen in other taxa. Gene flow and immigration estimates indicate that most populations are primarily self-seeding, however long distance dispersal is also occurring, maintaining connectivity across the entire Indonesian archipelago. A closer examination of connectivity on a regional scale was performed in the Bird's Head Seascape of West Papua, where conservation managers are currently incorporating genetic data into the design of marine protected area networks. Similar to the country-wise assessment, there do not appear to any major barriers to dispersal within the Bird's Head region. However, populations of both coral species are still primarily self-seeding, and the majority of genetic diversity is explained by within-population variation. A Bayesian assignment test and jackknifing approach were applied to examine the effect of population decline on overall connectivity in West Papua. Self-recruitment nearly always increased when populations were removed from the estimation of overall connectivity. This high sensitivity of the entire system to the decline of any individual population suggests that a network of marine protected areas covering a large geographic range is the best conservation strategy for maintaining connectivity in the Bird's Head Seascape. In general, coral populations exhibit much lower genetic structure on a regional scale than other taxa.

## 14-21

**Routine And Rare Genetic Connections in Corals Off Northwest Australia**

**Jim UNDERWOOD*[1]**, Luke SMITH[1], Madeleine VAN OPPEN[2], James GILMOUR[1]

[1]Australian Institute of Marine Science, Perth, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

The extent to which marine populations are connected by larval dispersal has profound influences on the ecology and evolution of species; from the short-term regulation and survival of communities to the long-term processes of adaptation to environmental change and speciation. Here, we use microsatellite DNA markers to quantify the genetic structure and infer the ecologically and evolutionarily relevant scales of dispersal of broadcast spawning coral (*Acropora tenuis)* and a brooding coral (*Seriatopora hystrix)* from isolated reefs off northwest Australia. For the brooder, whose larvae are competent to settle immediately after release, significant genetic subdivision over scales of tens of metres indicated that the majority of larvae recruit to within 100 m of their natal colony. However, occasional dispersal over tens of kilometres supplemented this localised recruitment, with putative source and sink dynamics associated with levels of disturbance and recovery from a recent and catastrophic coral bleaching. Additionally, prodigious genetic differences were detected among reef systems, indicating that dispersal over multiple generations of *S. hystrix* larvae over 100s of kilometres is rare. In contrast to the brooder, the broadcast spawned larvae of *A. tenuis* require about three days before competency is obtained, and as expected, levels of subdivision were an order of magnitude smaller compared with *S. hystrix*. However, significant differences were detected between sites separated by less than ten kilometres, providing evidence that these systems, reefs and some reef patches are predominantly self-seeding. However, genetic divergence between the coastal and offshore zones was greater than expected by the geographic separation of systems, indicating that connectivity between these zones via transport of *A. tenuis* larvae on oceanic currents occurs rarely. The primary management implication is that short-term recovery after severe disturbance requires the input of larvae from viable coral communities within kilometres to a few tens of kilometres away.

## 14-21

**Same, Same, But Different: Comparing Population Genetic Structures Of Two Species Of Coral (*Pocillopora Damicornis* & *Platygyra Daedalea*) In The Western Indian Ocean**

**Petra SOUTER*[1]**

[1]Australian Institute of Marine Science, Towsville MD, Australia

Improved management of coral reefs is vital, and information regarding levels of genetic diversity and scales of connectivity are factors that need to be considered when developing efficient management plans. This study was implemented in a geographic area where such knowledge is yet scarce but increasingly important.

Samples of *Pocillopora damicornis* were collected from 29 sites along the coast of East Africa; from Malindi in Kenya, to Mtwara in Tanzania, spanning a distance of over 800 km. Over 60% of all pair-wise comparisons showed a significant genetic differentiation, indicating predominant localised recruitment. The species exhibited mixed modes of reproduction, with 4 populations being dominated by asexual clones and another 3 populations showing signs of mixed sexual and asexual reproduction. All clonal genotypes were found to be homozygotes for a specific, and otherwise rare allele at one of the studied microsatellite loci. This finding indicates that asexual reproduction is genetically, rather than environmentally determined and that its prevalence is determined by the successful recruitment of clonal genotypes and their potential selective advantage within a given population.

*Platygyra daedalea* was sampled from 10 sites, mostly in Kenya. Genetic diversity was found to be low for this species, especially in near shore lagoonal waters. Populations sampled on reef-slopes and on the islands of Zanzibar and Mafia in Tanzania, were found to be significantly more genetically diverse, albeit not as diverse as populations studied on the GBR. The results indicate limited migration from the more diverse reef-slope populations into the lagoons, whereas the lagoonal populations were found to be largely panmictic.

Interestingly, both species show a clear divergence between populations north and south of Mtwapa creek, indicating a dispersal barrier at this location resulting in significantly different and isolated coral populations in Northern Kenya.

## 14-22

**Rapid Long-Distance Dispersal Of Pelagic Reef-Fish Larvae: Implications For Connectivity Models**

**Benjamin VICTOR*[1]**

[1]Ocean Science Foundation, Irvine, CA

There is a dearth of direct information on long-range connectivity among reef fish populations. This is mostly because little is known about the potential for distant dispersal of pelagic reef fish larvae on the scale of hundreds to thousands of kilometers. I collected a large sample of larvae in the open ocean along the equator about 1,000 km from the coast of Ecuador. The larvae were identified using mtDNA barcoding and the sequences revealed that the sample included a significant complement of the regional shore and reef-fish community, including pomacentrids, labrids, gobiids, blenniids, serranids, chaetodontids and holocentrids. In addition, freshwater eleotrid larvae were present that occur only on mainland South America. Barcoding sequences identified a microdesmid species endemic to Colombia as well as the Baja California razorfish *Xyrichtys mundiceps* (Baja California is more than 2,000 km from the collection site). Daily otolith increments from the reef fish larvae revealed that the ages of the youngest larvae converged on about 3 weeks. Given the origin of the larvae was at least as far as Colombia and likely from the Panama Bight, a surprisingly-high estimate of the rate of dispersal is obtained, about 70 km per day. This estimate is well higher than the usual South Equatorial Current velocity of 30 cm/s and indicates that the capacity of shorefish larvae to disperse far offshore in significant numbers may well be underestimated in connectivity models.

## 14-23

**Contrasting Patterns of Population Structure and Dispersal for the Giant Barrel Sponge (*Xestospongia muta*) within the Florida Reef Tract and Caribbean**

**Vince RICHARDS*[1]**, Kevin FELDHEIM[2], Mahmood SHIVJI[1]

[1]The National Coral Reef Institute, Oceanographic Center, Nova SE University, Florida 33004 USA, Dania Beach, FL, [2]Field Museum, Chicago, Illinois 60605 USA, Chicago, IL

Sponges are one of the dominant fauna on Florida and Caribbean reefs, with species diversity often exceeding that of scleractinian corals. Despite their importance as structural components and habitat providers on reefs, their dispersal dynamics are little understood. We utilized eight microsatellite markers to study the population structure and migration patterns of the giant barrel sponge (*Xestospongia muta*), a widespread species throughout Florida and the Caribbean. Bayesian multilocus genotype analyses clustered 157 samples from the Bahamas, Honduras, and the US Virgin Islands into three distinct groups. 159 samples from nine locations within 284 km of the Florida reef tract (Key Largo to the Dry Tortugas) formed a fourth group. Population structure among the four groups was high (FST = 0.155; P = 0.001), with no recent migration among the groups. In contrast, high levels of migration were detected within the Florida reef tract. Reefs in the Upper Keys (Long Key) appear to be sources of larvae to reefs in the north (Key Largo) and also to reefs in the south (Key West and the Dry Tortugas). This pattern of migration closely matches current pathways within the South Florida recirculation system, suggesting that currents play an important role in dispersing *X. muta* larvae within the Florida reef tract. Although there was an overall lack of isolation by distance among the four groups, a significant correlation between genetic and geographic distance was found among the Florida sampling sites indicating that mating within the reef tract is not random. Asexual reproduction appears not to be the cause as only 1.3% of individuals in Florida shared the same genotype (1.6% overall). Rather, limited larval dispersal along the reef tract and among Caribbean locations has probably led to inbreeding within reefs, explaining the significant deficit in heterozygosity detected ($F_{IS}$ = 0.219; P = 0.001).

## 14-24

**Genetic Population Structure Of Coral Reef Fauna In The Indo-Malay Archipelago: Implications For Connectivity And Conservation**

**Marc KOCHZIUS*[1]**, Janne TIMM[2], Agus NURYANTO[2,3], Wiebke KRÄMER[4], Leyla KNITTWEIS[5], Lemia HAMID[2], Janet HAUSCHILD[2], Stina KIRCHHOFF[2], Inga MEYER-WACHSMUTH[2], Christian SEIDEL[2], Patrick MESTER[2]

[1]Biotechnology and Molecular Genetics, University of Bremen, 28357 Bremen, Germany, [2]Biotechnology and Molecular Genetics, University of Bremen, 28359 Bremen, Germany, [3]Faculty of Biology, Jenderal Soedirman University, Purwokerto 53122, Indonesia, [4]Marine Botany, University of Bremen, 28359 Bremen, Germany, [5]Centre for Tropical Marine Ecology, Bremen, Germany

Even though the Indo-Malay Archipelago hosts the world's greatest diversity of marine shallow water species, studies on the genetic population structure and gene flow of marine organisms within this area are rather rare. Consequently, not much is know about connectivity of marine populations in the Indo-Malay Archipelago, despite the fact that such information is important to understand evolutionary and ecological processes in the centre of marine biodiversity. Therefore, the genetic population structure of several groups of coral reef organisms, such as fish, bivalves, gastropods, echinoderms, and corals was studied in the framework of the German-Indonesian research programme SPICE (Science for the Protection of Indonesian Coastal Marine Ecosystems). Most of the studied species show a complex genetic population structure characterised by restricted gene flow between some sites and panmixing between others, which can be attributed to the geological history and prevailing current regimes in the Indo-Malay Archipelago. The major observed genetic differentiation between the Indian Ocean and Western Pacific is most probably due to historical isolation by sea level changes, whereas current oceanographic conditions facilitate connectivity along the ITF on the one hand and separation at sometimes very small scales on the other hand. Prevailing current regimes at the western coast of Sumatra as well as the Halmahera eddy off north-western New Guinea prevent connectivity of populations in the Eastern Indian Ocean and Western Pacific to the central Indo-Malay Archipelago, maintaining the historical separation caused by sea level fluctuations. These factors cause vicariance between populations, which can lead to allopatric speciation, suggesting that the Indo-Malay Archipelago is a centre-of-evolutionary-radiation. These large scale genetic breaks as well as small scale genetic differentiations should be considered in conservation efforts and the spatial arrangement of marine protected areas.

## 14-25

**Population Structure And Connectivity Of The Neon Damselfish (Pomacentrus Coelestis) in The West Pacific Ocean**

**ShangYin LIU*[1]**, ChangFeng DAI[1]

[1]Institute of Oceanography, National Taiwan University, Taipei, Taiwan

The degree to which local populations are demographically connected by dispersal is important for the design of marine reserves and resource management. We studied the genetic connectivity of *Pomacentrus coelestis* populations in the West Pacific using partial mitochondrial control region and microsatellite loci. Based on the molecular data of 142 specimens collected from 7 populations ranging from Okinawa to eastern Australia, high haplotype diversity and low nucleotide diversity were detected in all populations. This suggests that *P. coelestis* populations may have experienced rapid expansion after a bottleneck event. The results of neutrality tests, shallow coalescence of mtDNA genealogies, and the mismatch distribution of pairwise differences also indicated that populations of *P. coelestis* have possibly suffered severe declines in the past. The dating based on the coalescent approach suggested that population expansions possibly occurred approximately 27,000 years ago. The results of AMOVA and Φst pairwise comparisons showed that populations were divided into 3 groups, i.e., the north-west Taiwan (Penghu and northern Taiwan), the South China Sea (Hainan, southern Taiwan and Okinawa), and the Australian groups. On a smaller spatial scale, a genetic break was defined between the north-west Taiwan group and the southern Taiwan population. We then assigned recruits from the same locality and adjacent localities based on the genotypes revealed by 7 microsatellite loci. The results of assignments indicated that the recruits in southern Taiwan were mainly from the South China Sea (approximately 50%) and the recruits in Penghu and northern Taiwan were mixed among their natal grounds. This study highlights the influence of present current patterns and historical events on the connectivity of *P. coelestis* populations. Furthermore, this pattern of population connectivity provides implications for the conservation and management of reef fishes around Taiwan.

## 14-26

**Spatial And Temporal Instability in The Genetic Structure Of Adult And Juvenile Bicolor Damselfish (Stegastes Partitus) Within The Mesoamerican Barrier Reef System**

**J. Derek HOGAN*[1]**, Roger J. THIESSEN[1], Daniel D. HEATH[1]

[1]Great Lakes Institute for Environmental Research, University of Windsor, Windsor, ON, Canada

Population connectivity is an important but poorly understood factor relevant to the ecology, evolution and conservation of marine species. Directly estimating dispersal and connectivity among populations is logistically difficult, but much can be inferred by comparing the population genetic structure of the young, dispersive life stage with that of the more sedentary adults through time. Here we examine the population genetic structure of adult and recently settled juvenile bicolor damselfish, Stegastes partitus, sampled at seven sites along the Mesoamerican Barrier Reef System (MBRS) over a two year period. Using genotype data at 12 microsatellite loci, we tested for genetic population differentiation among life stages and sites. Our results show spatial heterogeneity in adult and juvenile population structure; however, no evidence for an isolation by distance model of divergence was found. We show that allele frequency distributions change through time and between age classes in an unpredictable manner. Since juvenile and adult samples exhibit similar levels of genetic divergence we propose that the temporal instability we observed is due to pre-settlement effects. Our results suggest that the relative contributions of upstream sources likely changes through time as a result of stochastic processes such as oceanographic flow and meteorological events. We attempt genetic assignment of recently settled juvenile fishes to directly estimate ecological dispersal in an attempt to verify that cohorts are arriving from variable source populations.

## 14-27

**Connectivity And Climate Change: Impacts On A Reef Building Coral in The Eastern Pacific**

**Nicholas POLATO*[1]**, Iliana BAUMS[1]

[1]Biology, Penn State University, University Park, PA

Connectivity is a primary factor determining community structure, species cohesion, and population persistence. Weather phenomena which alter wind and current patterns will significantly impact patterns of reef connectivity. Long-distance dispersal to the east from the coral rich central Pacific may be favored during El Nino Southern Oscillation (ENSO) events due to reversal of surface currents, providing larvae to areas denuded by recurring high Sea Surface Temperatures (SSTs) caused by ENSO, and supplementing coral populations in marginal habitats in the Eastern Pacific. In an effort to understand patterns of connectivity influencing the origin, evolution, and regeneration of coral populations in the eastern Pacific, microsatellite loci were generated for *Porites lobata*, a massive reef building species found throughout the Pacific Ocean. Sequences from a coral genomic DNA library and publicly available shotgun reads were used to develop microsatellite markers that amplify reliably in widely separate populations. Genotype data were generated for individuals collected from geographically distant populations throughout the eastern and central Pacific using multiplexed PCR reactions. Results of STRUCTURE and Fst analysis were consistent with expectations that populations on opposite sides of the Eastern Pacific Barrier are significantly differentiated. Ongoing work will apply the genotyping markers to additional populations. Nuclear sequence markers will be used in conjunction with microsatellite data to estimate the timing and extent of long distance dispersal events from central to eastern Pacific populations, and patterns of connectivity will be combined with oceanographic current models to identify primary corridors for genetic connectivity. Whether recruits to eastern Pacific populations are produced locally or regionally will affect the rate of colonization following disturbance and the ability of populations to adapt to local conditions, with important implications for the design of reserves intended to protect these habitats.

## 14-28

**Small Scale Genetic Connectivity Of Bicolor Damselfish (*stegastes Partitus*) in Marine Protected Areas Of The Mexican Caribbean**

**Carmen A. VILLEGAS SÁNCHEZ*[1]**, Jesús E. ARIAS GONZÁLEZ[2], Renata RIVERA MADRID[3]

[1]Departamento de Recursos del Mar, Centro de Investigación y Estudios Avanzados-Unidad Mérida, Yucatán, Mexico, [2]Departamento de Recursos del Mar, Centro de Investigación y Estudios Avanzados-Unidad Mérida, Mérida, Mexico, [3]Departamento de Bioquímica y Biología Molecular de Plantas, Centro de Investigación Científica de Yucatán, A.C., Mérida, Mexico

Connectivity has been defined as the demographic connection maintained between neighboring populations of a species due to the migration of individuals between them. An analysis was done of variation in nine microsatellite loci to assess genetic structure in 13 bicolor damselfish (*Stegastes partitus*) populations (N = 718) from three marine protected areas and one unprotected area in the Mexican Caribbean, and infer its conservation implications. A combination of Nei distances (D) and FST showed significant genetic differentiation between populations, and this pattern was clearly not associated with geographic distance. Significant departure from Hardy-Weinberg Equilibrium was observed in the majority of the loci: i.e. 96 of the 117 tests, suggesting inbreeding is occurring. Small-scale population structure is probably being influenced by independent population dynamics, low dispersion levels, biological characteristics specific to this species and reefscape characteristics. Correspondence Factorial Analysis (CFA) indicated differentiation between groups. The two sites with the highest genetic distance values (range: 0.006-0.414 ) in the pairwise test were those with the most complex reefscapes. Our results suggest that local damselfish populations differ at a relatively small scale, and therefore coral reef management for this species, and other species with similar biological characteristics, requires local conservation strategies.

## 14-29

**Complex Patterns of Genetic Connectivity in a Brooding Coral on the Great Barrier Reef, Australia**

**Madeleine VAN OPPEN*[1]**, Adrian LUTZ[1], Glenn DE'ATH[2]

[1]Australian Institute of Marine Science, Townsville, MC, Australia, [2]Australian Institute of Marine Science, Townsvile, MC, Australia

An understanding of the extent of larval transport in and out of reefs, as well as the direction of larval dispersal will improve our ability to forecast whether and how fast reef organisms are likely to recover from disturbance events that cause massive mortality. Assessment of connectivity on the Great Barrier Reef (GBR) is complex, as the GBR is extremely large (~350,000 km2, of which ~21,000 km2 consists of coral reef) and comprises ~2,900 separate reefs. We assessed genetic connectivity among and diversity within GBR populations of the brooding coral, *Seriatopora hystrix*. Approximately 1,800 specimens were collected across ~8.5 degrees of latitude and genotyped at ten microsatellite loci. Although extensive mixing was obvious in some areas, for example along the outer-shelf Ribbon reefs in the northern section of the GBR, high levels of genetic subdivision were generally observed among populations. Nearby populations from the same reef were in some cases as genetically distinct as populations hundreds of kilometres away. A strong signature of recent admixture (i.e., linkage disequilibrium, heterozygote deficits and high allelic diversity) was present in a subset of the populations, and where both lagoonal and exposed sites were sampled on the same reef, the latter were much more admixed. A hydrodynamic model is available for the northern section of the GBR and a comparison of hydrodynamic and genetic data will be presented.

## 14-30

**Population Genetics, Larval Dispersal, and Demographic Connectivity in Marine Systems**

**Kimberley WEERSING*[1]**, Robert TOONEN[2]

[1]Oceanography, University of Hawaii at Manoa, Honolulu, HI, [2]Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kane`ohe, HI

We survey 300 published studies to synthesize life-history and population genetic structure data from a broad array of benthic marine taxa (including ten coral species and 62 reef-associated species) to determine how well pelagic larval duration (PLD) correlates with population genetic estimates of dispersal. Expanding on earlier studies, we also explore other potential biophysical correlates of population substructure (genetic marker class, habitat type, and larval swimming ability) that have not been considered in previous meta-analyses. In contrast to previous studies concluding that planktonic periods correlate well with inferred dispersal ability, we find that average PLD was poorly correlated with population connectivity ($F_{ST}$). Furthermore, even this weak correlation appears to be anchored by the zero PLD class, because removal of species that lack a pelagic phase from the analysis resulted in a non-significant relationship between $F_{ST}$ and mean PLD. A 3-way ANCOVA instead reveals that genetic marker class (mtDNA, allozymes, and microsatellites) is responsible for most of the variation in $F_{ST}$ ($F = 7.113$, $df = 2$, $p = 0.001$), while neither habitat nor swimming ability were significant factors. In contrast to the general expectation that microsatellite-based studies provide the finest resolution of population structure, we find that significantly higher values of $F_{ST}$ are obtained with mtDNA than with either microsatellites or allozymes (which were not significantly different). Useful predictors of the pattern and scale of dispersal play a central role in both ecological and evolutionary studies, but as yet remain elusive; this study suggests that mean PLD is at best a weak predictor of population genetic structure and that estimates of larval dispersal will need to encompass both behavioral and physical transport processes.

## 14-31

**Local And Regional Self-Recruitment in The Bicolor Damselfish (Stegastes Partitus) On Turneffe Atoll in The Mesoamerican Barrier Reef**

**Eva SALAS*[1]**, Helena MOLINA[1], Dan HEATH[2]

[1]Centro de Investigación en Ciencias del Mar y Limnología (CIMAR), Universidad de Costa Rica, San Jose, Costa Rica, [2]Great Lakes Institute for Environmental Research (GLIER), University of Windsor, Windsor, ON, Canada

The scale of larval retention is of critical importance to define units of conservation for reef fishes. By using genotype assignment techniques, we estimated the proportion of self recruitment of Stegastes partitus, a Caribbean damselfish with a long (30-day) pelagic larval phase. Adults and recently settled juveniles were collected from reefs located on Turneffe atoll and the Belize barrier reef, and were genotyped at 12 microsatellite loci. We found that self-recruitment rates are relatively low at a local, <1 km scale (18 to 23%), on two reefs located at the East and West of Turneffe atoll; however, approximately three-quarters of the larvae (76%) are retained at a 50 km, regional scale (across the atoll). The level of local self-recruitment did not differ significantly between the eastern and western sites, despite an expectation for differences in oceanographic retention regimes. The high levels of retention at the regional (atoll) scale likely reflect dispersal kernel size of the order of the atoll length (50 km). Although retention at the regional scale is high, there is still a contribution of migrants (the other 24%) that disperse longer distances, and such a level of migration explains the low level of genetic structure. Our results contribute to the understanding of the evolutionary persistence of dispersal, since a combination of dispersal and retention (as described here) provides the opportunity for both some level of local adaptation and dispersal-based risk-spreading. A 50-km regional retention scale is a size larger than most present-day marine reserves in the Caribbean. If reserves are small and isolated, they are unlikely to provide conservation and fisheries benefits when self recruitment levels are locally low.

## 14-32

**Direct Estimates Of Self-Recruitment And Local Connectivity in A Coral Reef Metapopulation**

**Geoffrey JONES*[1]**, Serge PLANES[2], Pablo SAENZ AGUDELO[2], Simon THORROLD[3]

[1]School of Marine and Tropical Biology, and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]Laboratoire Ecosystemes Aquatiques Tropicaux et Mediterraneens, CNRS-EPHE-UPVD, Universite de Perpignan, Perpignan, France, [3]Biology Department MS#50, Woods Hole Oceanographic Institute, Woods Hole, MA

Direct estimates of larval retention and connectivity are essential to parameterize marine metapopulation models and to optimize the design of marine protected area networks. For coral reef fishes, while there are some estimates of self-recruitment at isolated populations, there are no direct estimates of exchange between adjacent sub-populations or between protected and unprotected areas. Here we use a likelihood-based parentage analysis to assess the relative magnitude of self-recruitment and exchange among five sub-populations of the panda clownfish *Amphiprion polymnus* in Bootless Bay, Papua New Guinea. These small sub-populations varied in size between 28 and 84 individuals. Each was confined to a discrete ~1ha patch of shallow sand that was separated from other subpopulations by 2 to 5km. All adults were fin-clipped and all juveniles that settled over a 7 month period were collected for genetic analyses. We used nine microsatellite loci and the FAMOZ software to assign settlers to putative parents, with unassigned juveniles considered to be immigrants from other unknown populations. The overall level of self-recruitment for the combined 5 sub-populations was ~25%. This figure was apportioned to an average of 10% self-recruitment within subpopulations and ~15% exchange among the sub-populations. The data suggest that both fine-scale self-recruitment and exchange among populations 2-5km apart contribute to the persistence of this clownfish metapopulation, along with substantial larger-scale dispersal. We hypothesize that *A. polymnus* is characterised by a multimodal distribution of larval dispersal distances that varies according to the spacing of sub-populations.

## 14-33

**Temporal Patterns in Genetic Structure Within And Among Cohorts Of Settlement-Stage Larvae And New Recruits Of A Coral Reef Fish**

**Tauna RANKIN*[1]**, Su SPONAUGLE[1], Dean WILLIAMS[2]

[1]Marine Biology and Fisheries, RSMAS/University of Miami, Miami, FL, [2]Biology, Texas Christian University, Fort Worth, TX

High fecundity coupled with extensive and often variable mortality of early life stages leads to highly variable recruitment dynamics of many marine organisms, including coral reef fishes. Sources of variation in recruitment strength can be the result of random (e.g. temperature, current trajectories) and selective (e.g. starvation, predation) processes. Identifying sources of variation in and mechanisms important to early survival may provide a means of predicting population structure and connectivity among populations. Most population genetic studies have concentrated on spatial patterns of genetic structure. The goal of this study was to identify temporal genetic variation within and among cohorts of settlement-stage larvae and newly recruited juveniles and to determine 1) whether allelic frequencies vary among monthly cohorts of settling larvae due to fluctuating larval transport or chance reproductive success of a small proportion of adults, and 2) whether temporal variation within monthly cohorts is indicative of selective or random loss of alleles (i.e. genetic drift). To investigate the presence and mechanism of temporal shifts in a population's genetic composition, six monthly cohorts of newly settled bicolor damselfish *Stegastes partitus* were sampled in the upper Florida Keys, USA over four years. Late-stage larvae were collected in light traps and newly recruited juveniles were collected a few days later on the reef. Exon-primed intron-crossing polymerase chain reaction amplifiable introns (EPIC-PCR) and a 400 base pair region of the mitochondrial control region I were compared within cohorts and among different months and years. When differences in allelic frequencies among monthly cohorts were detected, calculations of relatedness were used to test for a Hedgecock effect. We also determined whether allele frequencies within cohorts resulted from selective processes acting on certain loci or over all loci equally, suggesting random genetic drift.

## 14-34

**Genetic Connectivity Of The Shallow And Deep Reef: Intra-Reef Genetic Structure Of *seriatopora Hystrix* On The Northern Great Barrier Reef**

**Pim BONGAERTS*[1]**, Norbert ENGLEBERT[1,2], Tyrone RIDGWAY[1], Cynthia RIGINOS[3], Ove HOEGH-GULDBERG[1]

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia, [2]IBED, University of Amsterdam, Amsterdam, Netherlands, [3]School of Integrative Biology, University of Queensland, Brisbane, Australia

Whilst many reef communities in the Great Barrier Reef Lagoon are limited to shallow waters, there are a large number of reefs that extend beyond 25m depth (especially along the Great Barrier Reef margin). These deeper reefs appear to be less prone to disturbance than their shallow counterparts as the effects of several major stressors on coral reefs (e.g. elevated sea surface temperatures and storm-induced waves) are largely confined to shallow depths. As such, the relatively undisturbed deep reef has the potential to function as a refugium and subsequently as a "re-seeding" reproductive source for the shallow, aiding in recovery after a disturbance. Coral species that transcend the distinct shallow and deep reef habitats (i.e. depth-generalist species) and thrive under a large range of environmental conditions have the highest potential to provide a viable recruitment resource for the shallow. However, due to the lack of appropriate markers, very little is known about local recruitment processes and the extent of recruitment occurring between shallow and deep reef habitats. In this study we explore the extent of gene flow in the brooding coral *Seriatopora hystrix* between the deep reef slope (27m), the reef crest (6m), and back reef (2-3m) on two outer-reefs of the northern Great Barrier Reef. Nine microsatellite loci, specifically developed for *Seriatopora hystrix* were amplified and their variation assessed. Preliminary results indicate that populations are largely self seeding, which challenges the idea that reef systems may be rapidly repopulated from external larval sources after a disturbance and rather highlights the importance of local recruitment processes for shallow coral reef recovery.

## 14-35

**Low Genetic Diversity And Gene Flow Suggests Vulnerable Atlantic Coral Outposts**

**Flavia NUNES*[1]**, Richard D. NORRIS[1], Nancy KNOWLTON[1]

[1]Scripps Institution of Oceanography, La Jolla, CA

Coral species diversity in the Atlantic Ocean is concentrated in the Caribbean Sea, but coral populations are also found along the coasts of Brazil and West Africa, and on mid-Atlantic islands. These coral "outposts" are typically rocky reefs harboring a low number of coral species, often rich in endemics. In order to study the levels of genetic diversity and gene flow among these low-diversity outposts and the Caribbean, 130 individuals of *Montastraea cavernosa* sampled from 6 Atlantic populations in the Caribbean (Panamá, Belize and Puerto Rico), North Atlantic (Bermuda), Western South Atlantic (Brazil) and Eastern Tropical Atlantic (São Tomé, West Africa) were genotyped at two nuclear and one mitochondrial loci. For the two nuclear loci, Caribbean and North Atlantic populations displayed high levels of genetic diversity and similar allele frequencies, whereas the Brazilian and West African populations each had markedly lower levels of genetic diversity and distinct allele frequencies relative to other populations. The mitochondrial locus had much lower diversity than the nuclear loci, with one fixed allele in the South Atlantic populations (Brazil and São Tomé), and one very common allele being nearly fixed in the Caribbean and North Atlantic populations. Surprisingly, no population differentiation was observed among Caribbean and North Atlantic populations of *M. cavernosa* over all loci, suggesting these populations are well-connected over evolutionary time scales. Populations from Brazil and West Africa, however, were significantly differentiated from all other populations over all loci, including each other, except for the mitochondrial locus, where they display the same genotype. Genetic diversity and connectivity may be important factors that contribute to the resilience of a coral population to disturbance. Low genetic diversity and low levels of gene flow in Brazil and West Africa suggest that isolated outposts may be more vulnerable to degradation and loss relative to Caribbean populations.

## 14-36

**Genetic Parental Analysis Reveals Both Local Retention And Large Scale Connectivity Of Clownfish in Kimbe Bay**

**Serge PLANES*[1]**, Geoffrey JONES[2], THORROLD SIMON[3]

[1]UMR 5244 - Laboratoire Écosystèmes Aquatiques Tropicaux et Méditerranéens, CNRS - EPHE - UPVD, Perpignan, France, [2]School of Marine and Tropical Biology, and ARC Centre of Excellence for Coral Reef Studies, James Cook University, TOWNSVILLE, Australia, [3]Biology Department MS # 50, Woods Hole Oceanographic Institution, Woods Hole, MA

Many marine species produce larvae that can be pelagic for weeks or months and the potential for long distance dispersal by prevailing currents is extremely high. Marine populations have, in turn, been assumed to be demographically "open", consisting of many sub-populations that are connected by larval dispersal. However recent work has consistently demonstrated high levels of self-recruitment in reef fish populations. Because of the technical difficulty of tracking larvae, direct measures of dispersal have not previously been obtained. We report on the potential of genetic parental analysis to estimate local self-recruitment and connectivity among distant areas by identifying the parent (and their location) of a new recruit settling at a certain location. We sampled (fin-clip) the entire adult population of clown fish (*Amphiprion percula*) from the reef around a small island, Kimbe Island, Papua New Guinea, together with new recruits from Kimbe Island and several other locations throughout Kimbe Bay. Parental analysis demonstrated significant self-recruitment (about 50%) to the Kimbe Island sub-population, but also significant connectivity among three distant locations within Kimbe Bay. As many as 10% of new recruits at these distant locations - up to 50km from Kimbe Island - were spawned by Kimbe Island adults. At small spatial scale, we observe strong retention (up to 50%) within small lagoon around Kimbe island that question about the ability of the species to achieve the pelagic larval phase within these lagoon. Finally, we demonstrate that some parents at specific sites within Kimbe Island were more efficient in producing self-recruitmenting juveniles than adults at other sites. Genetic parental analysis opens the possibility for new perspectives in understanding success of the larval phase and investigating process determining connectivity in the perspective of better management of marine populations.

## 14-37

**Genetic Connectivity in Philippine Waters: Insights On Patterns, Scales, And Processes Based On Various Marine Taxa**

**Rachel RAVAGO GOTANCO*[1]**, Marie Antonette JUINIO-MENEZ[1]

[1]Marine Science Institute, University of the Philippines, Quezon City, Philippines

An understanding of connectivity among reef environments is of critical importance to the design and implementation of management and conservation schemes. Predicting patterns of reef connectivity remains a challenge, as connectivity is the result of a complex interaction of biological and physical factors and processes operating across a wide range of spatial and temporal scales. Genetic patterns of a variety of reef-associated species with varying dispersal potential, from different marine biogeographic regions in the Philippines provide insights on ecological and historical processes that structure marine populations in these regions. Genetic patchiness at scales finer than expected from potential dispersal based on life history traits coupled with local hydrographic features indicate key factors affecting benthic recruitment success determine genetic patterns. For species such as Tridacna crocea, Linckia laevigata, and Siganus fuscescens, these include the influence of distribution and extent of suitable habitats and degree of environmental disturbance. Within biogeographic regions, genetic patterns coupled with community structure and hydographic regimes provide useful insights relevant for fishery management considerations. Patterns of genetic variability among northwest Luzon populations of S. fuscescens and Tripneustes gratilla provide insight into the spatial scales and putative boundaries for connectivity and gene flow. Genetic patterns across regions, as in the case of T. crocea, S. fuscescens and Siganus argenteus populations across the eastern Philippine seaboard, and South China Sea and Sulu Sea populations of T. crocea and L. laevigata, indicate the influence of broadscale hydrographic features on population genetic structure. In the case of the spiny lobster Panulirus longipes, genetic connectivity coupled with subspecies distribution patterns provides insight into long-term evolutionary scale processes shaping genetic structure and species biogeography.

## 14-38

**Long-Distance Gene Flow And Fine-Scale Genetic Differentiation in The Indo-Pacific Reef Fish, *zebrasoma Flavescens***

**Jeff EBLE*[1]**, Rob TOONEN[1], Larry BASCH[2], Brian BOWEN[1]

[1]Hawaii Institute of Marine Biology, Kaneohe, HI, [2]University of Hawaii Pacific Cooperative Studies Unit, Honolulu, HI

The remoteness of the Hawaiian Archipelago has proven to be a formidable barrier to the dispersal of marine species, resulting in high levels of endemism and corresponding genetic divergence. However, across the 2500 km of Hawaii's islands and atolls, marine populations have historically been assumed to be panmictic. To compare patterns of connectivity within the archipelago to broader trans-Pacific patterns, we surveyed both mtDNA and nuclear markers in the Indo-Pacific reef fish, *Zebrasoma flavescens*. Adults were collected at multiple spatial scales (N = 824) from 21 sites including: (a) four West Pacific locations, (b) six sites within the newly created Northwestern Hawaiian Islands (NWHI) Marine National Monument, and (c) 10 sites within the Main Hawaiian Islands, four being located around the largest island in the archipelago, the island of Hawaii. Additional tests for sweepstakes recruitment were conducted on 212 newly recruited fish collected from seven Hawaii Island sites. Analysis of cytochrome *b* sequences demonstrated modest population structure across the West Pacific ($\Phi$st = 0.04; P = 0.034) and stronger genetic differentiation between the West Pacific and Hawaii ($\Phi_{st}$ = 0.09; P = 0.004). Analysis of 14 microsatellite loci indicate restricted gene flow between the newly established NWHI reserve and the main Hawaiian Islands ($F_{st}$ = 0.008, P = 0.024), and genetic subdivision at scales of less than 50 km around Hawaii Island ($F_{st}$ = 0.019, P < 0.001).

## 14-39

**Population Structure And Genetic Connectivity Of Corals in Subtropical Eastern Australia**

**Annika NOREEN*[1]**, Peter HARRISON[1], Madeleine VAN OPPEN[2]

[1]Department of Environmental Science and Management, Southern Cross University, Lismore, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

This study examines the population differentiation, genetic diversity, and connectivity of corals in the eastern Australian subtropics and the Great Barrier Reef. Several eastern Australian subtropical reefs have high coral cover (up to 85%) and relatively high species richness (90-140 species). High-latitude reefs might be increasingly vulnerable because of ocean acidification, lower genetic diversity and lower connectivity among reefs. We address some of the issues underlying these ecological questions using population-level genetics of five coral species. Over 1,200 samples have been taken from *Seriatopora hystrix, Pocillopora damicornis, Acropora solitaryensis, Goniastrea favulus* and *Platygyra daedalea* from subtropical reefs (Lord Howe Island, Middleton and Elizabeth reefs, the Solitary Islands and Flinders Reef) and several Great Barrier Reef locations. Nuclear DNA was extracted from each sample, and between 5 and 10 fluorescently-labelled microsatellite markers were amplified for each species using PCR. The alleles were then genotyped and scored. *Seriatopora hystrix*, a brooding coral, has highly differentiated populations between most of the locations. However, some populations sampled are undifferentiated despite considerable environmental variability, e.g. Lord Howe Island east coast versus western lagoon. Additionally, the Elizabeth reef lagoon population clusters with the Middleton reef lagoon population, despite being 50 km apart, as do their respective outer channel populations. The *S. hystrix* population at Flinders reef, southern Queensland, is most similar to that of Lord Howe Island, over 600 km further south. The three Great Barrier Reef locations are admixtures of several genetic populations and, as a group, highly differentiated from subtropical reefs. There is discernable gene flow between some populations, notably Middleton and Elizabeth reefs' outer channel to Lord Howe Island.

## 14-40

**The Missing Link To Population Genetic Structure in Brooding Corals: How Far Do Sperm Swim?**

**Patricia WARNER*[1,2]**, Bette WILLIS[1], Madeleine VAN OPPEN[2]

[1]School of Marine and Tropical Biology and ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

The processes that govern the population genetic structure of brooding corals may be different to those that govern broadcast spawning species because of differences in the frequency and scale of dispersal characteristic of internal versus external fertilization. Given that small and isolated populations may be at greater risk of decline and extinction compared to large and panmictic populations, investigating genetically effective population sizes of brooding species is important. Effective population sizes in hermaphroditic reef corals are expected to be several magnitudes smaller than the census size, due to inter-annual variation in census population sizes and fecundity, as well as possible influences of both asexual reproduction and self-fertilization. Analysis of highly polymorphic DNA markers of the brooding coral, *Seriatopora hystrix*, on the Great Barrier Reef (GBR) shows that allelic diversity is high across the GBR, but much smaller in each population, suggestive of small effective population sizes. Heterozygote deficits, indicative of non-random mating, are common in this species, which is consistent with rapid settlement of the larvae shortly after release. Knowledge of fine-scale connectivity patterns within populations of brooding corals may help to elucidate the broad-scale patterns in genetic structure. Limited sperm dispersal may amplify signals of geographic subdivision, but current knowledge of the frequency and scale of dispersal of spermatozoa in brooding species is limited, and is absent for *S. hystrix.* To determine the spatial extent of spermatozoa dispersal, the genotypes of all colonies within a mapped study population in the Palm Islands, central GBR, were compared with those of the brooded larvae of adults sampled from the center of the mapped population. Furthermore, we assessed the timing of spermatozoa and larval release with histological monitoring of adult gametogenic tissue throughout the reproductive season.

## 14-41

**Fine-scale Spatial Genetic Structure in the Caribbean Staghorn Coral *Acropora cervicornis***

**Silvia LIBRO*[1]**, Steve VOLLMER[1]

[1]Marine Science Center, Northeastern University, Nahant, MA

Localized spatial genetic structure (SGS), i.e. the non-random association of genetic relatedness among individuals in space, can be caused by a variety of demographic and evolutionary processes including limited dispersal, inbreeding, and selection. SGS has been studied extensively in plants, in order to estimate fine-scale patterns of dispersal, but has rarely been examined in sessile marine taxa. Here we investigated the possibility that SGS might be important in the staghorn coral *Acropora cervicornis*. Staghorn corals from four populations were mapped along permanent transects and genotyped with five microsatellite loci. Our results show that *A. cervicornis* exhibits localized SGS within reefs (out to 14 meters) due to both the spatial aggregation of clones and the non-random association of genets on reefs. We show that patches of *A. cervicornis* can be highly inter-related as well with relatedness on the order of cousins. We also detected moderate to high levels of population genetic structure among reefs over spatial scales as small as 2kms, but no evidence of isolation by distance among reefs. We suggest that the localized SGS, high relatedness among genets within reefs, and strong population structure between reefs is the results of rare cohort recruitment.

## 14-42

**Understanding Patterns Of Gene Flow in Coral Reef Fishes: Multiple Species And Multiple Scales.**

**Joshua DREW*[1]**, Paul BARBER[2]

[1]Marine Program, Boston University, Woods Hole, MA, [2]Marine Program, Boston University, Boston, MA

Understanding the spatial scales over which populations of coral reef fishes are connected is important for elucidating evolutionary patterns as well as in setting conservation priorities. In this presentation we compare patterns of genetic connectivity of several common coral reef fishes over multiple spatial scales. On the finest scale, between the islands of Fiji we see broad scale genetic homogenization with most, but not all of the species we examine. However, on the next highest spatial scale (between Fiji and the rest of Melanesia) we see evidence for regional endemism within five species of fishes. Expanding further, we investigate two species of fish *Amphiprion melanopus and Pomacentrus moluccenis* [Pomacentridae] whose species ranges are entirely within Melanesia and Indonesia. Here we see evidence for restricted gene flow across the Indo-West Pacific archipelagos ultimately leading to the evolution of peripheral populations into reproductively isolated monophyletic clades. Finally at the largest spatial scales we use the widely distributed species *Halichoeres hortulanus* [Labridae], to investigate gene flow across the Indian and Pacific oceans, and discover significant barriers to gene flow between these oceans occurring in the Indonesian archipelago. Our results demonstrate that despite having pelagic larvae and the ability to distribute genes over broad geographic differences, some coral reef fish populations are geographically structured, but the magnitude of that structure depends on the spatial scale considered.

## 14-43

**Connectivity in A Caribbean Octocoral: A Tale Of Three Datasets**

**Howard LASKER*[1]**, Jaret BILEWITCH[1], Stefano GOFFREDO[2]

[1]Program in Evolution, Ecology and Behavior, and Dept of Geology, University at Buffalo, Buffalo, NY, [2]Department of Evolutionary and Experimental Biology, University of Bologna, Bologna, Italy

Characterizations of connectivity vary with the spatial and temporal scales inherent in the techniques used to assess connectivity. The Caribbean octocoral, *Pseudopterogorgia elisabethae* has been harvested on the Little Bahama Bank for over 10 years. The harvest, which involves cropping colonies, leaves areas with reduced numbers of reproductive colonies. This reduction in reproductive colonies should reduce local recruitment, since *P. elisabethae* surface broods and has negatively buoyant planulae. We examined connectivity among populations on the Little Bahama Bank and throughout the northern Bahamas on differing spatial and temporal scales by comparing recruitment before and after harvesting, comparing the population size/age structure between harvested and unharvested areas and examining population genetic structure.

Recruitment at sites in 2004 and 2005 varied with local population density, but changes in recruitment due to harvesting were no greater than inter-annual variation in recruitment at all sites. However, the size structure of populations that were subjected to up to 3 episodes of harvesting had depressed proportions of small colonies suggesting that local recruitment and the extended depression of local recruitment affected population demographics. Microsatellite analyses of populations on the Little Bahama Bank detected minimal population clustering but did identify significant $F_{ST}$ values. We found high levels of structure on larger scales. The data suggest that in any single year recruits readily move over scales $>10^{-1}$ km. However, over the scale of a decade and summed across harvesting encompassing several kilometers a substantial portion of recruitment is local. Over scales of decades and 10 to >100 km there is sufficient migration to reduce but not eliminate population genetic structure. There is limited migration across oceanographic barriers.

## 14-44

**Preliminary Analysis of *Acropora palmata* Gene Flow in Reefs of the US Virgin Islands**

**William SCHILL*[1]**, Caroline ROGERS[2], Erinn MULLER[3], Anthony SPITZACK[4], Iliana BAUMS[5]

[1]Natl. Fish Health Research Laboratory, USGS-Leetown Science Center, Kearneysville, WV, [2]Virgin Islands National Park, USGS-Florida Integrated Science Center, St. John, Virgin Islands (U.S.), [3]Florida Institute of Technology, Melbourne, FL, [4]USGS-Florida Integrated Science Center, St. John, Virgin Islands (U.S.), [5]The Pensylvania State University, University Park, PA

Two regionally isolated populations of *Acropora palmata* that were previously identified are generally demarcated by Mona Island, east of Puerto Rico. To further examine pathways of gene flow in the eastern zone, we determined the genotype at five polymorphic microsatellite loci of 256 colonies of *Acropora palmata* from six sites on St. John, and 92 additional colonies from two sites at Buck Island/St. Croix, USVI. Data analysis using AMOVA demonstrated that 98% of the genetic variation was within collections, while 2% was among the island groupings. Sixty-five of the 348 colonies were clonal. The incidence of clonality may be influenced by differential spatial scales of sampling at various sites, but was lowest in samples from the South Fore Reef of Buck Island (0 of 50 colonies), and highest at the Hawksnest Bay, St. John site (21 of 42 colonies). When clonemates were removed from the analysis, the differentiation of the island groupings disappeared and the algorithm used by the program, *structure v. 2.2*, failed to identify more than a single cluster. Pairwise population *F*ST and $R_{ST}$ values, however, indicated significant differentiation for combinations of the Yawzi Point or Saltpond Bay, St. John, collections with the two St. Croix collections. We also examined distributions of sample pairs' relatedness. Within collections, mean relatedness was significantly higher between sample pairs from the two St. Croix collections than between sample pairs of other collections. Thus, the St. Croix collections seem to exhibit some cohesiveness not generally found in the St. John collections. The Saltpond Bay collection, however, was distinct from the other five St. John collections in that 5.5% of the possible pairings shared at least one allele at each of the five loci. Analyses of individuals with similar genotypes suggest potential connections between reefs.

## 14-45

**Range-Wide Population Genetics Of The *gorgonia Ventalina*/*symbiodinium* Octocoral Holobiont**

**Jason ANDRAS*[1]**, Nathan KIRK[2], C. Drew HARVELL[1]

[1]Ecology & Evolutionary Biology, Cornell University, Ithaca, NY, [2]Biology, Auburn University, Auburn, AL

The conspicuous and ecologically dominant Caribbean seafan coral, *Gorgonia ventalina*, exists in an obligate mutualistic relationship with photosynthetic dinoflagellates of the genus *Symbiodinium*, ITS type B1. Here we describe the population genetic structure of the *G. ventalina*/*Symbiodinium* coral holobiont at 40 localities spanning more than 3,000 km throughout its range, using a total of 22 polymorphic microsatellite loci (13 loci from the *Symbiodinium* genome; 9 loci from the *G. ventalina* genome). The large majority of *Symbiodinium* populations within a single seafan colony were clonal, and seasonal sampling of marked colonies showed within-host symbiont populations to be temporally stable. Significant structure was detected between *Symbiodinium* populations among different coral hosts separated by as little as 5km, and overall divergence in symbiont populations followed a pattern of isolation by distance. Differentiation was also detected between *Symbiodinium* populations hosted by corals in different size/age classes at the same locality. A small fraction of seafan colonies sampled were found to host multiple symbiont genotypes. The relative proportions of these genotypes were dynamic and reversible in response to experimentally induced light and temperature stress, suggesting that the fine-scale *Symbiodinium* genetic diversity described in this study may have functional significance. Significant structure was also detected among populations of *G. ventalina*, though at a broader scale of hundreds to thousands of kilometers. The observed patterns of connectivity in populations of the coral host are consistent with data from biogeographic studies of other Caribbean marine organisms with broadly dispersing pelagic larvae. This is the first study we are aware of that considers the population genetics of both members of the obligate coral/algal holobiont. These results will have significance for our understanding of basic coral population biology, the establishment and maintenance of the coral/algal symbiosis, and conservation genetics and management of corals and other Caribbean reef creatures.

## 14-46

**Genetic Variability Of Acropora Cervicornis And A .palmata in Puerto Rico**

**Garcia Reyes JOSELYD*[1]**, Nikolaos SCHIZAS[1]

[1]Department of Marine Sciences, University of Puerto Rico-Mayaguez, Lajas, Puerto Rico

Genetic variation of natural populations may be used as a proxy for the long-term survival of populations or species. Effective conservation and management planning for the rapidly declining scleractinian species *Acropora cervicornis* and *A. palmata* require an understanding of the standing genetic variability. Over 100 colonies of *Acropora cervicornis* and *A. palmata* have been sampled from several reefs around Puerto Rico to assess levels of genetic variability. We used partial DNA sequences of the mitochondrial control region to estimate levels of genetic connectivity in adjacent and geographically distant reefs. Preliminary analysis shows that many of the reefs share haplotypes indicating historical genetic exchange between reefs. Genetic diversity is significantly different among reefs. Analysis of molecular variance suggests that most of the variability is observed within reefs than among reefs. $F_{ST}$ values were also significant for both species suggesting that there is fine scale population structure, as previous studies have indicated. Therefore, larval dispersal could be limited over long and even small distances restricting larval supply, which could influence recuperation between reefs. Populations that are considerably connected will not have a significant amount of restriction on gene flow, allowing the exchange of genes between populations. Presence of multiple mitochondrial haplotypes in a reef suggests that sexual reproduction may be contributing to the observed levels of genetic variation in Puerto Rico. The awareness of connectivity between large spatial and small spatial scales is important especially when dealing with a threatened species in order to set the degree of conservation and management strategies.

## 14-47

**Larval Retention And Population Connectivity in Two Coral-Reef Fishes**

**Mark CHRISTIE*[1]**, Christopher STALLINGS[2], Darren JOHNSON[1], Mark ALBINS[1], Jim BEETS[3], Brian TISSOT[4], Stephen THOMPSON[5], Mark HIXON[1]

[1]Department of Zoology, Oregon State University, Corvallis, OR, [2]Florida State University Coastal and Marine Laboratory, St. Teresa, FL, [3]Department of Marine Science, University of Hawaii at Hilo, Hilo, HI, [4]Washington State University, Vancouver, Vancouver, WA, [5]Cascadia Conservation Trust, Sisters, OR

Patterns of demographic connectivity among and retention within local populations of marine fish are poorly understood due to the difficulty of directly tracking pelagic larvae. To address this issue, we conducted population genetic analyses of two species of coral reef fishes. In 2005, bicolor damselfish (*Stegastes partitus*) were collected from 5 islands within the Exuma Sound, Bahamas, bordering an area of 100 by 175 km. Fifty adults and fifty recruits from each site were genotyped at 7 polymorphic microsatellite loci. In 2006, 500 adult and 500 recruit yellow tang (*Zebrasoma flavescens)* were collected from 9 sites distributed around the Big Island of Hawai'i and subsequently genotyped at 15 microsatellite loci. Overall levels of genetic differentiation (e.g., $F_{ST}$) were low for both systems, such that there were no significant patterns of isolation by distance when Euclidean or along-shore distances were employed. However, significant differences between populations of bicolor damselfish located on the eastern and western sides of the Exuma Sound were detected. This pattern suggests that there is limited dispersal across the eastern and western sides of the Exuma Sound and higher levels of connectivity among sites located north and south of one another, coinciding with prevailing northerly currents. Additionally, the high levels of polymorphism found within the genetic markers allowed for the detection of parent-offspring pairs in both species using novel statistical methods. The existence of parent-offspring pairs of fish in the same region provides unequivocal documentation of larval retention and self-recruitment. Given that the overall levels of genetic differentiation in both systems are low, parentage analysis in marine systems may prove to be a powerful tool for informing population-level genetic analyses as well as for providing insights into gene flow and dispersal at ecological timescales.

## 14-48

**Levels Of Population Genetic Structure Of Table Top Acropora Corals At Village, Island And Pacific-Wide Scales And The Value Of Local Marine Protected Areas.**

**Steve PALUMBI*[1]**, Jason LADNER[2]

[1]Department of Biology, Stanford University, Pacific Grove, CA, [2]Stanford University, Pacific Grove, CA

To estimate the movement of coral larvae among populations and to estimate the connectivity of coral populations at various geographic scales, we measured mtDNA variation in populations of the table top corals Acropora hyacinthus and A. cytherea from 20 populations from the Philippines to Palmyra atoll. The same thirteen mtDNA haplotypes are seen across the Pacific, indicating that long distance gene flow is possible. Between archipelagos (Philippines, Micronesia, Fiji, American Samoa, Palmyra), coral populations always showed strong genetic differentiation, suggesting such long distance gene flow is rare. Within archipelagos, coral populations on separate islands usually showed strong genetic differences. Populations on different reefs on the same islands showed strong differentiation in about half of the comparisons. The two coral species showed little mtDNA genetic differentiation from one another when sampled from the same reefs, but additional data from nuclear genes showed higher levels of genetic distinction. Results suggest that, over ecologically relevant time scales, coral larvae generally travel short distances along reef complexes on an island, and have low dispersal abilities among islands. Use of coral protected areas to house healthy stands of corals to reseed damaged reefs would require these coral gardens to be placed at short distances from one another.

**Quantifying The Spatiotemporal Trends in Marine Connectivity: Merging Seascape Genetics And Biophysical Modeling Within A Graph-Theoretic Framework**

**Eric TREML*[1]**, Patrick HALPIN[2]

[1]The School of Integrative Biology, University of Queensland, Brisbane, Australia, [2]Nicholas School of the Environment and Earth Sciences, Duke University, Durham, NC

Marine population connectivity, via larval dispersal, is critical for population persistence and is a key factor influencing how a species might cope with habitat loss and degradation due to local anthropogenic factors and future climate change. However, identifying the patterns in marine population connectivity poses one of the greatest challenges in marine ecology. Although several studies have discovered a general scale of population connectivity, little progress has been made in identifying the spatiotemporal structure of this connectivity. The objectives of this research were to 1) identify the probable dispersal routes and spatial population structure for several marine species throughout the Tropical Pacific, 2) test isolation-by-distance hypotheses of genetic differentiation for several marine species using traditional and graph-theoretic metrics, and 3) develop a framework for integrating these connectivity estimates into the regional marine conservation planning efforts. By exploiting techniques in population genetics, biophysical modeling, and graph theory, this work explored the hypothesis that the spatial genetic structure of marine populations is determined by the location and strength of biophysical connectivity. For this work, dispersal probabilities were derived for multiple species throughout the Tropical Pacific using a spatially-explicit biophysical modeling approach. These probabilities incorporated high-resolution hydrodynamics, pelagic larval duration, simplistic larval behavior, mortality, and settlement probability. The resultant spatiotemporal structure, including persistent dispersal corridors and barriers, were uncovered using clustering and connectivity algorithms from graph theory. The correlation between the biophysical connectivity predictions and the observed population genetic structure was tested within a Mantel regression framework. Finally, this research evaluated methods for integrating the spatial structure of marine population connectivity into regional conservation planning.

**Where Have All The Larvae Gone? Connectivity Within The Hawaiian Archipelago**

**Rob TOONEN*[1]**, Chris BIRD[1], Anuschka FAUCCI[2], Iliana BAUMS[3], Derek SKILLINGS[1], Brian BOWEN[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI, [2]Department of Biology, University of Hawaii, Kaneohe, HI, [3]Pennsylvania State University, University Park, PA

The Papahânaumokuâkea Marine National Monument, encompassing all of the Northwestern Hawaiian Islands, is the largest Marine Protected Area in the world (>350,000 km2), and studies of connectivity between reef habitats across this broad region are currently lacking. To this end, we are surveying a broad range of fish and invertebrate species to understand connectivity patterns throughout the Hawaiian Archipelago. We now have data for more than a dozen species, and using Monmonier's algorithm as implemented in BARRIER, we have determined areas of restricted gene flow across many species within the Hawaiian Archipelago. Comparing these concordant population genetic breaks with results of a layered Lagrangian model of larval dispersal developed by Kobayashi, we argue that connectivity among coral reef habitats is unlikely to match passive diffusion models based solely on fluid dynamics. We also show that variability among even closely-related species is the norm, and argue that such broad taxonomic surveys are necessary to draw robust conclusions about general patterns of connectivity that will guide management or conservation efforts. Our data show a number of concordant breaks that were previously unknown and suggest that population structure across the Hawaiian Archipelago does not fit predictions based on broad-scale oceanographic currents or advection-diffusion models of larval dispersal driven by geostrophic flow.

## 14-53

**Does Behavior Drive Population Genetic Structure in The Cardinalfish *ostorhynchus Doederleini*?**

**Gabriele GERLACH*[1,2]**, Jelle ATEMA[3], Michael KINGSFORD[4]

[1]University of Oldenburg, Oldenburg, Germany, [2]Marine Biological Laboratory, Woods Hole, [3]Boston University, Boston, MA, [4]James Cook University, Townsville, Australia

Many marine fish and invertebrates show a dual life history where settled adults produce dispersing larvae. While ocean currents are a major force in larval dispersal, recent studies and our own research show far greater retention than predicted by advection models. Based on microsatellite markers, we compared the genetic structure of adult cardinalfish, *Ostorhynchus doederleini,* at different reefs at the Capricorn Bunker Reef (Great Barrier Reef, Australia) at a geographical scale from 2 to 140 km over 5 different years. While the genetic structure in 2003 and 2005 showed statistically significant genetic differences between all reefs the populations seemed to have mixed up in 2006 probably driven by storm events. Surprisingly, significant differences were found again in 2007 and these populations were genetically similar to those from 2003 and 2005. Such a rapid reconstitution of the former genetic structure might be explained by behavioral mechanisms leading to different mortality of settling larvae. In order to test this, we collected adult *O. doederleini* at 4 different reefs and settling larvae from 2 reefs. In a random order we introduced a single larva into a tank containing 2 adults from either reef and observed the aggressive behavior towards this larva. The aggressive interaction of adults were significantly stronger when they originated from reefs different from those where larvae were collected; 7 out of 43 tested larvae were killed by foreign adults while no larvae were killed by adults from their own reef population. Our results indicate that differential aggressive behavior of adults might select against foreign, genetically dissimilar larvae and result in differential mortality of settling larvae from different origin.

## 14-54

**Connectivity And Gene Flow in The Dominant Caribbean Reef-Building Coral, *montastraea Annularis***

**Nicola FOSTER*[1]**, Claire PARIS[2], Iliana BAUMS[3], Mark VERMEIJ[4], Shannon GORE[5], Phillippe BUSH[6], Croy MCCOY[6], Sascha STEINER[7], Judith MENDES[8], Ernesto WEIL[9], Carolina BASTIDAS[10], Juan SANCHEZ[11], Claudia AGUDELO[11], Renata FERRARI[12], Patricia GONZALEZ[13], Michael MCCARTNEY[14], Reia GUPPY[15], Owen DAY[16], Jamie STEVENS[1], Peter MUMBY[1]

Understanding patterns of connectivity among populations of aquatic organisms is essential for the development of realistic, spatially explicit models of population dynamics and for determining the placement of effective marine reserve networks. Traditionally, two approaches have been used to infer levels of larval connectivity among aquatic (generally marine) populations. The first uses oceanographic models of currents to predict potential levels of dispersal among sites and the second uses population genetics to infer aspects of connectivity from observed gene flow. Rarely have both methods been applied simultaneously. Here, we analysed variation at six polymorphic microsatellite loci to assess gene flow among 30 populations of the reef-building coral, *Montastraea annularis,* across the Caribbean. This data was then compared to the results from a model of larval dispersal. Using geographical coordinates and genetic distance matrices, an area of reduced gene flow was identified between populations in the eastern and western Caribbean. A further area of lowered gene flow was detected between populations in Belize and those in Honduras and Nicaragua. The observed breaks in gene flow were consistent with the results of the larval dispersal model. Such information regarding the connectivity of populations should be incorporated into future management plans.

## 14-55

**The Importance Of Behavior On Self-Recruitment: A Modeling Approach**

**Jean-Olivier IRISSON*[1]**, Claire PARIS[2], Laurent CHERUBIN[2], Michel DE LARA[3], Serge PLANES[1]

[1]UMR 5244, Biologie et Ecologie Tropicale et Mediterranenne, Université de Perpignan, Perpignan, France, [2]RSMAS - University of Miami, Miami, FL, [3]CERMICS - Ecole des Ponts et Chaussées, Paris, France

All early models of the pelagic phase of coastal organisms made the simplifying assumption that larvae could be treated as passive particles in a flow. This was justified in the early nineties because of both computational limitations and lack of knowledge about the behavioral ecology of marine larvae. However, for more than a decade now, the swimming abilities of coral reef fishes, in particular, as well as their vertical distribution, have been investigated using several methods. All agree on the tremendous swimming speeds and endurance displayed by fish larvae, on their ability to influence their vertical and horizontal distributions and on the potential impact of these factors on connectivity. Yet, no numerical model integrates this kind of behavior more extensively than for the last instants of larval life.

We present two numerical models of the whole larval phase which both feature larval behavior. One explicitly integrates larval swimming in a mesoscale environment, around an island, and estimates the impact of swimming on self-recruitment. Because we still know very little about the orientation behavior of larvae in oceanic waters, we deduce their swimming decisions from an optimization method with realistic constraints and a biologically sensible objective (i.e. recruitment). Swimming along these optimal trajectories substantially enhances the possibility of self-recruitment compared to a passive scenario. The other model examines the influence of statistically modeled vertical distributions of larvae in the context of many inter-connected fish populations in the Caribbean. The distribution is shown to markedly modify the connectivity matrix. Overall, both models show that larval behavior has a great influence during the pelagic phase. Many studies show that larvae probably use their swimming abilities to reduce rather than to enhance dispersal, and our findings demonstrate that they can do so very efficiently.

## 14-56

**Long PLDs, Larval Behavior, and Connectivity in Spiny Lobster**

**Mark BUTLER*[1]**, Robert COWEN[2], Claire PARIS[2], Hirokazu MATSUDA[3], Jason GOLDSTEIN[4]

[1]Department of Biological Sciences, Old Dominion University, Norfolk, VA, [2]Rosenstiel School of Marine & Atmospheric Sciences, University of Miami, Miami, FL, [3]Fisheries Research Division, Mia Prefecture Fishery Research Center, Mia, Japan, [4]Department of Zoology, University of New Hamphire, Durham, NH

Among marine taxa, the pelagic larval duration (PLD) of spiny lobsters lies at the extreme. With PLDs ranging from 4 to 24 mos, spiny lobster larvae potentially disperse thousands of kilometers unless they possess behaviors or are captured in retentive environments that constrain their transport. Attempts to model connectivity in spiny lobsters have been hampered by a poor understanding of PLDs, ontogenetic changes in behavior, and by overly simplistic models. We have combined laboratory and field studies of larval behavior and distribution with advanced oceanographic modeling to predict dispersal of Caribbean Spiny Lobster (Panulirus argus). We successfully, and for the first time, reared P. argus from egg to juvenile and have determined its PLD (6 mos) along with stage-specific responses of larvae to light and chemical cues that may affect dispersal. Our experiments revealed distinct differences in response among larval stages consistent with observations of larval vertical distribution in nature, determined from monthly depth-stratified plankton tows. We also discovered that the strong-swimming postlarvae are attracted to coastal chemical cues up to 30 km from shore, particularly cues emanating from red macroalgae. These data have been used to parameterize a lobster Lagrangian particle model linked with the Hybrid Coordinate Ocean Model, similar to methods used for fishes. Simulations of P. argus larval dispersal suggest that with larval behavior: (a) the probability of successful recruitment increased by more than an order of magnitude, (b) median dispersal was ~200 km compared to ~ 800 km in simulations using passive dispersal, and (c) local patterns of retention and advection of larvae were idiosyncratic. We are now determining if model predictions of recruitment magnitude are consistent with empirical estimates of larval supply in the Caribbean.

## 14-57

**Combining Modeling And Empirical Approaches To Track Connectivity Across Temporal And Spatial Scales**

**Heather GALINDO*[1]**, Donald OLSON[2], Stephen PALUMBI[1]

[1]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [2]Rosenstiel School of Marine and Atmospheric Sciences, University of Miami, Miami, FL

Biological connections among marine populations via larval dispersal affect both demographic and evolutionary processes, yet describing the actual patterns of connectivity has remained a challenge. Recent integration of oceanographic and population genetic models has proven an effective tool for generating hypotheses about connectivity patterns we can then test with empirical datasets. We will present examples of this approach at various scales and discuss the advantages and limitations of this method in each case. First, we will describe how this approach has been successfully used to detect major geographic breaks in genetic structure for a free-spawning coral at the scale of the Caribbean basin. Next we will outline how this approach can be modified for application at both smaller spatial and temporal scales. Smaller spatial scales can potentially be achieved through finer geographic resolution of oceanographic models coupled with local collection of empirical data. In addition, better temporal resolution can be gained by matching recent oceanographic datasets with a cohort genetics approach where the genetic signatures of arriving larvae are tracked both within and between settlement seasons. The explicit integration of oceanography and population genetics gives us a powerful way to both generate and test hypotheses about patterns of marine connectivity. In addition, this modeling framework is extremely flexible and can be adapted to a variety of geographic regions and marine species.

## 14-58

**Realized Connectivity: Post-Settlement Survival Linked To Larval Source**

**Scott HAMILTON*[1]**, Robert WARNER[1]

[1]EEMB, UCSB, Santa Barbara, CA

Experiences during larval life may influence phenotypic traits, performance, and the probability of post-settlement survival. For a reef fish on an oceanic island, we used otolith (ear stone) elemental profiles of lead (Pb) to assign recent settlers to (1) a group that developed in nearshore waters elevated in Pb, or (2) those that developed in offshore waters depleted in Pb, potentially dispersing from upstream sources. Larval history influenced early life history traits: offshore developers initially grew slowly but compensated with fast growth upon entering nearshore waters, and metamorphosed in better condition with higher energy reserves. While 45% of settlers developed nearshore, only 23% of survivors after the first month displayed a nearshore otolith profile. Importantly, selective mortality was mediated by larval history, in that the post-settlement intensity of selection was much greater for fish that developed nearshore, potentially because only exceptionally strong offshore larvae survived to settle in the first place. Given the potential for asymmetrical post-settlement survival based on larval history, successful management may require knowledge of 'realized connectivity' on ecological scales, which is the proportion of individuals from different sources that survive to reproduce. Simply counting new settlers may be misleading.

## 14-59

**Fishy Chronology: Using The Chemical Chronology Of Otoliths To Investigate Shared Environments Among Reef Fish**

**Paul CHITTARO*[1]**, J. Derek HOGAN[2]

[1]NWFSC, NOAA, Seattle, WA, [2]GLIER, University of Windsor, Windsor, ON, Canada

Understanding the extent to which populations are connected is necessary for effective management. Although it is difficult to directly track fish during their pelagic larval stage, their otoliths have proven to be an invaluable tool since they record not only the time but also aspects of the environment in which the fish resides. The goal of this study is to provide information regarding the environments through which fish traveled, as well as the number of source populations that supply reef fish. To do this we use the otoliths of newly settled bicolor damselfish (Stegastes partitus), that were collected from Belize and Mexico in 2002 and 2003, and we determine the concentrations of elements (via laser ablation) along a transect from the otolith core to edge (representing their larval development and pelagic dispersal, until their settlement). We compare otolith chemical chronologies of individuals (at the site and regional scale, as well as at different time periods) in order to identify the extent to which individuals occupied similar environments during the course of their lives and the number of source populations from which they originated.

## 14-60

**Multiple Scales Of Larval Dispersal in A Coral Reef Fish**

**Mark TUPPER*[1]**

[1]The WorldFish Center, Penang, Malaysia

The management of coral reef fisheries is increasingly turning to an ecosystem-based approach involving networks of marine protected areas (MPAs). Central to this approach is knowledge of the connectivity between potential MPA sites. Recent studies have demonstrated high levels of retention in pomacentrids, which lay demersal eggs and have a short (9-21 days) planktonic phase. In this study, tetracycline was used to mass-mark goatfish (Parupeneus multifasciatus) embryos, taken by stripping ripe adults captured from a spawning aggregation site in Guam. This species has a planktonic phase of approximately 35 days. Marked fish were then recaptured by beach seining for newly settled juveniles and their otoliths examined for evidence of a tetracycline mark. A total of 11,000 otoliths were sampled, and 17 displayed a clear tetracycline mark. Goatfish settled over a range of dispersal scales. Some fish settled just tens to hundred of meters from the aggregation site. Most fish settled 1 km to 10s of km from the aggregation. Two fish settled about 100 km away at the downstream island of Rota in the Northern Marianas Islands (NMI). This has implications for transboundary management, as it is now evident that some of the NMI's reef fish stocks originate in Guam.

## 14-61

**Connectivity Of Coral Reef Fish Populations: Estimates From Transgenerational Mass-Marking Of Embryonic Otoliths Using Enriched Stable Isotopes**

**Simon THORROLD*[1]**, Geoffrey JONES[2], Serge PLANES[3]

[1]Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA, [2]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [3]Laboratoire Écosystèmes Aquatiques Tropicaux et Méditerranéens, CNRS-EPHE-UPVD, Université de Perpignan, Perpignan, France

Theoretical studies suggest that connectivity plays a fundamental role in the dynamics, community structure, genetic diversity, and resiliency to human exploitation of coral reef fishes. Modeling efforts have been hindered, however, by the paucity of empirical estimates of, and processes controlling, population connectivity in coral reef ecosystems. While progress has been made with older life stages, connectivity as a function of larval dispersal remains unresolved for most marine populations. We have developed a new technique, based on transgenerational marking of embryonic otoliths with enriched barium isotopes, to quantify population connectivity in coral reef fishes. Gravid females are injected with an enriched stable Ba isotope solution that generates a unique isotope signature in the otoliths of all larvae subsequently spawned by the individual for up to 3 months after the injection. Otoliths of juvenile fish are then scanned for the tag using laser ablation inductively coupled plasma mass spectrometry. Validated in benthic and pelagic spawning fishes, the first field study using transgenerational marking has recently being completed in Kimbe Bay, on the northern coast of New Britain, Papua New Guinea. Results suggest that natal homing of larvae may be a common life history strategy in reef fishes, and thus appropriate spatial scales for management and conservation of coral reefs are likely much smaller than previously realized.

## 15-1

**Hydrodynamic Modeling Of A Fringing Reef Embayment: Hanalei Bay, Hawaii**

**Ronald HOEKE*[1]**, Curt STORLAZZI[2]

[1]Joint Institute of Marine and Atmospheric Research(JIMAR), University of Hawaii/NOAA, Honolulu, HI, [2]Coastal and Marine Geology Program (CMG), USGS Pacific Science Cente, Santa Cruz, CA

Concerns about watershed management and its connection to nearshore ecological health at Hanalei Bay, Kauai, Hawaii, USA, have prompted a concerted interagency effort to gain better understanding of circulation, sedimentation, and water quality within the bay. Recent advances in computational hydrodynamics have resulted in the development of suites of software to model such coastal processes. These models have proven successful at a number of sandy, continental coastal sites, but few have been applied to insular coral reefs. Here we present the application of the Delft3D computational hydrodynamic software package to Hanalei Bay, a wave-dominated, microtidal coral reef embayment. Numerical output using model parameters traditionally used for sandy continental margins is contrasted with adaptations for microtidal, oceanic fringing reef environments and compared to in situ observations. Analyses reveal the importance of: (1) wave refraction/diffraction effects, (2) spatially varying bottom friction values that range over an order of magnitude, and (3) shortcomings of numerical solutions of these two processes when applied to fringing reef environments. The relative contribution of tides, winds, and waves to the bay's hydrodynamics are calculated for a range of conditions. The contribution of waves is several orders of magnitude greater than other physical processes in determining overall circulation and flushing of the bay, and dominates the near-bed shear stresses at most locations in the bay.

These findings show the precision of current computational hydrodynamics in high-energy, morphologically complex environments, such as Hanalei Bay, to be relatively poor at this time. Despite this, these techniques do provide valuable order-of-magnitude estimates of hydrodynamic processes and create a qualitative synoptic picture. These spatially explicit, fine scale estimates would be difficult with other methods.

## 15-2

**Modelling Larval Retention Around Reefs By Local Scale Circulation Features**

**Paulina CETINA-HEREDIA*[1]**, Sean CONNOLLY[2,3], Michael HERZFELD[4]

[1]School of Marine & Tropical Biology, James Cook University, Townsville, Australia, [2]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [3]ARC centre of Excellence, Coral Reef Studies, Townsville, Australia, [4]Division of Marine and Atmospheric Research, CSIRO, Hobart, Australia

Larval transport is mediated by circulation patterns. Low frequency, large scale currents can advect larvae for long distances, connecting populations over 100 km. However, local scale circulation features, such as lee reef eddies, can retain larvae near reefs and enhance self-recruitment. To accurately estimate larval dispersal, it is necessary to consider these local scale circulation processes. This study aims to approximate larval retention around reefs as a consequence of recirculation and stagnant flows provoked by the interaction of currents with the complex reef bathymetry that reefs normally display. To characterize eddies formed in the lee of reefs (different shapes) under different circulation regimes (low and/or high frequency dominant) and quantify the retention of larvae we simulate larval transport with a 3D finite difference hydrodynamic model (Sparse Ocean Hydrodynamic Code) in the Northern Section of the Great Barrier Reef. The life span, strength and size of eddies is quantified, using vorticity and the Okubo Weiss invariant as diagnostic variables. Finally, an approximation of larval retention as a function of reef geometry and prevalent circulation regime is attempted to provide a novel tractable approach accounting for local scale circulation features on larval dispersal in regional scale metapopulation models.

## 15-3

**Characterization Of Hydrodynamic And Biophysical Anomalies On The Florida Reef Tract**

**Lewis GRAMER*[1]**, Elizabeth JOHNS[2], James HENDEE[2]

[1]Cooperative Institute of Marine and Atmospheric Studies, University of Miami, Miami, FL, [2]Atlantic Oceanographic and Meteorological Laboratory, National Oceanographic and Atmospheric Administration, Miami, FL

NOAA's Integrated Coral Observing Network (ICON) project uses an artificial intelligence software system to implement heuristic models of coral reef ecosystem response to physical, chemical and biological conditions. These heuristic models use categorical, "if-then" rules to recognize and report patterns in environmental data integrated in near real-time from multiple external sources. One such model is described that detects and distinguishes episodic, biologically significant hydrodynamic processes acting upon coral reefs in the Florida Keys National Marine Sanctuary. Data are gathered from in situ sensors, satellites, and high-frequency radar at three shallow reef locations 100-200m inshore of the outer edge of the reef crest: Sombrero Reef in the Middle Keys, Molasses Reef in the Upper Keys, and Fowey Rocks off the Miami coast. The model recognizes apparent changes in biological production and circulation that may impact the reef ecosystem. Primary model criteria are in situ sea temperature variability occurring at near-tidal periodicities, wind velocity variability, and sea color-derived satellite chlorophyll a concentrations. Model forecasts are then verified using secondary data not utilized by the model as input, including satellite-derived regional sea surface temperature and ocean color imagery, radar-derived ocean surface currents, in situ salinity, and divers' visual reports. Three classes of nutrient delivery events are characterized by the model products: those forced respectively by wind-driven upwelling and downwelling; by net tidal transport of eutrophic water from Florida Bay; and by interaction of Florida Current frontal features with topography, which may be modulated by internal waves breaking on the reef slope. Multiple events of each type are characterized within a 23-month period in 2006-2007.

## 15-4

**Spatial And Temporal Variability in Velocity Shear Over Fringing Coral Reefs And Its Implications On Water Column Structure And Particulate Flux**

**Curt STORLAZZI*[1]**

[1]Coastal and Marine Geology Team, US Geological Survey, Santa Cruz, CA

Long-term hydrodynamic data from a number of bottom-mounted instruments and spatially-extensive, but temporally-limited, hydrographic surveys have been collected to better understand coastal dynamics on and among fringing coral reefs in Hawaii, USA. These high-resolution data (waves, currents, temperature, salinity, and turbidity) suggest that wave- and wind-driven flows appear to be the primary control on flow over shallow portions of the reefs while tidal and subtidal currents dominate flow over the deeper, outer portions of the reefs and insular shelf. Near-surface current directions over the fore reef vary on average by more than 40º from those near the seafloor, and the orientation of the currents over the reef flat differed on average by more than 65º from those observed over the fore reef. This shear occurred over relatively short vertical (O~meters) and cross-shore (O~100's of meters) scales, causing material distributed throughout the water column, including the suspended particles causing turbidity (e.g. sediment or larvae) and/or dissolved nutrients and contaminants, to be transported in different directions under constant oceanographic and meteorologic forcing, depending on its initial location. When the direction of the flows over the fore reef and the reef flat are counter one another, which is quite common, they cause a zone of cross-shore horizontal shear and often form a front, dividing turbid, lower-salinity water inshore from clear, higher-salinity water offshore. It is not clear whether these zones of high shear and fronts are the cause or the result of the location of the fore reef, but these features appear to be correlated alongshore over relatively large horizontal distances (O~kilometers). When two flows converge or when a single flow is bathymetrically steered, eddies can be generated that, in the absence of large ocean surface waves, tend to accumulate suspended particulate material.

## 15-5

**Experimental Characterization Of The Oceanic Water Fluxes in A Macro-Tidal Intermittently Open Lagoon Bounded By Semi-Submerged Coral Reef**

**Cristele CHEVALIER*[1]**, Jean-Luc DEVENON[2], Gilles ROUGIER[3]

[1]Cyroco, IRD, Marseille, cedex 09, France, Metropolitan, [2]Laboratoire d'Océanologie et de Biogéochimie, Université de la Méditerranée, Marseille, cedex 09, France, [3]Laboratoire d'Oceanographie et Biogeochimie, Université de la Méditerranée, Marseille cedex 9, France, Metropolitan

In the macro-tidal lagoons, of the Indian Ocean, coral reefs can be momentarily submerged by water at high tide and partially emerged at low tide. This process contributes to lagoon and open sea exchanges, although the reefs are often considered as impervious and the water fluxes assumed to occur only through the passes. We study the influence of this reef hydrodynamic control, by developing an original experimental approach combining small ship side mounted ADCP measurement following transects thru passes and near reefs, with more classical high resolution ADCP moorings. The aim is to gain insight in spatial variability of fluxes at a reasonable cost that moorings alone cannot be able to provide. This new strategy of measurement is exemplified at the occasion of an experimental campaign on the Mayotte lagoon and the results of this experiment are presented. Particularly, it is shown how the mounted ADCP data are validated. A specific tidal analysis methodology is then proposed to get the spatial variability of the tidal component of the current thru the passes and above the reef. This variability is identified by least square fitting of spatial distribution of the tidal amplitudes owing the availability of repeated transects associated with fixed point temporal sequences of current issued from moored ADCP currentmeters. This method has been validated against a priori known theoretical spatial distribution as well as in-situ already available data. All these analysis allow us to estimate the tidal induced fluxes thru the passes and above the reefs and to evaluate their respective part in water lagoon renewal.

## 15-6

**Morpho-Space Exploration Of Simulated Coral Morphologies And Three-Dimensional Images Of Scleractinian Corals**

**Maxim FILATOV*[1]**, Chris KRUSZYÑSKI[2], Jaap KAANDORP[1], Robert VAN LIERE[2], Mark VERMEIJ[3], Rolf BAK[4]

[1]Section Computational Science, University of Amsterdam, Amsterdam, Netherlands, [2]Center for Mathematics and Computer Science, Amsterdam, Netherlands, [3]University of Hawaii at Manoa, Maui fieldstation, Lahaina, HI, [4]Netherlands Institute of Sea Research (Nioz), Den Burg, Nepal

We developed a method for the quantitative analysis of three-dimensional images of complex-shaped scleractinian corals obtained with X-ray Computed Tomography scanning techniques. The analysis is based on a number of morphometric quantities, i.e. branching rate, branch thickness, branch spacing etc. We use this method for the quantitative comparison of morphological variation in closely related species in the Caribbean coral genus *Madracis*: *M. decactis, M. carmabi, M. Formosa* and *M. mirabilis*. We compare the *Madracis* morphologies with a range of simulated morphologies. In the simulations the morphologies were obtained in an accretive growth process where layers of materials are deposited on top of previous ones. The local thickness of new layers is controlled by the simulated physical environment (local availability of light and nutrient) and the amount of translocation of nutrient over the surface of the object. With the simulation model, varying a model parameter representing the amount of local translocation of nutrient over the surface of the object, we simulate a range of morphologies where branching forms gradually transform into more spherical shapes. By varying a parameter controlling the contribution of local light intensity we can change the overall branching pattern. Some of the simulated morphologies are almost indistinguishable from three-dimensional images of actual *M. mirabilis* and *M. decactis* colonies; some three-dimensional images (*M. formosa*) cannot be completely captured by our model. Our aim now is to find missing model parameters and to detect which actual morphologies can be predicted by our model using a systematic comparison of actual and simulated morpho-spaces.

## 15-7

**Use Of The Coral-Sel Technique in Water Flow Research**

**Carolyn MARGOLIN*[1]**

[1]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

When flow experiments are carried out in open flow-through systems, several non-targeted variables also change with changing flow rate. These may include temperature, oxygen level, and food availability. In order to keep these factors constant across flow treatments, it is necessary to place all corals into a single water system while still exposing them all to different water flow rates. In order to accomplish this, a rotating "coral-sel" was constructed in an outdoor tank at the University of Miami's Aplysia Resource Center on Virginia Key. The coral-sel allows corals to be placed at three set distances from the center of rotation of the apparatus. This allows the corals to experience one of three set water flow rates while simultaneously being immersed in water with identical characteristics other than flow rate. These rates can be adjusted using a gear system on the external component of the coral-sel. Clod card techniques were used in order to test differences in flow rates at each of the specified distances prior to attachment of coral to each site. Fragments of *Montastraea faveolata* were attached to plates at each of the tested positions. Each fragment was monitored for survival, change in weight, change in surface area, and zooxanthellar activity. These data were used to determine the effects of water flow on the coral holobiont in terms of growth, calcification, and zooxanthellar activity. Statistical analysis showed that changes in fragment surface area were inversely related to water flow speed. However, the greatest increases in weight occurred at mid-flow rates (15.7 cm/s). Area and weight data were used to determine calcification rates. Apparent calcification rates were greatest for fragments exposed to mid-speed flow rates (15.7cm/s).

## 15-8

**Importance of the infragravity band in the wave energy budget of a fringing reef**

**Anne-Christine PEQUIGNET*[1]**

[1]Oceanography, University of Hawaii, Honolulu, HI

In an effort to understand and quantify wave energy at the shoreline of fringing reefs, a series of pressure sensors and current meters were deployed across fringing reefs on Guam and Oahu, Hawaii as part of the PILOT (Pacific Island Land-Ocean Typhoon) experiment. Spectral transformation of waves from the forereef to the shoreline is analyzed in terms of energy flux along the cross shore transects. Reflection, dissipation and non linear interactions are estimated during various offshore wave conditions and phases of the tide.

The wave transformation across the reef is strongly dependent on wave frequency and the wave energy spectrum on the reef flat is dominated by infragravity waves. This results from the combined effects of strong dissipation of sea and swell through breaking and friction, weaker dissipation of infragravity energy through friction and the generation of infragravity energy as the waves cross the forereef and the reef crest. Infragravity waves are reflected both at the forereef and the shoreline, whereas sea and swell waves are not reflected despite the steep reef face.

The wave energy in the sea and swell band at the shoreline of a fringing reef depends predominantly on the reef platform water depth, whereas the infragravity energy appears to depend more strongly on the offshore wave energy.

Although general trends in wave transformation may be observed on fringing reefs of different bathymetries, the presence of morphological features (such as porous reef face, longshore variation due to spurs and groove...) significantly affects wave transformation and makes each reef a unique breakwater system.

## 15-9

**Nonlinear Wave Transformation Over Shallow Fringing Reefs**

Okey NWOGU[1], **Zeki DEMIRBILEK*[2]**, Mark MERRIFIELD[3]

[1]University of Michigan, Ann Arbor, MI, [2]U.S. Army Engineer R & D Center, Vicksburg, MS, [3]Univeristy of Hawaii, Honolulu, HI

A set of field experiments were conducted to investigate spectral wave transformation over shallow fringing reefs due to nonlinear wave-wave interaction and wave energy dissipation. The experiments were conducted at a site located along the southeast coast of the Island of Guam. A cross-shore transect of four Aquadopp current profilers and three pressure transducers were used to measure the waves and currents over the reef. The offshore wave conditions were recorded with a directional wave buoy.

Numerical simulations were conducted with a nonlinear Boussinesq wave model. The effect of wave breaking is parameterized in the Boussinesq equations with an eddy viscosity based turbulent shear stress while the effect of bottom friction is parameterized with a quadratic drag law shear stress term. The Boussinesq model was initialized at the offshore boundary with buoy data. Comparisons of the measured and predicted spectral densities over the reef flat showed that the quadratic drag law parameterization for bottom friction could not adequately reproduce wave energy dissipation over rough coral surfaces. Although the bottom friction factor could be tuned to match the overall wave height, it dissipates wave energy across a broad range of frequencies including the infragravity band, in contrast to the field data that showed a preferential dissipation of the wave energy in the incident wind-wave frequency band.

One hypothesis for wave energy dissipation over shallow rough surfaces with the characteristic roughness scales of the order of 10 percent of the water depth is that the turbulent boundary layer is no longer restricted to a thin layer near the bottom but rather permeates the entire water column. This would lead to an eddy-viscosity type formulation for bottom friction as opposed to the quadratic shear stress formulation. Preliminary tests conducted with an eddy-viscosity based formulation of frictional dissipation matched the measured data much better.

## 15-11

**Hydrodynamics And Circulation On Monsoonally Influenced Reef Platforms: Interactions Between Processes And Morphology**

**Paul KENCH*[1]**

[1]Geography, Geology and Environmental Science, The University of Auckland, Auckland, New Zealand

Improved understanding of hydrodynamics and controls on circulation processes in coral reefs systems has been highlighted in numerous studies due to the importance of such processes on ecological and biological functions. In contrast, few studies have considered the importance of reef platform hydrodynamics on geomorphic processes (e.g. sediment transport and island building) or interactions between reef morphology (other than the reef rim) and hydrodynamic processes. The hydrodynamics of reef platforms are controlled not only by the deep water to reef flat transition but subsequent transformations of energy on reef surfaces. This study examines the wave and current processes on reef platforms in the Maldives. Specific aims are to examine the influence of predictable shifts in monsoons on reef platform hydrodynamics and to evaluate morphological feedbacks on reef circulation. Detailed wave and current records were obtained from three small reef platforms in the central Maldives. The reef platforms vary in shape, have similar size, and all have vegetated reef islands that occupy 21 to 45% of reef area. Instruments were deployed at six locations on each reef to capture spatial variations in wave and current processes and experiments were repeated under differing monsoon conditions. Results show that the magnitude of wave energy and wave direction is modulated by variations in monsoon conditions (from the west and northeast). The presence of reef islands and moats exerts a major control on circulation patterns. However, circulation changed markedly between different monsoon phases. The degree of alteration in circulation is related to reef shape, reflecting the sensitivity of different shaped reefs to changes in wave approach and wave transformation. Consequently, circulation is shown to reverse between monsoon phases on circular reef platforms but exhibited more subdued changes on elongate reefs.

## 15-12

**Aster Bathymetry in Computational Fluid Dynamic Simulation Of Rongelap Atoll Hydrodynamics, Marshall Islands**

**Eric PETERSON*[1]**

[1]Institute for Sustainability and Innovation, Victoria University, Melbourne MC VIC, Australia

ASTER green, red and near infra-red (NIR) imagery with a resultion on the order of handheld GPS echo soundings was calibrated to model bathymetry of Rongelap Atoll to a depth of 10 meters. Beyond that depth nautical charts and echo soundings were used to model bathymetry. The combined result is illustrated in Figure 1.

Figure 1 Bathymetric model of Rongelap

Shape files of depth contours were converted to ordered ASCII X,Y,Z vertex files input into the finite element meshing program GAMBIT (FDI and ANSYS). These data were then ordered in volumetric and substrate surface elements of coral reefs and input to the FLUENT computational fluid dynamics (CFD) package. Bluelink (Australian Bureau of Meteorology and CSIRO) was used to apply boundary conditions, and results are hydrodynamic charts of the atoll. The resulting map of substrate shear stress at Rongelap is displayed in Figure 2.

Figure 2 Benthic shear stress of Rongelap Atoll

## 15-13

**Finite-element model of the Great Barrier Reef circulation**

**Jonathan LAMBRECHTS*[1]**, Eric DELEERSNIJDER[1], Vincent LEGAT[1], Emmanuel HANERT[2], Eric WOLANSKI[3]

[1]Institute of Mechanics Materials and Civil Engineering, Université catholique de Louvain, Louvain-la-Neuve, Belgium, [2]Department of Meteorology, University of Reading, Reading, United Kingdom, [3]James Cook University, Townsville, Australia

An unstructured-mesh, finite element, depth-integrated model of the hydrodynamics of the whole Great Barrier Barrier Reef (GBR), Australia, has been developed and implemented on a parallel computer. Far away from reefs, islands and important bathymetric features, the mesh size may be as large as a few kilometres,whereas, in the vicinity of reefs and islands, the grid is drastically refined, leading to meshes that can be 100 metres in size. This enables our model to simulate motions characterized by a wide range of space and time scales. Large scale currents, i.e. the tides, the wind-induced circulation and the bifurcation of the East Australian Current, are reproduced with an accuracy that is comparable to that achieved by today's large-scale models of the GBR. The model is also successful at representing small-scale processes, such as tidal jets, their instabilities, as well as the eddies developing in the wake of islands and headlands. Both large and small scales have been validated.

A study of multi-scale reef connectivity has been undertaken.

Biological applications based on this hydrodynamical model have been undertaken such as a model of the threat from lethal jellyfish at the GBR coast and a study of multi-scale reef-connectivity.

## 15-14

**Momentum Balances Across A Wave-Dominated Coral Reef**

**James HENCH*[1]**, Hunter LENIHAN[2], Stephen MONISMITH[1]

[1]Environmental Fluid Mechanics Laboratory, Stanford University, Stanford, CA, [2]University of California, Santa Barbara, Santa Barbara, CA

For many coral reefs, circulation is dominated by waves breaking over the reef crest that drive a strong circulation over back reef habitats. Unlike classical work on beaches, where the primary momentum balance is between radiation stress gradients and set-up of the free surface, flows over coral reefs typically have mean flows into a lagoon, and thus friction can also be important in the momentum balance. Unfortunately friction on coral reefs is difficult to estimate a priori due to the remarkably high rugosity. Here we studied a nearly tideless system in Moorea, French Polynesia to isolate the effect of wave forcing on coral reef circulation. An array of 7 stations spanning the forereef, reefcrest and backreef areas, were each instrumented with pressure sensors and velocity profilers. The resulting data were used to estimate the contribution of each term in the cross-reef momentum balance, as well as corresponding bottom friction coefficients. Initial results show that the momentum balance varies markedly with distance from reefcrest and transitions from a radiation stress and set-up balance, to a friction and set-up balance.

## 15-15

**Defining Drag Coefficients For Coral Reefs**

**Johanna ROSMAN*[1]**, James HENCH[1]

[1]Environmental Fluid Mechanics Laboratory, Stanford University, Stanford, CA

Coral reefs form a very rough bottom boundary that is porous to water flow. Drag due to a coral reef is typically modeled using a simple quadratic drag law with a bulk drag coefficient; however, several different definitions have been used in the literature and a wide range of values have been reported. We have developed a formal framework for estimating drag coefficients for flow over coral reefs in the absence of surface waves. We consider three different definitions, in which the above-canopy, within canopy and depth-average velocity are used for the drag parameterization. Using a simple two layer model we derive expressions for the drag coefficient in terms of morphological and flow parameters. We show that drag coefficients can vary by more than an order of magnitude for the same geometry and flow, depending on the definition used.

## 15-16

**Roughness and the Effects of its Spatial Variability on Coral Reefs**

**Clifford HEARN*[1]**

[1]ETI Professionals at USGS, St Petersburg, FL

Topographic and bathymetric complexity are key controls on the hydrodynamics of coral reefs. They exist on all spatial scales from microns to kilometers on reefs and within hydrodynamic studies are all treated as part of the spatial spectrum of the generalized concept of 'roughness'. Coral reef hydrodynamics treats roughness in a variety of ways at different spatial scales. Roughness has a major influence on the way that currents flow over reefs and the processes by which energy is transported and dissipated. A fundamental property of roughness is that the average roughness below any specified spatial scale is itself spatially variable on that scale. This means that a hydrodynamic model of a reef will necessarily include spatially varying smaller-scale roughness. This paper considers one feature of this phenomenon which is the change in roughness length, or frictional drag coefficient, encountered between distinct topographic zones of a reef such as the fore-reef, reef-flat and back-reef. The analysis is based on frictional Reynolds numbers for the individual zones of the reef which are combined into a 'reef Reynolds number' which is a measure the relative magnitudes of large scale and small scale roughness. The paper examines the implications of the larger scale variability of roughness on the connectivity between the zones of a reef as provided by the transport of materials and turbulence.

## 16-1

**Sampling State And Process Variables On Coral Reefs**

**Roger GREEN*[1]**, Brian MCARDLE[2], Robert VAN WOESIK[3]

[1]Department of Biology, The University of Western Ontario, London, ON, Canada, [2]Department of Statistics, The University of Auckland, Auckland, New Zealand, [3]Biological Sciences, Florida Institute of Technology, Melbourne, FL

Contemporary coral reefs are forced to survive through and recover from disturbances at a variety of spatial and temporal scales. Understanding disturbances in context of background processes will lead to accurate predictive models of population trajectories over time. Most reef studies and monitoring programs examine the state (variables) of reefs, by assessing the coverage of major benthic organisms; few studies examine the key ecological processes that drive the state variables. Here we outline a sampling strategy that captures both state and process variables, at a spatial scale of 10s of kilometers. Specifically we are interested in 1) examining spatial and temporal patterns in coral population size-frequency distributions, 2) determining vital processes, including rates of recruitment and mortality, 3) examining relationships between processes and state variables and whether size distributions reflect population performance, and 4) assessing which state and process variables relate to environmental forcing functions. Our effective sampling units are randomly selected 75 x 25 m stations, spaced approximately 250-500 m apart, representing a 103 m spatial scale. Stations are nested within sites, spaced approximately 2 km apart, representing a 104 m spatial scale. Three randomly selected 16 m2 quadrats placed in each station, and marked for relocation, are used to assess processes across time; while random belt-transects, re-randomized at each sampling event, are used to sample state variables. Both quadrats and belt-transects are effectively sub-samples from which we derive estimates of means for each station at each sampling event. This nested sampling strategy is allowing us to examine population performance, critical stages in demographic performance and vital rates across locations that can be easily applied to Marine Protected Areas to examine whether and how protecting areas may influence major state and process variables.

## 16-2

**Synoptic Ecological Tools For Coral Reef Science**

**Bruce HATCHER*[1]**, Jinyu SHENG[2], Serge ANDREFOUET[3]

[1]Bras d'Or Institute for Ecosystem Research, Cape Breton University, Sydney, NS, Canada, [2]Dalhousie University, Halifax, NS, Canada, [3]Institut de Recherche pour le Développement, Nouméa, New Caledonia

Coral reefs are well-suited to applications of spatial ecology because of their clear geomorphologies, sessile life forms and water-borne vectors of interaction. The challenges of portraying the pattern and pace of change in coral reef ecosystems are increasingly addressed through emerging technology and theory that permit the depiction of the spatial distribution of ecological units at relevant scales of reef existance, and the prediction of interaction parameters across ecological time-space. Acquisition and interpretation of remotely sensed data and imagery provides the maps, and hybrid numerical models of physical advection and bio-physical dispersion provide the movies that combine to support hypothesis testing. The addition of numerical optimization models to the domain supports scenario-based adaptive management. The devil is in the details of scaling and interfacing the pixelated technologies and reconciling the physical versus biological variabilities. Ecological connectivity among coral reef ecosystems is the current test bed the integration of synoptic ecological tools. Through our collaborative experience, we have learned a set of lessons and techniques, which are offered for your consideration.

## 16-3

**Multi-Scale Approach For Assessing The Effects Of Land-Based Contamination On The Southeast Fringing Reef Of Molokai**

**Laetitia HEDOUIN*[1]**, Bernardo VARGAS ANGEL[2], Amanda REICHELT-BRUSHETT[3], Xavier POCHON[1], Ruth D. GATES[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI, [2]Coral Reef Ecosystem Division, NOAA Fisheries, Pacific Islands Fisheries Science Center, Honolulu, HI, [3]School of Environmental Science and Management, Southern Cross University, Lismore, Australia

On a global scale, there is now deep concern as to whether coral reefs will survive shifts in the marine environment associated with global climate change; however, on a local scale, many of the reefs in Hawaii are most imminently and seriously threatened by coastal development and changes in land use. Few tools are currently available for assessing the impacts of land-based contamination on the health of reef corals. The first step in developing such tools is to identify biological traits in corals that are responsive to land-based contamination. The current project focuses on corals sampled on the SE coast of Molokai that are threatened by sediment stress e.g. high to low sediment deposition rates. Ecological, physiological and histological characteristics have been measured in corals sampled at 8 stations along the fringing reef of Molokai that cross a gradient of sediment stress. Data have been statistically analyzed to identify biological traits that most tightly correlated with the stress exposure regimes measured at each sampling station. Protein concentration, chlorophyll a concentration, and zooxanthellae densities decrease with increasing sediment loads suggesting that these physiological measures are useful indicators of sediment exposure in corals. Ecological, physiological and histological data represent different temporal windows of the biological response of corals to sediment stress. We are currently exploring whether the integration of these data streams collectively provide greater insight into the biological effects of sediment stress on coral health than each of them alone.

## 16-4

**Using Cellular Diagnostics To Link Land-Based Sources Of Pollution With Coral Reef Degradation in South Florida**

**Phillip DUSTAN*[1]**, John FAUTH[2], Kenneth BANKS[3], Eric PANTE[4], Bernardo VARGAS-ANGEL[5], Craig DOWNS[6]

[1]Department of Biology, College of Charleston, Charleston, SC, [2]Department of Biology, University of Central Florida, Orlando, FL, [3]Department of Environmental Protection, Broward County, Fort Lauderdale, FL, [4]Department of Biology, University of Louisana at Larayette, Lafayette, LA, [5]Coral Reef Ecosystem Division, NOAA Pacific Island Fisheries Sciences Center, Honolulu, HI, [6]Cellular Diagnostics and Proteomics, Haereticus Environmental Laboratory, Amherst, VA

This project is a first step in identifying the chain of causality between land-based pollutants, responses of individual reef-building corals, and health of coral reef communities in the South Florida watershed. We tested the feasibility of using cellular diagnostics to link land-based sources at four paired inshore and offshore stations off Broward Country, FL (control, sewage wastewater outfall, an inlet mouth and a wastewater outfall adjacent to an inlet). Live coral coverage was <4% at all sites and cluster analysis grouped all inshore sites (except one) together based on having the least bare substrate and co-occurrence of the cyanophyte, Lyngbya spp.

Cellular diagnostics performed on tissue samples of a scleractinain coral (Porites astreoides) revealed that corals at all sites were stressed compared to colonies from a more pristine site in the Bahamas. Offshore corals consistently had higher accumulations of stress markers than inshore colonies. Stress responses of corals from the wastewater outfall and additional samples collected within the Florida Keys National Marine Sanctuary were consistent with sewage exposure, while responses of offshore colonies were consistent with xenobiotic detoxification. Accumulations of biomarkers of xenobiotic response and decreased protein turnover were associated with decreased rates of coral regeneration. In addition, lesion regeneration rates were significantly greater than zero only at three inshore sites and the offshore control site. Results of our study confirm the assessment of The World Research Institutes's Reefs at Risk Program; coastal development and treated wastewater discharge are chronic sources of stress for coral reefs along Florida's extensive reef tract.

## 16-5

**Development and Application of Variable Fluorescence Techniques and Instrumentation for Monitoring and Assessing Coral Reefs**

**Maxim GORBUNOV*[1]**, Dan TCHERNOV[2], Liti HARAMATY[3], Yael HELMAN[3], Frank NATALE[3], Sophia JOHNSON[3], Paul FALKOWSKI[3]

[1]Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, [2]The Interuniversity Institute of Eilat, The Hebrew University of Jerusalem, Eilat, Israel, [3]Rutgers University, New Brunswick, NJ

The development of advanced technologies for environmental monitoring of coral reef ecosystems requires an understanding of how different environmental factors affect the key elements of the ecosystems and the selection of specific monitoring protocols that are most appropriate for the identification and quantification of particular stressors. Documenting the environmental state of reef communities is critical to developing remediation strategies that can both reduce anthropogenic insult and distinguish between common natural factors and anthropogenic stressors. Bio-optical methods are particularly useful for rapid and non-destructive assessment of the viability of coral reef organisms. Here we present a methodology and instrumentation called Fluorescence Induction and Relaxation (FIRe) System for assessment of photosynthetic and physiological status of coral. We have designed and developed bench-top, diver-operated and moorable instruments. The variable fluorescence technique relies on the relationship between chlorophyll fluorescence yield and the efficiency of photosynthetic processes and provides a comprehensive suite of photosynthetic and physiological parameters, including the quantum yields of photochemistry in Photosystem II (PSII), the functional absorption cross section of PSII, the rates of photosynthetic electron transport on the acceptor side of PSII and between PSII and PSI, coefficients of photochemical and non-photochemical quenching. In combination with conventional biochemical and molecular biological methods, the FIRe technique was employed to study the impact of common natural stresses (episodes of elevated temperature and excess irradiance), as well as selected anthropogenic factors (heavy metal contamination and pollution) on coral. The analysis revealed that different stressors lead to specific damage to the coral symbioses and are characterized by unique FIRe fluorescence signatures that can be can be used for quantitative assessment of coral health and selective identification of the stressors.

## 16-6

**Potential Application Of Pam Fluorometry in Reactive Coral Health Monitoring Programs: A Pilot Study**

**Jeremy SOFONIA*[1]**

[1]Marine and Coastal Science, Sinclair Knight Merz Pty. Ltd., Perth, Australia

Regulatory authorities in Australia increasingly require proponents of commercial development to detect, and respond to, changes in water quality and coral heath prior to the onset of mortality. The use of pulse-amplitude modulated (PAM) fluorometry as an instrument to detect sub-lethal change within photosynthetic organisms is well documented, however, the use of this tool on scleractinian corals *in-situ* is challenging as ambient environmental conditions directly affect the measured result, monitoring is often restricted to daylight hours and dark adaptation of individual colonies logistically difficult. The use of PAM in reactive coral health monitoring programs is currently limited as sampling is implemented on a set schedule, under a wide range of ambient conditions, and often comprising large coral populations over a wide geographic area. Here two photosynthetic corals, *Turbinaria mesenterina* and *Porites lobata*, are observed *in-situ* across a natural range of light (0 – 320 µmol m-2 s-1) and temperature (18.9 – 30.0 °C). Three fluorescence parameters were estimated including effective quantum yield of photosystem II (ΦpsII), slope of the initial linear range, alpha (α), of the photosynthesis-irradiance (P-I) curve and the maximum relative electron transport rate (rETRmax). Of these, obtaining ΦpsII was comparitively faster and better correlated to changes in ambient light (PARamb). Mean ΦpsII was significantly higher in *T. mesenterina* than *P. lobata* in both regimes, however, responses to PARamb were virtually identical (*T. mesenterina*: y= -0.0011x + 0.668, R2= 0.59; *P. lobata*: y= -0.0009x + 0.621, R2= 0.67) and temperature had no significant effect. The use of α and rETRmax from so-called rapid light curves (RCL) were comparatively non-informative and logistically restrictive. It is hypothesised that specific correlations between ΦpsII and PARamb, if established prior to development, may be used as a benchmark to compare the photosynthetic condition of coral symbiotes and potentially provide a rapid assessment of sub-lethal change.

## 16-7

**A Comparison Of Thermal History And *fv/fm* in Inner Lagoon And Outer Barrier Reef *montastrea Faveolata.***

**Karl CASTILLO*[1]**

[1]Marine Science Program, University Of South Carolina, Columbia, SC

Pulse amplitude modulated (PAM) fluorometry has been suggested as a tool to complement monitoring efforts for predicting environmental stress in corals. However, documented changes in maximum quantum yields ($F_v/F_m$) of corals during non-bleaching periods have been limited. Here, thermal exposures of inner lagoon and outer barrier reef *Montastrea faveolata* were examined. The hypothesis that inferred differences in thermal histories would be reflected in $F_v/F_m$ values was tested. Ambient seawater temperatures adjacent to corals at 1, 3, 6, 9 and 15 m depth were measured every 10 min from October 2006 to June 2007 in the inner and outer reefs of southern Belize. Maximum and mean diel seawater temperature and number days above the local bleaching threshold of 29.8 °C were not significantly different between locations and across each depth. However, minimum and standard error of the mean diel seawater were significantly different between locations and across several depths. Since aspects of seawater temperature varied across locations and depths, the photophysiology of these corals was assessed to test for an association between physical and biotic factors. In June 2007, $F_v/F_m$ for *M. faveolata* were measured *in situ* across the same gradient and compared between both locations. $F_v/F_m$ correlated positively with depth in both locations, and was significantly higher in the inner reefs. To test for a cause-and-effect relationship between temperature and photophysiology, samples of *M. faveolata* were collected and exposed to controlled temperature treatments. Exposure to elevated temperature caused $F_v/F_m$ to be depressed to a greater extent in corals from the outer compared to inner reef, but this effect was not constant at all depths. These results suggest that thermal stress though important may not be the only factor influencing the observed difference in $F_v/F_m$ values for *M. faveolata* from the inner lagoon and outer barrier reefs at this location.

## 16-8

**Shifting Bleaching Thresholds: Acclimatization Or A Flawed Model?**

**Ray BERKELMANS*[1]**

[1]Australian Institute of Marine Science, Townsville, Australia

Time-integrated bleaching thresholds are one of a suite of locally specific bleaching indices that have been developed based on *in situ* measured temperature data. In recent years these have been adopted as an early warning system on the Great Barrier Reef (GBR), augmented by satellite-based early warning systems such as 'HotSpots' and 'ReefTemp'. The original bleaching thresholds were developed after the 1998 bleaching event, but how well have they performed since then, especially in predicting the 2002 GBR bleaching event? This study reviews the efficacy and accuracy of the time-integrated bleaching thresholds using statistical and empirical techniques. The results show that time-integrated bleaching thresholds accurately predicted bleaching (and non-bleaching) at most reefs in 2002. However, a number of reefs in the central GBR exceeded bleaching thresholds in 2004 and 2005 without bleaching. These anomalies are not explained by selective mortality or other meteorological factors, including global radiation and UV. They are also not explained by pre-season acclimatization. Long-term thermal acclimatization remains the most likely explanation. Mortality thresholds based on 50% mortality of thermally sensitive and locally abundant coral taxa were derived for six reefs that suffered high mortality during past bleaching events. An analysis of these curves in relation to their bleaching thresholds indicates that at most of these sites thermally sensitive taxa die <1 °C above their bleaching threshold and many <0.5 °C above their bleaching threshold. These results highlight the fine line that exists between recovery and death of thermally-sensitive corals following bleaching.

## 16-9

**Integrating Satellite and In Situ Light, Wind and Temperature Data for Ecological Forecasting of Coral Bleaching at Four Sites in the Caribbean**

James HENDEE[1], Tao ZHENG[2], Lew GRAMER[3], **Erik STABENAU*[4]**, Derek MANZELLO[5], Shunlin LIANG[6]

[1]Atlantic Oceanographic and Meteorological Laboratory, National Oceanic and Atmospheric Administration, Miami, FL, [2]Department of Geography, Central Michigan University, Mount Pleasant, MI, [3]Cooperative Institute for Marine and Atmospheric Studies, University of Miami, Miami, FL, [4]South Florida Natural Resources Center, Everglades National Park, Homestead, FL, [5]Rosenstiel School for Marine and Atmospheric Sciences, University of Miami, Miami, FL, [6]Department of Geography, University of Maryland, College Park, MD

Satellite and in situ irradiance instruments provide different perspectives on the ocean environment, the former providing regional coverage of incident radiation, the latter providing both site-specific light penetration data, as well as validation of the satellite readings. Physiological studies of corals reveal that sea temperature and light, under elevated and sustained conditions, induce coral bleaching. At the Atlantic Oceanographic and Meteorological Laboratory (AOML), ecological forecasts (ecoforecasts) such as coral bleaching are produced using an artificial intelligence tool that integrates various data sources (e.g., satellite and in situ) in near real-time, and includes heuristic and numeric modeling capabilities. To improve upon existing ecoforecasts of bleaching, satellite acquired Photosynthetically Available Radiation (PAR) data were produced by Central Michigan University during April through August, 2007 for four stations of AOML's Integrated Coral Observing Network (ICON), located in the Bahamas, Jamaica, Puerto Rico and St. Croix. The satellite derived instantaneous PAR values were estimated within nine pixels of a 3x3 window centered on a site's latitude and longitude. In situ sea surface PAR values at each site were used to validate the average of the nine estimated values, with time interpolation applied to match surface measurement and satellite observation times. The satellite and surface PAR data agreed well at all four sites. Irradiance at the coral surface was calculated using attenuation coefficients ($K_d$) derived from readings from well-maintained sub-surface irradiance sensors at each site and were extrapolated to each region using the satellite PAR readings. Satellite and surface wind and sea temperature data were combined with these readings to produce regional bleaching ecoforecasts. Inherent problems of high spatial and temporal variability in solar radiation at any defined point provide unique challenges to large-scale implementation. Although major bleaching was not observed during this time frame, output from the ecoforecasting construct shows promise for future implementation.

## 16-10

**GBROOS – An Ocean Observing System for the Great Barrier Reef**

**Scott BAINBRIDGE*[1]**

[1]Australian Institute of Marine Science, Townsville, Australia

The Great Barrier Reef Ocean Observing System (GBROOS), a geographic node of the Australian Integrated Marine Observing System (IMOS), is an observation network currently being deployed along the Great Barrier Reef (GBR) in Northern Australia. The project aims to quantify and monitor the impact of the Coral Sea, in particular cool and warm water intrusions, on the GBR and to provide the real-time physical data required to understand the impact of climate change and other environmental factors on coral reef ecosystems.

The project has four components. Sets of long-term oceanographic moorings consisting of paired deep (200m) and shallow (30-70m) moorings will be deployed to detect water moving onto and long the GBR from the pole-ward East Australian and the equatorial Hiri western boundary currents. Upgraded Remote Sensing capacity (SST and Ocean Colour), coupled with real-time underway sampling to validate the remotely sensed data, will give large-scale information about the GBR.

Sensor networks located at seven sites, using high-speed communications and a range of buoy mounted sensors, will provide real-time information about small-scale phenomena. This component provides a platform for the development and testing of the next generation of smart technologies and approaches for real-time observing systems.

The observational data will have significant impact on our understanding of global change, its potential impact on the physical and chemical conditions in marine environments and the associated changes to the biology and structure of the GBR. GBROOS is setting up the infrastructure to support a new generation of observation systems from sophisticated real-time moorings to the communication and data systems for 'smart' sensor systems. This data, coupled with model and scenario engines, will increase our ability to understand changes in the physical environment and the impact these have on coral reef systems.

## 16-11

**Ecological Forecasting for Coral Reef Ecosystems**

**James HENDEE*[1]**, Lew GRAMER[2], Derek MANZELLO[3], Erik STABENAU[4], Chris LANGDON[3], Mike JANKULAK[2]

[1]Atlantic Oceanographic and Meteorological Laboratory, National Oceanic and Atmospheric Administration, Miami, FL, [2]Cooperative Institute for Marine and Atmospheric Studies, University of Miami, Miami, FL, [3]Rosenstiel School for Marine and Atmospheric Sciences, University of Miami, Miami, FL, [4]South Florida Natural Resources Center, Everglades National Park, Homestead, FL

Assessment of coral reef ecosystems implies the acquisition of precision data and observations appropriate for answering questions about the response of multiple organisms to physical and other environmental stimuli. At the National Oceanic and Atmospheric Administration's Atlantic Oceanographic and Meteorological Laboratory, we model marine organismal response to the environment in terms of a Stimulus/Response Index (S/RI). S/RI is computed using an approach called heuristic programming, from parameters bounded in subjective terms, which are defined within the software numerically, so as to match research and our understanding of the process in question. The modelled organismal response is called an ecological forecast, or ecoforecast, and the likelihood and severity of the response is reflected in a rising S/RI. We have had success to date in modelling coral bleaching response to high sea temperatures plus high irradiance and other parameters. The approach requires, a) highly robust instrumentation (in situ, satellite, or other) deployed for long periods and producing high quality data in near real-time, b) a basic understanding of the process, behavior and/or physiology being modelled, and, c) a knowledge of approximate threshold levels for single or synergistically acting environmental parameters that elicit the phenomenon in question. We use both traditional (e.g., sea temperature, salinity, light), as well as novel (e.g., pCO2, pulse amplitude fluorometry) oceanographic instruments to produce a continuous S/RI that has been used as an overall indicator of ecosystem health at all ICON coral reef monitoring locations. We are now actively researching ecoforecast models of species-specific spawning, and of enhanced water column productivity on reefs. Results from recent monitoring efforts, as well as the implications of adapting this technique for use in other locations or on data streams managed by other agencies, will be presented.

## 16-12

**Advancing Spatial-Temporal Continuity in Coral Reef Ecosystem Pattern Detection: The Morphology, Distribution And Chemical Environments Of Coral Habitats Encompassing Coiba National Park, Panamá.**

**Luis CAMILLI*[1]**, Oscar PIZARRO[2], Richard CAMILLI[3]

[1]Center for Habitat Studies, Moss Landing Marine Laboratories, Moss Landing, CA, [2]Australian Centre for Field Robotics, University of Sydney, Sydney, Australia, [3]Applied Ocean Physics & Engineering Dept, Woods Hole Oceanographic Institution, Woods Hole, MA

Quantitative study of environmental change in coral ecosystems is challenging, costly, and hindered by inadequate scales of observation. A synoptic perspective of reef biogeochemical dynamics and community structure was revealed using new technologies and methods designed to enable high resolution underwater habitat assessment with non invasive monitoring capabilities and rapid information output. A towed, chemical sensor platform and a diver-based, automated imaging system were developed to compare reef architecture and benthic morphology across spatial scales ranging from centimeters to kilometers, and resolve sub-meter variability in ambient water chemistry across basin scale seascapes. Acoustic bathymetry, stereo-optical imaging, in-situ underwater mass spectrometry, CTD, chlorophyll, and CDOM data were coupled with precision navigation to enable multi parameter biogeochemical and structural comparisons of coastal and island coral habitats surrounding Parque Nacional Coiba, a UNESCO World Heritage site in Pacific Panamá. Baseline chemical data (O2, CO2, CH4, N2) and 3-D digital reef mosaics generated in this research were augmented with traditional monitoring protocols, time series data from a moored observatory, video sampling and remote sensing analysis to create and validate comprehensive, thematic water chemistry and benthic habitat maps. This integrated approach shows considerable promise for locating, predicting and quantifying natural and anthropogenic environmental stressors affecting the distribution, diversity and health of tropical coral communities.

## 16-13

**Landscape Mosaics Of Coral Reefs: A New Survey Technology For Mapping And Monitoring Reef Condition**

**Brooke GINTERT*[1]**, Nuno GRACIAS[2], Diego LIRMAN[1], Arthur GLEASON[1], Philip KRAMER[3], R. Pamela REID[1]

[1]University of Miami, Rosenstiel School of Marine and Atmospheric Science, Miami, FL, [2]Department of Electronics, Computer Engineering and Automatics, Universitat de Girona, Girona, Spain, [3]The Nature Conservancy, Summerland Key, FL

Efficient survey methodologies that provide comprehensive assessment of reef condition are fundamental to coral reef monitoring. Current state-of-the-art techniques in coral reef assessment rely on highly trained scientific divers to extract indices of reef health (e.g. substrate cover, species richness, coral size, coral mortality, and coral recruitment). Landscape video mosaics are an innovative survey technology that provide large scale (up to 400m2), spatially accurate, high resolution images of the reef benthos without extensive survey times or a need for scientific divers. Based on diver-acquired video of the reef benthos and novel mosaicing algorithms, landscape mosaics have been used in the laboratory to extract indices of benthic cover, coral colony size, and colony health that compare favorably with diver surveys. The spatially explicit images allow users to make accurate benthic measurements (such as colony area and diameter, as well as distance relationships for spatial analysis) directly from mosaic products. Repeated mosaic surveys of the same area are easily referenced for change detection analysis and provide an image-based monitoring capability that can survey hundreds of coral colonies over time without the use of *in situ* tagging and underwater relocation. In addition, landscape mosaics provide a large-scale visual permanent record of the state-of-the-reef at the time of collection that is accessible to both the scientific community and general public. To date this technology has been used to detect and monitor changes in reefs responding to hurricanes, ship groundings, and mass bleaching events.

## 16-14

**Imaging Coral Community Structure At High Resolution Over Large Areas On The Reef Terraces Of The Chagos Archipelago**

**John TURNER*[1]**, Robert GIBBS[1]

[1]School of Ocean Sciences, Bangor University, Bangor, United Kingdom

A new technique is described to image large areas of coral reef at high resolution to analyse coral community structure and improve public awareness of reef environments. A major problem encountered in mapping any benthic community is obtaining an *optical* image that covers sufficient area at high resolution to identify species and investigate spatial relationships. Such large images are difficult to obtain in turbid waters (hence acoustic methods are used) and also in clear waters, where either the water depth is so shallow that camera to subject distance is short, or in deeper water where distance is long but resolution poor. Previous research on reef biotope mapping has identified the need to formulate an image *within* a 20-30 m2 pixel, so typical of satellite remote sensing imagery used in wider scale mapping. A diver-operated rig was designed to carry a high resolution digital underwater video camera and lighting, such that accurate circular tracks of reef could be sequentially imaged about a central point. Each ring increased in diameter to overlap the preceding circle, ensuring 100 % cover. The technique was deployed at 5 sites between 10 and 20 m depth on different reef slopes around 4 atolls of the Chagos archipelago. Software was written to mosaic 3,570 video images recorded across 21 rings to create a 76 square metre image of each site, resulting in a resolution of 2 mm at 1m distance from the reef. Images of the different sites were analysed using MapInfo GIS to assess spatial relationships between coral colonies, and to examine recovery at colony scale on a previously bleached reef. The images are being used for monitoring and conservation policy formulation. Sections of images will be reproduced at life-size in the new London Zoo Chagos reef exhibit, to assist in the public understanding of reefs.

## 16-15

**Bioeroding Sponges Need To Be Monitored**

**Christine SCHÖNBERG*[1]**, Katherine E. HOLMES[2]

[1]Dept. of Animal Biodiversity and Evolution, Carl von Ossietzky University, Faculty 5, Biology and Environmental Sciences, Oldenburg, Germany, [2]Center for Biodiversity and Conservation, American Museum of Natural History, New York, New York, NY

Bioeroding sponges are important in the balance of coral reef construction and destruction. Due to changes in environmental conditions, these sponges can become epidemic and have occasionally been recognised for their value as bioindicators. Recent studies revealed increases in bioeroding sponge abundances in the Caribbean and on the Australian Great Barrier Reef, which was largely explained with deteriourating conditions or disturbance events that led to an increased availability of suitable substrate for the settlement of bioeroders. The sponges appear to be hardier than corals, even if they are zooxanthellate. We propose to incorporate the most common species of bioeroding sponges into long-term monitoring projects. Species of the '*Cliona viridis*' complex are thought to be most suitable for this, because they occur at all study sites, but species such as the Caribbean *Cliona delitrix* should also be considered. If the procedure is kept simple (see proposal on poster), replicate studies can be conducted at very different sites and in consecutive approaches, eventually leading to a sound database on the leading endolithic agents of warm water bioerosion.

## 16-16

**Solar Radiation Dosimetry In Florida Coral Reefs Determined From Remote Sensed, Modeled, And In Situ Data**

**Mace BARRON*[1]**, Deborah VIVIAN[1], Susan YEE[1], Debbie SANTAVY[1]

[1]U.S. Environmental Protection Agency, Gulf Ecology Division, Gulf Breeze, FL

Solar irradiance has been increasingly recognized as an important determinant of bleaching in coral reefs, but measurements of solar radiation exposure within coral reefs have been relatively limited. Solar radiation dosimetry within multiple coral reef areas of South Florida was assessed using remote sensed, modeled, and measured values during a minor bleaching event (August 2005). Coral reefs in the Dry Tortugas and Upper Keys had similar diffuse down welling attenuation coefficients (Kd, m-1), but Kd values were significantly greater in the Middle and Lower Keys. Mean one percent attenuation depths varied by reef region for ultraviolet B (UVB; 9.7 to 20 m), ultraviolet A (UVA; 22 to 40 m) and visible (27 to 43 m) solar radiation. Solar irradiances determined from remote sensed surface intensity and Kd were significantly correlated with measured values, but were generally over estimated at the depth of corals. Solar irradiances modeled using an atmospheric radiative transfer model parameterized with site specific approximations of cloud cover showed close agreement with measured values. Estimated daily doses (W*hr/m2) of UVB (0.01-19), UVA (2-360) and visible (29-1653) solar radiation varied with coral depth (2 to 24 m) and meteorological conditions. These results indicate large variation in solar radiation dosimetry within coral reefs that may be estimated with reasonable accuracy using regional Kd measurements and radiative transfer modeling.

## 16-18

**Estimating Three-Dimensional Coral Colony Surface Area from Simple Field Measurements**

Lee COURTNEY[1], **William FISHER*[1]**, Sandy RAIMONDO[1], Leah OLIVER[1], William DAVIS[1]

[1]National Health and Environmental Effects Research Laboratory, Gulf Ecology Division, US Environmental Protection Agency, Gulf Breeze, FL

Topographic surface area (SA) of coral colonies is a critical descriptor for biological and physical attributes of reef-building (scleractinian) corals. SA is directly related to coral sustainability (e.g., living tissue) and anthropocentric values (e.g., fish habitat, shoreline protection). Most existing methods to estimate colony SA are destructive and limited to laboratory settings. However, a recently-described photographic method was tested and found applicable to field colonies. A highly accurate 3-dimensional digital reconstruction is generated using specialized computer software and multiple images of a coral colony. SA determined from the reconstructed colony is within 2-5% of SA determined by laser-scanning. The method was used to evaluate three approaches, or models, for calculating SA of coral colonies from simple morphological measurements made in the field. The models included a volumetric size-class (SA = 5 sides of a cube), a hemispheric surrogate (SA = $2\pi r2$, where r is determined from height, diameter and width), and a suite of log-linear formulae generated from stepwise multiple regression of reconstructed colony SA against colony height, diameter and width. When SA determined using field collected data were compared to SA of reconstructed images, the log-linear model was most accurate (12% difference from reconstruction values), followed by the hemispheric surrogate (17% difference) and size-classes (40% difference). While only four species were included in these analyses (*Montastraea faveolata, M. cavernosa, Diploria strigosa* and *D. clivosa*), SA of specimens from seven additional species were credibly estimated (<20% difference) using the log-linear and hemispheric models. Greater differences were observed with more complex colonies which may require different models. Results from this study have been used in the Environmental Protection Agency's *Stony Coral Rapid Bioassessment Protocol* to support indicators of coral reef value and sustainability.

## 16-19

**Coral Surface Area Estimation by Computer Tomography – Comparison with Established Methods and Application in Ecological Studies**

**Malik NAUMANN*[1]**, Wolfgang NIGGL[1], Christian LAFORSCH[2], Christoph MAYR[3], Christian GLASER[4], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany, [2]Department Biology II and GeoBio-Center, Ludwig-Maximilians-Universität München, Martinsried, Germany, [3]GeoBio-Center & Department of Earth and Environmental Science, Ludwig-Maximilians-Universität München, München, Germany, [4]Institut für Klinische Radiologie, Ludwig-Maximilians-Universität München, München, Germany

In coral reef ecology, the surface area of coral colonies serves as an important reference parameter for the standardisation of coral metabolism measurements. Nevertheless, precise quantification of coral surface area remains a difficult approach. Here, we present a non-invasive alternative for improved coral surface area estimation composed of geometric measurements and surface area approximation indices (SAI) derived from comparison of new and established methodologies used in coral reef ecology. Skeleton surface areas of scleractinian reef corals from six genera (warm water corals: *Acropora*, *Fungia*, *Galaxea*, *Montipora*, *Pocillopora*, cold water coral: *Lophelia*) representing the most common morphological growth forms were quantified using computer tomography (CT) and subsequent computerised 3-dimensional surface area reconstruction. Surface area estimates for the same coral colonies were also obtained by application of three established methodologies: simple and advanced geometric approximation, paraffin-wax-coating and planar-projection photography. Comparison of the respective results yielded SAIs applicable in the calculation of the estimated surface area for the particular genus. Cumulative analysis (all six genera) of SAIs revealed closest approximation to CT-derived data by the advanced geometric approximation (AG, 30 ± 23 % average deviation), representing a non-destructive and feasible approach for coral surface area estimation in ecological studies. The commonly used and destructive paraffin-wax-coating technique showed a slightly bigger deviation from the CT reference, (37 ± 14 % average deviation), whereas the planar-projection photography differed maximal (82 ± 13 % average deviation) Advanced geometry and specific SAIs were used in field studies investigating surface area related particulate organic matter (POM) release rates of several dominant scleractinian coral genera. Results were consistent with literature data involving invasive surface area quantification techniques, thereby confirming the wide applicability of non-destructive geometric approximation in combination with CT-derived SAIs.

## 16-20

**Area-Calibrated Automation Of Coral Classification For Near And Subsurface Reef Videos**

**Ma. Shiela Angeli MARCOS*[1]**, Laura DAVID[2], Maricor SORIANO[1]

[1]Instrumentation Physics Laboratory, National Institute of Physics, University of the Philippines, Quezon City, Philippines, [2]Remote Sensing Working Group, Marine Science Institute, University of the Philippines, Quezon City, Philippines

We have developed groundwork for a computer-automated system for coral reef classification through underwater video. Unlike in common reef monitoring protocols that take weeks to finish, data acquisition through an underwater video camera is less expensive and processing can be done in one day. Two video acquisition schemes were considered: (1) near-reef videos, where the diver maintains a height of 30 cm from the reef surface, and (2) subsurface video of a reef filmed with a camera fixed beneath the surface of the water. We implement a downsampling method where rapid classification is done per block region of the reef image. This method is quicker than applying the operation to every pixel of the image.

We classify near-reef images obtained from a Philippine reef. In this data set, we classify benthic components into living and nonliving categories. We have achieved an overall success rate of 79% for test images that were not in the training set which is high considering that corals occur in a variety of appearance. Color and texture features derived from video stills were used as inputs to the classifier system.

The same automation system is tested on subsurface underwater reef video. An overall recognition rate of 60 – 70% was achieved. A more accurate recognition rate can be achieved for depths of up to 2 meters only with a small average false positive rate (24.3%). Greater depths (or camera–reef distance) incurred high false positives due to limitations incurred by camera optics and loss of clarity from the water column. A comparison between the automated coral classification system and point-count sampling is also presented. The development of an automated rapid reef classification system is most promising for reef studies that need fast and frequent data acquisition of percent cover of living and nonliving components.

## 16-21

**New Approach For Coral Surface Area Calculation Using Computerized Tomography And 3d Modelling**

**Wolfgang NIGGL*[1]**, Malik NAUMANN[1], Christian GLASER[2], Christian WILD[1], Christian LAFORSCH[3]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, Munich, Germany, [2]Institut für Klinische Radiologie, Ludwig-Maximilians-Universität München, Munich, Germany, [3]Department Biology II and GeoBio-Center, Ludwig-Maximilians-Universität München, Munich, Germany

The surface area (SA) of coral colonies represents a major reference parameter for the standardisation of flux rates involving release and uptake of organic and inorganic compounds, coral growth investigations, as well as for investigations of coral metabolic processes, e.g. photosynthesis and respiration. To date, a variety of methods used to determine the SA of corals has been developed with a set of coherent problems if applied in ecological coral studies, i.e. imprecise and rather approximate approaches that lack accuracy, or invasive and often destructive approaches that are inapplicable for experiments involving living corals and continuous SA determinations. Thus, coral science is in need for a non-invasive and precise methodology for coral surface area determination. This study introduces such a novel technique applying computerized tomography (CT) and subsequent 3D modelling. Several living coral colonies of differnt taxa were scanned by conventional medical CT. Resulting CT-data sets were processed by 3D modelling software delivering realistic 3D coral skeleton surface reconstructions and coherent SA measurements. Comparisons of CT- data sets obtained from standard bodies and coral colonies proved the accuracy of surface area determination. Our results emphasizes the usefulness and feasibility of computer tomography for surface related studies in the field of coral reef ecology.

## 16-22

**Interdisciplinary Environmental Assessments of Coral Reefs Using Remote Sensing and Numerical Circulation Models**

Serge ANDREFOUET[1], **Frank MULLER-KARGER*[2]**, Jinyu SHENG[3], Craig STEINBERG[4], Pascal DOUILLET[1], Inia SOTO[2], Bruce HATCHER[5], Sylvain OUILLON[1], Chuanmin HU[2], Bo YANG[3], Severine CHOUCKROUN[4], Guillaume DIRBERG[1], Christine KRANENBURG[2], Christopher MOSES[2]

[1]Institut de Recherche pour le Developpement, Noumea, New Caledonia, [2]College of Marine Science, University of South FLorida, St Petersburg, FL, [3]Dept of Oceanography, Dalhousie University, Dalhousie, NS, Canada, [4]Australian Institute of Marine Science, Townsville, Australia, [5]Center for Marine Ecosystem Research, Cape Breton University, Sydney, NS, Canada

An interdisciplinary international team investigated oceanographic processes that constrain coral reef ecosystems of the Meso-American Barrier Reef System (MBRS), Great Barrier Reef (GBR) and New Caledonia Lagoon (NCL). Reef connectivity, coral bleaching and sediment transport were targeted for MBRS, GBR and NCL respectively. These sites either lacked any in situ data (MBRS) or benefited from extensive time-series of measurements (GBR and NCL). Our methodological goal was to combine numerical circulation models and remote sensing to study the specific processes at each site.

The circulation of MBRS was simulated using a nested model to understand larvae propagation between reefs and river runoff dispersals, including during hurricanes. SeaWiFS climatology and time-series were used to investigate connectivity in MBRS and validate model outputs. On the southern GBR, the objective was to enhance prediction of thermal stress at reef-scale. In Both MAR and GBR shallow water bathymetry were computed from Landsat images to improve high resolution model outputs in shallow reef areas. GBR shallow bathymetry was validated against Lidar data. In NCL, numerical models provided suspended matter concentrations under different forcing, and we revisited local Landsat and MODIS optical algorithms for suspended matter estimation.

Remote sensing tools quickly provided synoptic information for each site (connectivity matrices, bathymetry, suspended matter) with useful accuracies for model calibration/validation. However, for each site, numerical models were more difficult to adapt to these new calibration/validation data sets due to the computation time and resources required to run new sensitivity analysis. The integration was faster for MBRS, motivated by limited oceanographic field data. Combining numerical output with remote sensing is promising to monitor and hindcast-forecast connectivity, thermal stress and sediment transport and we conclude by the perspectives highlighted by this program.

## 16-23

**Creios: Noaa's Coral Reef Ecosystem Integrated Observing System**

**Jessica A. MORGAN*[1]**, C. Mark EAKIN[2], Russell E. BRAINARD[3], James C. HENDEE[4], Joyce E. MILLER[3], Mark E. MONACO[5], Tyler R.L. CHRISTENSEN[1], Dwight K. GLEDHILL[1], Scott F. HERON[2], Gang LIU[1], William J. SKIRVING[2], Alan E. STRONG[2]

[1]IMSG at NOAA Coral Reef Watch, Silver Spring, MD, [2]NOAA Coral Reef Watch, Silver Spring, MD, [3]NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [4]NOAA Atlantic Oceanographic & Meteorological Laboratory, Miami, FL, [5]NOAA Center for Coastal Monitoring and Assessment, Silver Spring, MD

Coral reefs are complex ecosystems with high biodiversity and significant economic importance. Modern *in situ* and satellite-based observations show declining trends of reef health and extent on both local and global scales. With U.S. coral reef resources stretching across 13 time zones, NOAA has responsibility for observing and managing coral reefs over a wide area. To carry out this task, NOAA has implemented an integrated coral reef ecosystem observing system to map and monitor coral reefs, their biota, and their environments. The Coral Reef Ecosystem Integrated Observing System (CREIOS) is an important component of NOAA's Coral Reef Conservation Program (CRCP) and provides a NOAA contribution to the Global Earth Observing System of Systems (GEOSS). The current configuration of CREIOS includes a wide variety of observing systems providing coverage of U.S. coral reef resources in the waters of States, Territories, U.S. flag islands and Freely Associated States in both the Pacific and the Atlantic. Key components include: (1) physical and environmental monitoring using satellite, *in situ*, and paleoclimatic observations; (2) reef mapping and benthic habitat characterization using satellite, airborne, ship-based, and diver observations; (3) ecological monitoring of benthos, mobile invertebrates, and fishes by divers and instruments; and (4) monitoring for coral bleaching and disease outbreaks by divers. NOAA makes data from these observations accessible through the Coral Reef Information System (CoRIS) and provides integrated information products to satisfy scientific and management needs.

## 16-24

**Ecological Count-Based Measures: How To Prevent And Correct Biases in Spatial Sampling**

**Assaf ZVULONI*[1,2]**, Yael ARTZY-RANDRUP[3], Lewi STONE[3], Robert VAN WOESIK[4], Yossi LOYA[1]

[1]Department of Zoology, Tel-Aviv University, Tel-Aviv, Israel, [2]The Interuniversity Institute for Marine Sciences of Eilat, Eilat, Israel, [3]Biomathematics Unit, Department of Zoology, Tel-Aviv University, Tel-Aviv, Israel, [4]Department of Biological Sciences, Florida Institute of Technology, Melbourne, FL

Ecological count-based measures (ECBMs; i.e., measures which relate to the number of individuals in an area), such as population density, size-frequency distribution, average size, species richness and diversity, are often used to assess the ecological status of different populations or communities in a variety of ecosystems. Incorrect evaluations of ECBMs may lead to biased estimations of the ecological status of ecosystems and may result, among other things, in erroneous nature reserve management policies. The major objective of the study is to elucidate biases that can arise in the application of popular and traditional sampling methods (e.g., *quadrat*, *belt-transect* and *line-intercept*) and to develop mathematical corrections, which provide unbiased estimations for present and past collected data. We show that biases on the estimated ECBMs may arise due to boundary effect of the sampling units and that the intensity of the bias increases with proportion to the size-ratio between the sampled individuals and the sampling unit in use. Our analysis is based on analytical calculations, simulations and field observations. We developed simple mathematical corrections, which provide unbiased estimations for presently and previously collected data acquired by these widely used methods. In addition, we offer a decision rule, which do not suffer from these shortcomings. Eliminating these types of sampling errors will not only provide better assessments of the status of a given coral reef, but will also make way for more precise comparisons among coral reefs in different regions. Although we discuss the biases of ECBMs in regard to reef coral populations, the work is equally relevant in other marine and terrestrial ecosystems.

## 16-25

**Considerations in The Design Of A Monitoring Program For Fish And Macrobenthos On A Caribbean Fringing Reef**

**John MCMANUS*[1]**, Lee-Ann HAYEK[2], Felimon GAYANILO[1], Daniel HOLSTEIN[1], Kristine STUMP[1], Marilyn BRANDT[1], Wade COOPER[1]

[1]NCORE/Marine Biology and Fisheries, RSMAS, University of Miami, Miami, FL, [2]Smithsonian Institution NHB, Washington, DC

The highly heterogeneous nature of coral reefs in space and time complicates the process of designing reasonably objective, representative monitoring programs focused on fish and macrobenthos. In one-time sampling designs, one is sampling a defined space, in which the characteristics of interest of the space are the abundances of fish and macrobenthos, and often the spatial correlation relationships among these. The sample design may thus be focused on accounting for the variance in one or more combinations of these parameters over space, sometimes based on preliminary sampling. In monitoring, the characteristics of space of primary concern are the changes over time anticipated in these abundances. Because change over time may correlate weakly or unpredictably with abundance, the use of preliminary one-time sampling as a design tool may be of limited value. For both sampling and monitoring designs, factors such as high variability in sand and hard substrate patch sizes and dispersion, and 'intrusion' into hard substrate of sandy grooves in spur-and-groove systems, create problems in determining the sampling regime to be represented. These, in addition to extremes in slope and holes of various sizes in the substrate, often cause the introduction of considerable subjectivity into the design – often via decisions made in the field. We use a combination of multiple prior surveys, satellite data analysis and computer simulation, analyzed with respect to variance in time and space and practical field time limitations, to determine the pros and cons of a variety of approaches to the design of a monitoring program for a fringing reef of approximately 20 sq km in eastern Dominican Republic.

## 16-26

**Solar Irradiance And Coral Reefs: Modeling And Management Tools**

**Lore AYOUB*[1]**, Pamela HALLOCK[1], Paula COBLE[1]

[1]College of Marine Science, University of South Florida, St Petersburg, FL

Although mass coral bleachings are generally triggered by supraoptimal seawater temperatures, experiments have demonstrated that corals and reef-dwelling foraminifers bleach more readily when exposed to high energy, short wavelength solar radiation (blue, violet and ultraviolet (UVR; $\lambda \sim 280$ - 490 nm). In seawater, colored dissolved organic matter (CDOM), also called gelbstoff, preferentially absorbs these shorter wavelengths, which consequently bleach and degrade the CDOM. Alteration and destruction of watershed and coastal wetlands have reduced natural sources of CDOM that are tidally flushed into reefal waters. We have measured absorption of UVR and incident UVR at various reefs in the Florida Keys that differ in distance from shore and the degree of anthropogenic development and intact mangrove hammock of the adjacent shoreline. The absorption measurements were used to calculate the intensity of UVR reaching the benthos. Underwater irradiance (UVR and PAR) was also measured using a multichannel profiling radiometer. Preliminary results show that reefs associated with intact shorelines tend to be exposed to lower intensities of UVR than reefs associated with developed shorelines. Absorption due to CDOM at 320 nm ($a_{g320}$) also was less variable at reefs associated with intact shorelines. Inshore reefs tended to be exposed to lower intensities of UVR than offshore, clear-water reefs at similar depths. Spectral slope of $a_g$ for shallow water coastal areas was modeled from absorption data collected in the spring and summer of 2004, 2005, 2006 and 2007. Spectral slope was generally greater at offshore sites, indicating photobleaching of CDOM remaining in offshore waters. These results provide support for resource managers to protect CDOM sources to reefal waters, such as preservation of natural coastal vegetation including mangroves and tidal wetlands. Other potential applications include ground-truthing inherent optical properties and a new algorithm for satellite-derived measurements of $a_g$ and UV Irradiance.

## 16-27

**Light And Motion Sensor Program: Low Cost Coral Reef Monitoring**

**Burton JONES*[1]**, Ivona CETINIC[1], Gerardo TORO-FARMER[1], Karli HERZOG[1], Albert BIANCULLI[2], Ramon DE LEON[3], Matthew RAGAN[1], Tom REYNOLDS[1]

[1]Marine Environmental Biology, University of Southern California, Los Angeles, CA, [2]Sea Monitor Foundation, Bonaire, Netherlands Antilles, [3]Bonaire National Marine Park, Bonaire, Netherlands Antilles

The "Light and Motion Sensor Program" is an observational network comprised of low cost sensor arrays deployed along the coral reef on the lee side of Bonaire. This effort is intended to observe variability of organic components in the water column over the reef that may indicate nutrient inputs or groundwater seepage into the water column over the reef. The arrays contain temperature and light sensors at three discrete depths, providing vertical temperature structure and downwelling light attenuation. Volunteer divers download the data weekly, transmit it to the laboratory where it is processed and posted on the web, making the data from the sensor network available in "semi-real time". Data collected at each site enable us to follow daily temperature oscillations, and to evaluate processes that include upwelling, water column mixing, and along-coast propagation of variability. Downwelling irradiance in three ranges, broadband light, blue and green color bands, allows the calculation of the diffuse attenuation coefficient for those wave bands. By coupling measured light with temperature data, it is possible to evaluate the role of natural and anthropogenic sources affecting fluctuations of light attenuation. The choice of wavelengths provides an index of the presence of organic matter (Organic Index), including planktonic algae, dissolved organic matter and detrital material that can affect the fragile coral reef ecosystem. This unique, inexpensive monitoring network provides the scientific community and environmental managers with temporal and spatial information that can be used to assess environmental variability. It can also be used for recreational purposes by divers and tourists with near real-time observations of the Bonaire reef environment.

## 16-28

**Novel Optical Technique For Characterization Of Light Absorption And Distribution in Reef-Building Corals**

**Vadim BACKMAN*[1]**, Erin DALY[2], Andrew FANG[2], Margaret SIPLE[2], Mark WESTNEAT[3], Vladimir TURZHITSKY[1], Jeremy ROGERS[1], Luisa MARCELINO[2]

[1]Biomedical Engineering Department, Northwestern University, Evanston, IL, [2]Civil and Environmental Engineering, Northwestern University, Evanston, IL, [3]Zoology, Field Museum of Natural History, Chicago, IL

Light transport in coral skeleton plays an important role in coral physiology. In particular, characteristic length-scales of light diffusion in coral skeleton (mean free-path length) are long, which results in the redistribution and homogenization of the illumination of coral tissue and amplification of light availability to the algal-symbionts by several fold. We describe a novel optical technique, low-coherence enhanced-backscattering (LEBS), for characterization of light absorption and distribution in corals. Here we describe the characterization of coral colonies of different species regarding: 1) the light transport properties of their coral skeleton and tissue; 2) light absorption by coral tissue; and 3) the micro- and nano-architecture of the coral skeleton and tissue and their relationship to the optical properties. These findings help to clarify the efficiency with which different coral species collect and distribute light to their algal-symbionts and the structure-function relationship in coral skeletons and tissue.

## 16-29

**Patterns Of Vertical Zonation in Mesophotic Reef Communities Of Southwestern Puerto Rico And Vieques Island**

**Sara RIVERO*[1]**, Roy ARMSTRONG[1]

[1]Marine Sciences, University of Puerto Rico, Lajas, Puerto Rico

Mesophotic reefs (30-100 m) may be the last frontier in coral reef ecology. These reefs remain largely unexplored since they require special diving technology or the use of underwater vehicles for benthic characterizations. Mesophotic reefs in three areas of Puerto Rico: La Parguera and Guanica, Southwestern Puerto Rico, and Vieques Island were characterized. In 2004 the Seabed Autonomous Underwater Vehicle (AUV) provided seven phototransects of approximately 1 km which allowed qualitative and quantitative assessments of species diversity, percent cover, and reef geomorphology. The depths sampled by the AUV ranged from 20-112 m. Percent cover of five main benthic categories were recorded: scleractinian, macroalgae, gorgonians, sponges, and black corals. Special attention was given to sponges and scleractinian corals, the latter (mainly *Agaricia* sp.) were found up to 91 m depth. Coral dominance (up to 62 % cover) in shallow depths is shifted to sponge dominance (up to 33 % cover) in deeper areas. Gorgonians, which rapidly disappear after a depth of 40 m are replaced by black corals. Maximum percent cover for all benthic groups other than scleractinians is at around 50-60 m depth, which seems to coincide with the lower limit of scleractinian distribution and increasing availability of bare substrate. The Guanica transects show high sediment, turbid waters with a higher attenuation coefficient (Kd), lower coral cover and a more gentle slope than those from La Parguera. Future plans include new deployments of the AUV in 2008 that will permit the assessment of temporal variations within some of these transects, the role of incident spectral irradiance on community structure, and the assessment of autotrophy versus heterotrophy in these little-known environments.

## 16-30

**Listening To The Reefs Of Oman: Can Sound Be Used As A Predictor Of Marine Fauna?**

**Mark PRIEST*[1]**, Stephen SIMPSON[2], Jenny MCILWAIN[1], Andrew HALFORD[1]

[1]University of Guam, Mangilao, Guam, [2]University of Edinburgh, Edinburgh, United Kingdom

Coral reefs are noisy places which can be detected from 10's of kilometres away. A cacophony of sound is produced by a variety of reef dwelling organisms; fish drum on their swim bladders and grind their teeth, urchins scrape across algae covered rocks, and snapping shrimp implode bubbles of air fired from their claws. Settlement-stage reef fish have been shown to respond to reef noise, implying it is not haphazard, and transfers useful information regarding the surrounding environment. If we can decipher nature's song what will we are able to learn from the tune?

The coastal waters of Oman contain an unusual variety of reef habitats, both tropical and temperate in nature. We used a hydrophone to record the sounds of differing reefs, spanning the Arabian Sea and Gulf of Oman, and used standard UVC techniques to assess the fish assemblages and benthic communities. Reef noise proved to be consistent over time and varied in composition between geographic locations, with each site producing unique sound profiles. This was also the case for fish and benthic communities, which also showed remarkable levels of dissimilarity. We investigate the degree to which properties of reef noise can be translated and used to predict reef quantity, quality, and species composition. Results suggest this is possible and with further refinement sound may have an application as a monitoring tool.

## 16-31

**Coral Reef Soundscapes: The Underwater Acoustic World From A Larval Reef Fish's Perspective**

**Adel HEENAN*[1]**, Stephen SIMPSON[1], Mark PREIST[2], Emma KENNEDY[3], Chantal HUIJBERS[4], Ivan NAGELKERKEN[4], Victoria BRAITHWAITE[5]

[1]The University of Edinburgh, Edinburgh, United Kingdom, [2]University of Guam, Mangilao, Guam, [3]Heriot-Watt University, Edinburgh, United Kingdom, [4]Radboud University Nijmegen, Nijmegen, Netherlands, [5]Penn State University, University Park, PA

Previous work in temperate and tropical marine reef systems has found that larval fish are attracted to generic biological reef noise during settlement (the period of transition from the plankton to the reef benthos which precedes metamorphosis into the adult form). As we develop our understanding of how sound functions in larval coral reef fish navigation, a more intriguing and complex picture unfolds. Larval fish are able to detect and locate sound sources and distinguish between artificial sounds and those they would encounter in their natural environment. Furthermore, fish larvae are selectively attracted to different components of reef noise, dependent on their life history stage. After presenting an overview of the behavioural function sound plays in the settlement process of coral reef fish, the focus of the talk will shift towards the actual acoustic environment of the reef, and what information this could potentially portray to a settlement stage fish. The results of a worldwide study of reef noise shall be presented, where we compared different tropical habitats in Curaçao and Aruba (reefs, mangroves, seagrass), different quality habitats in the Philippines (pristine, protected, overfished, decimated), and different periods of the lunar cycle at Lizard Island. Reef noise is mainly biological noise produced by resident fish and invertebrates, as such it is a clear indicator of reef type, quality, and even species composition and density. Sound is transmitted at intensities above ambient levels for kilometres, and would be audible by fishes and other migrating animals. This work highlights the value of reef noise as a cue for larval fish orientation and habitat discrimination. It also suggests that through human activity altering the natural soundscapes around reefs, there is a whole suite of anthropogenic impacts on marine systems that are currently poorly understood and largely unmitigated.

## 16-32

**Passive Acoustic Mapping Of Grouper Aggregation Sites**

**David MANN*[1]**, James LOCASCIO[1], Michelle SCHARER[2], Michael NEMETH[2], Richard APPELDOORN[2]

[1]College of Marine Science, University of South Florida, St. Petersburg, FL, [2]Dept. of Marine Sciences, University of Puerto Rico-Mayaguez, Mayaguez, Puerto Rico

Many fishes, including groupers, drums and damselfishes, produce sounds associated with mating behaviors. Passive acoustic techniques can provide synoptic, long-term time series of sound production associated with reproductive activities of these species at widely spaced sites. Passive acoustic techniques were used to study the behavior of red hind (*Epinephelus guttatus*) at spawning aggregation sites off the west coast of Puerto Rico and Mona Island, Puerto Rico. Underwater video cameras with hydrophones were used to record red hind behavior along with sound production. Male red hind produced sounds composed of a series of pulses that graded into a tonal-like sound, with most of the energy below 400 Hz. Most sound production took place during apparent patrolling of male territories. Sound production was also recorded during interactions of males with females. Not all interactions, including male-male interactions at the edges of territories, involved sound production. Long-term acoustic recorders (LARS) were used to record sound production for longer periods of time than could be accomplished with the underwater video. Two LARS were deployed on previously identified red hind aggregation sites on the west coast of Puerto Rico and five LARS were deployed on Mona Island from January-March 2007. Analysis of LARS data from the west coast of Puerto Rico and Mona Island showed similar diel periodicities of sound production, but the two sites had different peaks in sound production during the month. These results demonstrate the potential of passive acoustics for mapping spawning aggregation sites of soniferous species over large spatial and temporal scales.

## 16-33

**Utilizing Acoustic Data in Establishing Reef Fish Recruit Abundance**

**Victor TICZON*[1]**, Badi SAMANIEGO[2], Greg FOSTER[3], Sonia BEJERANO-CHAVARRO[4], Eileen PENAFLOR[1], Shiela MARCOS[5], Joseph Dominic PALERMO[1], Peter MUMBY[4], Laura DAVID[1]

[1]Ocean Color and Coastal Oceanography Lab, The Marine Science Institute, University of the Philippines-Diliman, Quezon City, Philippines, [2]Apercu Consultants Inc., Makati City, Philippines, [3]National Coral Reef Institute, Nova Southeastern University, Fort Lauderdale-Davie, FL, [4]Marine Spatial Ecology Laboratory, University of Exeter, Devon, United Kingdom, [5]National Institute of Physics, University of the Philippines-Diliman, Quezon City, Philippines

Reef fish recruitment patterns have been observed to be strongly dependent on the physical and biological habitat features of the reef. The reefs' habitat structure mediates the process of predation and competition by providing refuges and resources for settling recruits. Overall, the study aims to (1) determine the influence of rugosity and shelter features on the diversity and abundance of reef fish recruits and, (2) generate reef fish recruit diversity and abundance map of Ngaderrak Reef, Republic of Palau. Fish visual census, habitat classification, and shelter dimension measurements of major habitats, were conducted in Ngaderrak reef, and, Puerto Galera and Anilao, Philippines. Acoustic habitat mapping was only conducted in Ngaderrak. While the first three tasks were conducted in specific detail for ecological analysis, the Biosonics DTX was used to generate broad scale spatial information on habitat type, rugosity and shelter features of the entire reef area of Ngaderrak. Preliminary results show higher recruit abundance in the more physically complex microhabitats. This corroborates past studies which reflects correlation between reef fish recruit abundance and diversity with substrate complexity. The strong correlation with reef fish recruit abundance and the physical characteristics of the reef supports the use of remote sensing techniques such as Acoustic Ground Discrimination Systems (AGDS), to spatially characterize habitat features of the reef and possibly, identify areas with high recruitment potential based on the physical structure of the substratum. Acoustic survey results demonstrate the ability of AGDS to distinguish microhabitats based on the physical structure of the corals, rugosity, and substrate hardness. However, initial results show that habitat information derived from acoustic remote sensing was limited to structures with notable vertical relief. Acoustic mapping accuracy of benthic microhabitat features remains to be determined using geo-referenced video-transects of the study area.

## 16-35

**Mapping Reef Structure And Bathymetry In Belize Using Cobratac**

**Peter STETSON*[1]**, Burton SHANK[1], Phil LOBEL[1]

[1]Boston University Marine Program, Boston University, Boston, MA

The Cobratac underwater navigation system (manufactured by RJE International, Irvine, CA, USA) was tested for its mapping capabilities in shallow (<20m) hard- and soft-bottom habitats on lagoonal reefs and in the inter-reefal around Wee Wee Caye, Belize. The Cobratac was created as an autonomous underwater diving navigation system that measures depth and altitude for hydrographic and positioning purposes. It computes position using a fluxgate compass and a Doppler velocity log. The Cobratac's effectiveness as a measuring tool for the rugosity of reef structure and for mapping bathymetry was evaluated. The accuracy, density, and breadth of data collection are dependent upon speed of travel and altitude above the bottom. Multiple passes over the desired area may be necessary to collect a complete dataset. Maps will be presented illustrating the capabilities of the Cobratac in conjunction with GIS software, Surfer and ArcGis, and MatLab. Provided that the limitations of the system are understood, the Cobratac appears to be a powerful tool for easily mapping the topography of small-scale and shallow marine systems and producing readily intelligible and informative bathymetric maps. This project was supported by the Boston University Marine Program, Conservation International's Marine Management Area Study and the US DoD Legacy Program.

## 16-36

**A Web-Based Information Management Solution For Experimental Data From The Field Of Coral Reef Ecology**

**Florian MAYER*[1]**, Sven DUEWEL[2], Andreas HAAS[1], Carin JANTZEN[1], Malik NAUMANN[1], Jonathan M JESCHKE[3], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany, [2]Procon IT GmbH, München, Germany, [3]Dept. Biology II, Evolutionary Ecology, Ludwig-Maximilians-Universität München, Martinsried-Planegg, Germany

In the profit-oriented business and industry sector, information management (IM) solutions are well established. But in coral reef ecology, the IM aspects of experimental design, data acquisition & evaluation, documentation and publication follow the individual workers' experience rather than established standards. Although many aspects of these tasks are automatable, no useable guidance tool has been established so far, which would lead the worker through the experimental life cycle and enforce validation, documentation, completeness, correctness and consistency of data. Often, this results in loss of information, deterioration of data quality and diminished data compatibility. In this study, a dynamic web application was created to automate the scientific work process conforming to recognized scientific work practices. The application was built using Grails, a new programming framework, which combines well-proven technologies and allows for rapid software development. Initially focusing on data from coral reef field experiments, the application's data model is capable of managing any kind of manipulative or monitoring ecological experiment. The user operates the software through an intuitive Graphical User Interface and focuses on the scientific experimentation process. The software is secured by user authentication, but data can be shared among team members. It is scalable from a single-user, single-desktop environment up to a distributed network connecting teams worldwide. As the application is easily adapted to many different scientific experiments, it can serve as a prototype model for useable scientific software tools, as is shown by two adaptations: 1) COREweb automates bulk import and error-prone evaluation of an elemental analyzer's complex and varying output, 2) AZEZAweb connects to existing databases and provides pre-formed real time queries to the remotely logged in user. The application makes valuable data, especially from ecological long term studies, better available to decision makers in coastal management.

## 16-37

**Identification Of Sediment Sources Using Geochemical Fingerprinting At Pear Tree Bottom Reef, Runaway Bay, Jamaica**

**Isaac WESTFIELD*[1]**, Steven DWORKIN[1], Rena BONEM[1], Emyris LANE[1]

[1]Geology, Baylor University, Waco, TX

Pear Tree Bottom Reef, near Runaway Bay, Jamaica, has been studied by many reef scientists since T. F. Goreau's initial descriptions of Jamaican reef morphology and zonation in the 1950's. This reef is regarded as a significant example of "Buttress Zone" morphology and is noted for the presence of sclerosponges at water depths less than 30 m. Like many coral reefs worldwide, the Pear Tree Bottom Reef has seen a gradual decline since the late 1970's. Since 2005, increased sedimentation has resulted in a more drastic decline in live coral cover on the reef. It is thought that this increased sedimentation is related to two concurrent construction projects: the expansion and resurfacing of the north Jamaican costal highway near the Pear Tree Bottom River, and construction of the Gran Bahia Principe Resort along the coast adjacent to the reef.

Three major rock formations occur adjacent to the coast and within the drainage basin of the Pear Tree Bottom River: the Falmouth Limestone (~125 ka), the Hopegate Limestone (~250 ka), and the Montpelier Limestone (~1.9 ma). The Gran Bahia Principe Resort was constructed on the Pleistocene Falmouth and Hopegate Formations. The Jamaican coastal highway was also constructed on the Falmouth and Hopegate, but the road material used for its construction was quarried from the Pliocene Montpelier Formation. Sediment samples from Pear Tree Bottom and nine other reefs east and west of PTB were taken in August, 2007 before the arrival of Hurricane Dean. X-ray fluorescence, x-ray diffraction, insoluble residue and particle size measurements, and Sr 87/86 isotopic analysis have been employed to quantitatively identify the main sources of increased sedimentation on the Pear Tree Bottom Reef.

## 16-38

**The Semantic Reef: A Hypothesis-Based, Eco-Informatics Platform To Support Automated Knowledge Discovery For Remotely Monitored Reef Systems**

**Trina MYERS*[1]**, Ian ATKINSON[1]

[1]School of Maths, Physics and IT, James Cook University, Townsville, Australia

Eco-informatics is regarded as the combination of *multiple* environmental datasets and modelling tools that are used to test ecological hypotheses and derive information about environmental systems. The Semantic Reef project is developing automated data-processing, problem-solving and knowledge discovery systems to better understand and manage reef ecosystems. This project uses three core tools; the Semantic Web, Grid Computing and workflow based e-Research approaches. The resulting technology platform is designed to evaluate complex hypotheses queries and provide alerting for unusual events (e.g. spawning, algal growth, bleaching).

Remote environmental monitoring (including sensor networks) are being widely trialed and deployed with the goal of gathering data in real-time. As the volume of raw data increases, it is expected that bottlenecks will develop in the data analysis phases - current data processing still involves human intervention and manual manipulation of data.

Semantic Web technologies are standardised approaches to address the problem of machine-readable, interoperable datasets. Explicit descriptions of the data sets and structures, called *ontologies* allow machines to understand both meaning and context of data, and therefore process information into new knowledge *automatically*.

The Semantic Reef project has developed a reef ontology that has been coupled to datasets to derive *inferences* between data. This permits us to 'ask' the system questions for semantic correlation and analysis. Our initial validation of the reef ontology used ocean temperatures and community composition datasets to ground truth the ontology. Currently, the model is being further extended to map dynamic data from reef based sensor networks into the ontology in real-time. This eco-informatics project represents a new approach to solving problems of scale across reefs and the GBR in particular.

Keywords: eco-informatics, semantic web, ontologies, coral reefs

## 16-39

**Divers For The Environment: Volunteers And Scientists in Marine Biodiversity Monitoring**

Stefano GOFFREDO[1], Patrizia NERI[1], Antonio ORLANDI[1], **Francesco PENSA*[1]**, Maria SCOLA GAGLIARDI[1], Angela VELARDI[1], Corrado PICCINETTI[2], Francesco ZACCANTI[1]

[1]Department of Evolutionary and Experimental Biology, University of Bologna, Bologna, Italy, [2]Laboratory of Fisheries and Marine Biology at Fano, University of Bologna, Fano (PU), Italy

Global monitoring of the biodiversity status is recognized as a priority necessity by the international scientific community. Research institutes often lack funds and necessary manpower to perform large scale monitoring. For land environments it has been shown that citizens can be involved in research, by contributing significantly to the collection of data. Underwater research requires special operational skills and SCUBA certification, and it may be difficult to involve large numbers of volunteers. We show that, in a short time, thousands of recreational divers can be recruited for monitoring the marine biodiversity status. On a specially formulated questionnaire, volunteers reported the presence of 61 marine taxa encountered during recreational dives. During the 4-year study, 3825 divers have completed 18,757 questionnaires, corresponding to 13,539 diving hours. The volunteer sightings-based index showed that in the monitored area the environmental quality did not change significantly on the time scale, but it had a significant correlation with latitude, suggesting improvement in the southernmost areas. This condition could be related to the main presence of stressors in the northern areas, and has been corroborated by professional investigations. Our experience shows that recreational divers can collect a considerable amount of data, over a vast geographical area, thus decreasing the costs for research institutes. The greatest drawback with this collaboration is the difficulty to obtain sampling distributed uniformly in space. Projects that invite citizens to get involved in ecological research provide members of the community of every age valuable opportunities to improve their science literacy and environmental awareness. This research, patronaged by the Italian Ministry of the Environment, was supported by the ASTOI-Association of Italian Tour Operators, the Association of Diving agencies operating in Italy (IDEA, PADI, PSS, SNSI, SSI) and the popular scientific magazine Quark.

## 16-40

**Auvs Explore Reef Sustainability**

**Noelle RELLES*[1]**, Mark PATTERSON[1]

[1]Biological Sciences, VIMS, Gloucester Point, VA

The reefs surrounding the island of Bonaire are the most pristine in the Caribbean, with high percent coral cover (40-60%) and low abundance of macroalgae. The Bonaire National Marine Park sets an important precedent regarding marine protection policy and was nominated for United Nations World Heritage in 2004 due to the high number of endemic marine species. However, surveys of Bonaire's underwater biota have been few, particularly of the deeper reef (65-170 m depth). In 1985, Dr. Fleur van Duyl completed an underwater atlas of Bonaire, mapping the bottom type and benthic community to a depth of 10-12 m. During a 5 week NOAA signature expedition in 2008, the reefs were remapped using a combination of 3 Autonomous Underwater Vehicles (AUV) for survey, and Nitrox and Trimix SCUBA diving. The twilight zone of the reef was investigated using high frequency side scan sonar, multibeam sonar, video, and water quality sensors that were fixed to the AUVs. AUV technology was utilized in this project due to its cost effectiveness, and capability for deeper surveying and greater coverage over shorter time periods than previous mapping efforts. Divers using Nitrox and Trimix SCUBA served to groundtruth data collected by AUV missions at several points on the reef. At select locations, the resulting data were compared to van Duyl's snapshot from the 1980s. The resulting maps are maintained in ArcGIS, with kmz layers available for use by coral reef scientists, managers, and the public using Google Earth. The resulting maps are compared to the previous work by van Duyl (1985) and more recent work by Bak et al. (2005) and used to assess the success of Bonaire's experiment in Marine Protected Areas.

## 16-42

**Shallow And Deep-Water Gorgonian Surveys on Saba Bank, Netherlands Antilles**

**Peter ETNOYER*[1]**, Herman WIRSHING[2], Juan Armando SANCHEZ[3]

[1]Harte Research Institute, Texas A&M University, Corpus Christi, TX, [2]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [3]Departamento Ciencias Biológicas, Universidad de los Andes, Santa Fe de Bogota D.C, Colombia

Saba Bank is a large submerged platform (~2200 km2) mostly within scuba diver depth range (< 50 m), located 4 km southwest of Saba Island in Netherlands Antilles, Caribbean Sea. Ships traveling to and from oil terminals on nearby St. Eustatius occasionally anchor on the Bank, damaging benthic megafauna. Concerns about the practice prompted a recent series of investigations. Gorgonian corals are among the most common and conspicuous benthic megafauna in local shallow and deep-water (> 50 m) environments, so we sought to characterize gorgonian habitats and estimate species richness using a combination of remote sensing, scuba diving transects, and a Seabotix LBV200L remotely operated vehicle (ROV) for deeper collections. Landsat imagery and multibeam bathymetry were employed to create a block design with random survey sites. A total of 14 scuba dives and 5 ROV dives were completed in 10 days. During that time, 47 species were collected down to 130 m depth, including undescribed species in the genera *Pterogorgia* and *Lytreia*. Two different shallow-water gorgonian habitat types were identified by multidimensional scaling and hierarchical cluster analyses of species density values: 1) a higher diversity, higher density 'reef crest' environment characterized by *Eunicea* spp., *Gorgonia* spp., and *Pseudopterogorgia* spp. and 2) a lower diversity, lower density 'reef flat' environment predominantly composed of *Pseudopterogorgia acerosa, Pterogorgia guadalupensis,* and *G. mariae*. These analyses support hypotheses of habitat similarity within zones, and a gradient in diversity and abundance from the reef crest to the reef flats. Some degree of heterogeneity in gorgonian assemblages occurred along the 40 km southeast rim of Saba Bank. Our discoveries of two undescribed gorgonian species argue strongly that continued scientific exploration of Saba Bank is necessary.

## 16-43

**Crustaceans Of Saba Bank, Netherlands Antilles**

**Morgan KILGOUR*[1]**, Thomas SHIRLEY[2]

[1]Texas A&M University- Corpus Christi, Harte Research Institute, Corpus Christi, TX, [2]Texas A&M University-Corpus Christi, Harte Research Institute, Corpus Christi, TX

Saba Bank is a large (~2200 km$^2$) submerged atoll approximately 4 km west of Saba Island in the Netherlands Antilles whose crustacean fauna is poorly known. Concerns about anchor damage from oil tankers to coral habitats on the Bank prompted a study to characterize its fauna. We focused on the decapod crustaceans and used three methods to collect samples. Random collection sites were sampled within habitat types (fore reef, reef flat, back reef slope, lagoon, patch reef and atoll slope) delineated from Landsat imagery and high-resolution multibeam bathymetry data. Scuba (14 dives) was used to observe, photograph, and collect decapod specimens and also to collect sponges, small corals, gorgonians and other biogenic habitats containing cryptic and saxicolous crustaceans. A Seabotix ROV (Remotely Operated Vehicle) was used for 5 days to collect gorgonians, sponges and other biogenic debris containing crustaceans, below diver depths to 130 m. Two crab traps, each fitted with smaller shrimp traps, were baited with multiple kinds of bait and set for three 24 h periods in 300 to 400 m depths to collect specimens below ROV and scuba depths. Crustaceans collected with scuba were differentiated by depth, habitat, and reef zone; depth and location were recorded for specimens collected with the ROV or traps. More than 95 crustaceans were collected, with many representing range extensions or rare species. Assemblage composition and species richness were heterogeneous among habitats, and many species had pronounced depth distributions. Species accrual rates imply that only a portion of the decapod fauna has been sampled; additional quantitative sampling is warranted to complete an inventory of the decapod community and more fully describe their assemblage patterns.

## 16-46

**Caribbean Shallow Reef Coral $\delta^{15}$n Variability Among Species And Depth**

Kirby WEBSTER[1], Steve MACKO[1], **Kiho KIM*[2]**

[1]Department of Environmental Sciences, University of Virginia, Charlottesville, VA, [2]Department of Biology, American University, Washington, DC

Long-lived coral accumulate available nutrients as they grow, and have potential to provide a temporally integrated view of environmental conditions. Nitrogen stable isotope analysis has been a powerful tool for reconstructing inputs into aquatic ecosystems. Although isotope analysis has typically been used to infer sources of N, δ15N may also be used as a proxy for concentration of N and other inputs. However, use of any one species for such a proxy will limit the spatial and temporal extent over which the reconstruction can be addressed. Comparative analyses may be difficult if a species which is common to one area or depth is not observed in the location of interest, or if the proxy has seasonal variation. This study addresses the question as to whether a range of closely related species of the same taxa can be used in this regard. Stable nitrogen isotope analyses of Gorgoniidae family corals were measured to determine the variation among a range of species and with increasing depth in the water column. Gorgonians are common to many shallow reefs in the Caribbean and thus represent an excellent test organism over which the observations at one location could then be extended to another location in a different gorgonian species. Isotope analyses of axial surface skeletal material revealed no significant variation in δ15N values within Gorgoniidae collected from the same reef indicating that observations on species within this taxa are interchangeable. However, in *Pseudopterogorgia americana* collected over a 9 m depth gradient, a significant variation with depth was observed ($r^2 = 0.54$, $p < 0.0001$) suggesting that depth must be kept constant across sampling locations. The results of this study, combined with knowledge of general abundance and N-rich axial skeleton, support the hypothesis that gorgonian corals are an ideal candidate species for use as environmental proxies.

## 16-47

**Light Attenuation Measurements In Bermuda Reefs**

**Gerardo TORO-FARMER*[1]**, Burton JONES[2]

[1]Ocean Sciences, University of Southern California, Los Angeles, CA, [2]Marine Environmental Biology, University of Southern California, Los Angeles, CA

The implementation of low cost and effective methodologies for long term monitoring programs in coral reefs is needed, especially in geographic areas where economic and scientific resources are limited. Specifically, in-situ optical measurements can be utilized to estimate light attenuation due to suspended particles from terrestrial runoff or resuspension of bottom sediments from navigation activities near coral reef areas. Spatial and temporal variations of light penetration and attenuation were estimated using two different methods: water column hyperspectral radiometric measurements, and long term deployments of low cost underwater light intensity logger sensors. These methods were compared at stations across the north reef in the Bermuda Islands. Existing radiative transfer models were also used to compare the observations from these sensors against theoretical values. Variations in the diffuse attenuation coefficient were found among the different stations and between seasons, suggesting temporal changes in the optical field due to natural and possibly anthropogenic disturbances. Regardless of the intrinsic differences between high end and low cost methodologies, the correct interpretation of data from these light intensity loggers can facilitate and improve monitoring and management of coral reef and other coastal ecosystems.

## 16-48

**Mining ICON/CREWS Data Sets for Discovering Relationships between Environmental Factors and Coral Bleaching**

**Marc BOUMEDINE*[1]**

[1]University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.)

In order to assist researchers in assessing the impact of climate change on coral reefs, NOAA Integrated Coral Observing Network (ICON/CREWS) stations collect large amounts of in-situ oceanic and atmospheric data in the Caribbean region. Local effects of environmental factors such as sea temperature, wind speed and direction, light intensity, tides and water salinity on coral reef bleaching are determined by expert system technologies. Since expert knowledge is largely heuristic, the expert system knowledge base is constantly refined and enhanced as new axioms, theories or rules of thumb become available. Since expert systems can not learn independently, an approach to automatically extract new patterns and ultimately knowledge from historical ICON/CREWS data sets is proposed. In this study, patterns have been extracted from data sets generated by the Lee Stocking Islands (Bahamas) ICON/CREWS station from the May 21, 2005 till December 31, 2005. The *Apriori* association rules algorithm generates patterns in the form of rules such as: "if event $e_i$ occurs then event $e_j$ also occurs". Frequent patterns are observed between *Pulse Amplitude Modulation* (*PAM*) yield and light intensity, such as photosynthetically active radiation (*PAR*). Additional relationships between PAM yield and salinity, as well and *PAM* yield and wind speed are derived. In addition to rule generation, two classifiers have been designed in an attempt to predict *PAM* yield values from environmental factors. Our preliminary results are encouraging since more than 85% of the test instances are correctly predicted with both neural network and decision tree algorithms. These preliminary results suggest that data mining techniques are valuable approaches for complementing existing coral bleaching predictive models.

## 16-49

**The Reefpad: A Handheld Underwater Computer Aimed At Improving The Speed And Accuracy Of In-Situ Monitoring Of Coral Reefs**

**Frederic CHARPENTIER*[1]**, Peter GAYLE[2], Bernadette CHARPENTIER[3]

[1]Duwatech, Ottawa, ON, Canada, [2]Center for Marine Sciences, Discovery Bay Marine Lab, Discovery Bay, Jamaica, [3]Research an Development, Duwatech, Ottawa, ON, Canada

Coral reef monitoring is a labor and time-intensive process with inherent challenges related to increasing spatio-temporal resolution. It requires the collection of various data ranging from individual counts to photo surveys. The collected data needs subsequent transcription and processing. The hardware used today to conduct coral monitoring ranges from pencils and slates to photo cameras and other ad hoc instruments which are usually adequate but poorly integrated. The ReefPad is a low-cost handheld underwater computing device specifically designed to simplify in-situ work by decreasing data collection time while improving the accuracy and quantity of the collected data. The electronic circuitry is housed in a 10 x 16.5 cms. acrylic cylinder rated to a depth of 70 meters. It houses a main computer based on an ARM micro-processor, in addition to a PIC microcontroller, a number of sensors (depending on variables being investigated) and a 10 cms. color screen. The basic sensor configuration includes a 3-axis magnetometer and two dual-axis accelerometers. The device can also be custom fitted with digital cameras, lasers, photometers, temperature sensors and RFID readers. The accelerometers and the magnetometer allow the use of dead reckoning for underwater navigation after an initial GPS calibration at the surface prior to the dive. The motion sensors also allow the researcher to interact with the software using gestures thus eliminating the need for buttons, keyboards or writing surfaces. The graphical user interface of the ReefPad was specifically designed to facilitate immediate access to maps, hierarchical lists and referencing software through simple hand motions. The software is configurable and designed to support existing methodologies while decreasing collection times, increasing data accuracy and broadening the investigative scope.

## 16-50

**Variations in The Symbiotic Algae (Zooxanthellae) Associated With Dominant Scleractinian Corals in Hong Kong Sar, China**

**Yu Man TSANG *[1]**, Put ANG[2]

[1]Marine Science Laboratory, Department of Biology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, [2]Marine Science Laboratory, Department of Biology, The Chinese University of Hong Kong, Shatin, Hong Kong

Hong Kong is a marginal environment for coral growth. This study aims at investigating the potential linkages between variation in environmental parameters (mainly seawater temperature) and variation in symbiotic algal density, chlorophyll content (chlorophyll a and c2) and the photosynthetic capacity of two dominant Hong Kong corals *Porites lutea* and *Platygyra acuta*. The phylogenetic information on *Symbiodinium* associated with *Platygyra acuta* was also examined based on restriction fragment length polymorphism (RFLP).

Seasonal photophysiological parameters of algal symbionts in *P. acuta* and *P. lutea* were monitored from October 2006 to April 2007 at A Ye Wan and A Ma Wan in Tung Ping Chau Marine Park. Investigation on their zooxanthellae density and pigment contents throughout the 18 months sampling period revealed no significant bleaching occurring in these corals. However, significant temporal variations in the zooxanthellae density (from $2 \times 10^6$ to $10 \times 10^6$ cells $cm^{-2}$ of coral surface area) for both species were recorded. Concentrations of chlorophyll a per zooxanthella were significantly higher in winter than in summer for both species (ANOVA and Kruskal Wallis Test, $p < 0.05$).

Molecular phylotyping showed *Symbiodinium* clade C to be the dominant zooxanthellae associated with *P. acuta* irrespective of their location (i.e., top or shaded region) in the coral host. *Symbiodinium* clade C formed a stable association with this coral host over the sampling period. This result supported the finding that *Symbiodinium* clade C is the major clade of zooxanthellae associated with scleractinian corals in the Pacific.

## 16-51

**Large Scale Coral Mortality in Barbados: A Delayed Response to the 2005 Bleaching Episode**

**Hazel OXENFORD*[1]**, Angelique BRATHWAITE[2], Ramon ROACH[2]

[1]Centre for Resource Management and Environmental Studies, University of the West Indies, Cave Hill, Barbados, [2]Coastal Zone Management Unit, Ministry of Energy and the Environment, Bridgetown, Barbados

In common with many Caribbean countries, coral reefs in Barbados suffered significant bleaching during the high temperature event of late summer 2005. Six reef sites, including shallow (< 10 m) and deep (> 15 m) communities were monitored over the following year (October 2005 – November 2006) to determine mortality impacts and rate of recovery from the bleaching event. Quantitative benthic surveys along five 1 x 20 m band transects and five 20 m line transects at each site, were undertaken every four months. Bleached condition (measured as % of colonies fully or partially bleached) gradually dropped from a mean of 71% in October 2005, 38% in February to 17% in June, before rising again to 25% in November 2006 after summer warming. Coral mortality (measured using two independent indices: estimated % of coral colony surface recently dead; and % of benthic coral cover recently dead) remained surprisingly low for most species five months after the onset of bleaching (means: 3.8% colony surface dead; or 4.8% dead cover), but rose sharply after 10 months (means: 18.7% colony surface; or 25.9% cover), eventually declining after 15 months to a near ambient levels (means: 2.0% colony surface; or 6.1% cover). In common with other eastern Caribbean islands, recovery from bleached condition was slow, persisting for many months after water temperatures had cooled, and overall mortality impact was high on both deep and shallow reefs. In contrast were the delayed onset of significant mortality and the low incidence of coral disease following the bleaching event on Barbados reefs. High losses in live coral cover have significant economic implications for the island which derives a major proportion of its GDP from tourism, and relies heavily on healthy reefs for coastal protection. This emphasises the extreme vulnerability of small Caribbean islands to the global warming trend.

## 17-1

**Mapping Coral Reef Benthic Zones From High-Spatial Resolution Image Segmentation And Photo Transect Data**

**Stuart PHINN*[1]**, Chris ROELFSEMA[2], Ian LEIPER[2], Peter MUMBY[3]

[1]Geography, Planning and Architecture, University of Queensland, Brisbane, Australia, [2]University of Queensland, Brisbane, Australia, [3]University of Exeter, Exeter, United Kingdom

The objective of this work was to test an approach for integrating field survey data and high-spatial resolution satellite image data to map coral reef benthic zones. Commonly accessible field survey techniques and image data sets were used to define map classes based on statistical analysis of benthic cover features defined from field photos. Our approach was applied to field survey data from georeferenced photo transects and a coincident high spatial resolution Quickbird multi-spectral satellite image from Heron Reef, southern Great Barrier Reef, Australia. The first stage identified benthic cover type and percentage cover from 3592 geo-referenced benthic photos. In the second stage, frequently recurring assemblages of benthic cover types were defined from discriminant and cluster analyses of the geo-referenced photos. A label for each cluster was determined from the mean percentage cover values of each major benthic-cover class for all photo-points present in the resultant cluster. For the third stage, Definiens® image segmentation was used to generate a multi-scale segmentation of the Quickbird image into maps of reef features of a specific size. A final stage labelled the polygons at each of the different scales of image segmentation. This was done by overlaying half of the classified photo-points on the segmented image and developing training sites for labelling reef zones. Next, the remaining set of labelled polygons was used to conduct a standard error assessment. The output reef community zone map matched the validation data, while each other scale corresponded to a repetitive collection of reef features, making up "zones" which could be classified later according to communities or geomorphic features. This work presents an example of an approach suitable for the spatial scale of high spatial resolution satellite image data, the heterogeneous nature of coral reefs, and their regional variation.

## 17-2

**The Status Of The Millennium Coral Reef Mapping Project Worldwide**

**Serge ANDREFOUET*[1]**, Christine KRANENBURG[2], Damaris TORRES-PULLIZA[2], Frank MULLER-KARGER[2,3]

[1]Institut de Recherche pour le Developpement, Noumea, New Caledonia, [2]College of Marine Science, University of South FLorida, St Petersburg, FL, [3]Univ. Massachusetts Dartmouth, New Bedford

The Millennium Coral Reef Mapping Project (MCRMP) is a unique program that uses Landsat 7 satellite imagery to map the extent and diversity of coral reef worldwide at geomorphological level. The project was supported by NASA and IRD. After the creation of a suitable archive of Landsat images in 2004, a classification scheme was designed, tested, updated and applied to all coral reef regions worldwide. In late 2006, the definitive format for product distribution as GIS files was created in partnership with WorldFish/Reefbase. Since 2004, GIS products result from mostly visual interpretation of satellite images, and from automatic image classification procedures if reef types and image qualities are suitable. Geomorphological layers are interpreted and labeled to provide a first temporary product. Then, the validation process assigns a final label for each polygon from a hierarchical typology of 800 different geomorphological classes, and ensures the consistency between products from different areas. Landsat 7 data had to be complemented by Landsat 5 and ASTER images in several areas due to persistent cloud cover.

Products offer for the first time a thematically rich, spatially accurate and consistent representation of all reef systems worldwide. Accurate statistics on the extent, diversity and spatial structures of coral reefs are available as GIS files and regional atlases. This information has been used by a variety of research and management projects that took advantage of the hierarchical scheme to integrate the exact level of information needed.

The communication will take first the example of atolls worldwide as a model to describe the different steps involved, from the Landsat image interpretation to the GIS products and to different research and management applications. Then, an overview of the different products, statistics and applications worldwide by nations will be presented.

## 17-3

**Coral Reef Habitat Responses To Disturbance Events in Time: A Remote Sensing Approach**

**Julie SCOPELITIS*[1]**, Serge ANDREFOUET[2], Stuart PHINN[1], Pascale CHABANET[3], Odile NAIM[4], Terry DONE[5]

[1]University of Queensland, Brisbane, Australia, [2]Institut de Recherche pour le Developement, Noumea, New Caledonia, [3]Universite de la Reunion, Saint-Denis de la Reunion, Reunion, [4]Universite de Bretagne Sud, Vannes, France, Metropolitan, [5]Australian Institute of Marine Science, Townsville, Australia

Coral reef monitoring programs documenting benthic changes over time seldom work at the habitat scale. Our ability to predict post-disturbance habitat distributions can be improved by combining historical *in-situ* monitoring data with remote sensing imagery, to provide maps of temporal change. This study aimed to interpret habitat scale changes from high spatial resolution imagery and *in-situ* data for three Indo-Pacific reefs (Abore Reef, New-Caledonia, Saint-Leu Reef, Reunion Island, Heron Reef, Australia). The reefs were selected for their different disturbance histories and recovery dynamics. A reef was considered as a mosaic of habitats. A habitat was a hierarchical assemblage of geomorphology, substratum, coral cover and growth form. High spatial resolution aerial photographs and satellite Quickbird images were available for each site, as far back as 1973 for Saint-Leu. Field surveys were conducted in 2007 on each reef to create habitat typologies. Ten, eight and twenty habitats were characterized on Abore, Heron and Saint-Leu respectively. This information, along with historical monitoring data where available, was used to create multi-date habitat maps. Linking the map series to the disturbance histories for each reef allowed us to interpret the habitat response and retrace the history of the 2007 habitats. The maps revealed cyclone-induced reef degradation on Abore (2002) and Saint-Leu (1989), with coral recovery on the latter by 1997. On Heron, coral colonisation was observed across decades as channel dredging and bund wall constructions in 1965 increased the sea-level, altering reef flat hydrodynamics. This study showed that coral reef response to disturbances can be retraced at the habitat scale using remote sensing imagery and field data. This will be used to develop agent-based spatially-explicit models to help management and monitoring site selection with predictive habitat maps under natural and anthropogenic influences.

## 17-4

**Combining The Benefits Of Satellite And in Situ Data To Determine Location And Benthic Cover Of Patch Reefs in The Florida Keys**

**David PALANDRO*[1]**, Melanie PETERS[1], Luke MCEACHRON[1], Michael CALLAHAN[1], Jim BURD[1]

[1]Florida Fish and Wildlife Research Institute, St. Petersburg, FL

The abundance of live coral cover has declined dramatically over the past three decades in the Florida Keys. Research and monitoring in Florida has focused most of its effort on the offshore platform reefs located seaward of Hawk Channel. Of the offshore reef sites monitored annually by the Coral Reef Evaluation and Monitoring Project (CREMP), live coral cover averages less than 4%. These reef sites were once covered with dense live coral cover, dominated by *Acropora palmata* and *A. cervicornis*. Although much is known about the location and benthic cover, including change over time, for the offshore reefs, comparatively little is known about the patch reefs located in and around Hawk Channel. The ten patch reefs included in the CREMP surveys average 14% stony coral cover. Here we used the synoptic coverage made possible by IKONOS satellite imagery in conjunction with rapid *in situ* benthic ground-truthing to produce a map for the Lower Keys, extending from Big Pine Key to the Marquesas Keys. Specifically, we address the number, location, size and an estimate of live coral cover of patch reefs. Initial results show approximately 2500 patch reefs, which were previously estimated at 420. Mean live coral cover is 17%, ranging from 0.3% to 52% and dominated by *Montastraea annularis* and *M. cavernosa*. The high variability in live coal cover can only partially be explained by their geographic location and overlying environmental parameters, which require further detailed inquiry. The new findings provided by this study suggest that more effort may be required to better understand the patch reefs in this area, which are now home to the dominant abundance of live coral in the region.

## 17-5

**Calibration And Validation Of Coral Reef Benthic Community Maps From High-Spatial Resolution Satellite**

**Chris ROELFSEMA*[1]**, Stuart PHINN[2]

[1]Centre for Remote Sensing and Spatial Information Science, University of Queensland, St.lucia, Australia, [2]Centre for Remote Sensing and Spatial Information Science, University of Queensland, St.Lucia, Australia

Our ability to map coral reef environments using remote sensing has increased, through availability of suitable images, field methods and software. Appropriately developed and validated maps are essential for management agencies to decide if they will use these data for science and management decisions. The objective of this paper is to present a simple approach for calibrating and validating maps of coral reef benthic communities derived from high-spatial resolution satellite images. Two forms of field data for calibration and validation were applied in a supervised classification of high spatial resolution Quickbird image data to map coral reef benthic communities. Data were acquired in 2006 for three Fijian reefs representing areas with variable water clarity and benthic cover composition. The two types of field data were benthic cover estimates derived from: (1) photo transects and (2) spot checks. Each of the two field data sets were used separately with the satellite imagery to digitise two sets of polygons around target benthic community types. These polygons were used as training sites for two supervised image classifications, producing two maps of benthic community classes for each site, based on transects and point data respectively. An independent subset of the polygons was used as reference data for accuracy assessment. For the three sites mapped, no differences in overall map accuracy were observed between the two types of benthic community maps: 66 % for transect and 65% for spot check based maps. However, the transect based calibration polygons were considered to be more representative of the benthic cover due to the number of sample points and their spatial distribution. This approach showed that standard digital camera and GPS, can provide adequate field calibration and validation data for mapping coral reef communities from high spatial resolution satellite imagery for a ranges of environments.

## 17-6

**Spatial Prediction Of Reef Bathymetry And Geomorphology Using High-Resolution Satellite Imagery**

**Joaquin R GARZA-PEREZ*[1]**, Eugene C RANKEY[2], Robert N GINSBURG[2,3], Stacy L REEDER[4,5], Sean A GUIDRY[6], Humberto GUARIN[7]

[1]UMDI-Sisal, Fac. de Ciencias, UNAM, Sisal, Mexico, [2]MGG, RSMAS, U. Miami, Miami, FL, [3]Ocean Research and Education Foundation, Coral Gables, [4]MGG, RSMAS, U. Miami, Miami, Mexico, [5]Schlumberger-Doll Research, Cambridge, [6]ExxonMobil Development Company, Houston, TX, [7]Bert Instruments, Inc., Hollywood, FL

In general, geomorphology and depth are the basic drivers behind many physical and biotic processes on reefs and coastal environments. These factors shape hydrodynamics and gradients of environmental factors as water energy, light absorption and temperature, therefore the distribution of organisms varies accordingly. To better understand the morphology of reef systems, we generated 3-D models of bathymetry by applying generalized regression analysis and spatial prediction (GRASP) models based on high-resolution (2.4 -5 m resolution) satellite imagery. This technique utilizes the spatial structure of the sea bottom in imagery to generate accurate geomorphology models and bathymetry maps. The innovation of this methodology is the virtual independence of the differences in bottom albedo to generate a predictive map of depth. The technique has been successfully implemented in different Caribbean reef environments. The resulting grids/rasters and 3-D surfaces are used as a basis for static and dynamic modeling and spatial predictions of reef habitat distribution, biodiversity hotspots, reef condition, fish biomass and abundance, sediment transport, and hydrodynamics and connectivity.

## 17-7

**Casi Mapping Of The Farasan Islands (Saudi Arabia): Ecosystem Processes in An Atypical Red Sea Setting**

**Gwilym ROWLANDS*[1]**, Sam PURKIS[1], Bernhard RIEGL[1], Philip RENAUD[2]

[1]National Coral Reef Institute (NCRI), Nova Southeastern University, Dania, FL, [2]Khaled bin Sultan Living Oceans Foundation, Landover, MD

The Red Sea is typified by expansive fringing-reefs affixed to a narrow and steep coastal shelf. We present work from the South of the Red Sea where a rather different geomorphology exists. The little studied marine system of the Farasans consists of vast shallow sediment-rich banks rising from deep water, a morphology that profoundly affects the depositional environment. Satellite imagery and 3,000 km2 of airborne CASI imagery were acquired over this remote seascape. Hydrodynamic measurements atop the banks revealed low flushing rates and temperatures notably higher than encountered in adjacent deep water. These stressful factors appear to render the setting sub-optimal for corals. The hyperspectral CASI data coupled with exhaustive field survey allowed mapping of benthic character across the Farasan archipelago at exceptionally fine spatial resolution. In addition, bathymetry was retrieved from a spectral derivation of the CASI data, trained using numerous acoustic soundings made during the field campaign. The investigation reveals an abundance of fine-grained sediment sheets on-lapping topographic highs dominated by algal meadows. Despite the unfavourable environmental conditions, expansive areas of live coral were also found. These were concentrated either within shallow micro-atoll fields in the bank interior, or in deeper habitats within large but diffuse 'coral fields' interspersed with high algal cover. Though the region does not lack suitable substrate and is locally rich in coral, little evidence for frame-building was observed. The mapping revealed that the location of coral-dominated habitat was not random, but rather clustered in the northern (upstream) sector of the archipelago. Corals were not found to favour a particular depth regime, but the axis of orientation for these areas was consistent between banks. The study highlights an unusual coral setting in the Red Sea and successfully proves the existence of a vibrant but atypical ecosystem.

## 17-8

**An Investigation of Seagrass Patterns at Alphonse Atoll, Seychelles: Linking Structure To Function In Marine Landscapes**

**Sarah HAMYLTON*[1]**, Tom SPENCER[1]

[1]Department of Geography, Cambridge Coastal Research Unit, Cambridge, United Kingdom

The idea of landscapes as shifting patch mosaics, structured by a range of biological and physical stochastic forces, is well suited to shallow tropical environments, where seagrass patches lie within a matrix of soft sediments or rocky substrates. The interaction of wave fields and tidal currents with reef growth, carbonate sediment transport, erosion and accretion can result in linear morphologies, such as shore-normal spur and groove, striation of reef flat material and alternating sand tongues and seagrass beds. Patch-level metrics capture phenomena such as linearity in one variable, which can be evaluated over a gradient of predictable environmental change. A shift in focus, from the properties of the individual patch to the statistical properties of ensembles, enables the links between observed structures and the processes that govern them to be empirically investigated, yet studies of shallow benthic communities at this scale have tended to be restricted to qualitative descriptions only.

Remote sensing technology provides the opportunity to investigate critical controls of landscape mosaics through the application of geostatistical techniques to patch assemblages. Alphonse Atoll in the Seychelles was mapped using an aircraft-mounted, high resolution (1 $m^2$ pixel), multispectral (17 band) Compact Airborne Spectrographic Imager (CASI). Subsequent image processing and classification procedures generated habitat maps composed of vector data structures that represent reef features as discrete units, analogous to the concept of patches conventionally adopted by landscape ecologists. Combining habitat maps with georeferenced attribute data yields spatial data matrices that can be manipulated in a GIS environment to develop models that simplify natural processes by linking structure to function on coral reefs. This study demonstrates how remotely sensed habitat maps can be used to generate quantitative spatial variability models based on the geography of the data, a key property of remotely sensed imagery.

## 17-9

**Mapping The Habitats And Biodiversity Of Ningaloo Reef, Western Australia Using Hyperspectral Imagery**

**Halina KOBRYN*[1]**, Nicole PINNEL[1], Thomas HEEGE[2], Lynnath BECKLEY[1], Matt HARVEY[1], Suzanne LONG[3]

[1]Environmental Science, Murdoch University, Murdoch, WA 6150, Australia, [2]EOMAP GmbH&Co KG, D-82205 Gilching, Germany, [3]Department of Conservation and Environment, Kensington, Australia

The largest hyperspectral survey of a coral reef (3400 km$^2$) was undertaken in April 2006 and forms the core data set for mapping habitat components and biodiversity of the Ningaloo Marine Park, Western Australia. Optically deep waters of this region are ideally suited for remote sensing techniques and airborne data were collected by HyVista. The data are at 3.5 m spatial resolution for a 1km wide terrestrial coastal strip and out to 20m depth over lagoon and reef areas and covers wavelengths from visible to near infrared at 15nm intervals. Hyperspectral data were corrected for atmospheric, air-water interface and water column effects using the physics-based Modular Inversion & Processing System. This approach allows for quantitative and automated steps as well as the removal of subjectivity from the classification process, allowing improved transferability to additional sampling locations, field spectral datasets and extension of the monitoring to other seasons. Underwater field spectra were collected using an OceanOptics spectrometer as well as underwater photographs, to allow for accurate interpretation and validation. Results of this mapping can be compared to the transect data collected by divers from other studies and also to earlier habitat maps prepared by expert interpretation of aerial photography. Comparisons of classification results for Coral Bay area show promising results in the discrimination of branching, tabulate and massive corals as well as macro-algal assemblages. Remote sensing offers unique tools which are non-invasive, quantitative and enable mapping of large areas into a seamless data set which can be integrated with human use data, oceanographic circulation models and other spatial data sets. The hyperspectral data are being used to develop a high-resolution characterisation of the entire reef, shallow water habitats and terrestrial landforms of the coastal strip in order to support sound conservation and management of the Ningaloo Marine Park.

## 17-10

**Development Of A Field Test Environment For The Validation Of Coastal Remote Sensing Algorithms: Enrique Reef, Puerto Rico**

**James GOODMAN*[1]**, Miguel VELEZ-REYES[2], Samuel ROSARIO[2], Shawn HUNT[2], Fernando GILBES[2]

[1]University of Puerto Rico at Mayaguez, Miami, FL, [2]University of Puerto Rico at Mayaguez, Mayaguez, Puerto Rico

Remote sensing is increasingly being used as a tool to quantitatively assess the location, distribution and relative health of coral reefs and other shallow aquatic ecosystems. As the use of this technology continues to grow and the analysis products become more sophisticated, there is an increasing need for comprehensive ground truth data as a means to assess the algorithms being developed. The University of Puerto Rico at Mayagüez, one of the core partners in the NSF sponsored Bernard M. Gordon Center for Subsurface Sensing and Imaging Systems, is addressing this need through the development of a fully-characterized field test environment on Enrique Reef in southwestern Puerto Rico. This reef area contains a mixture of benthic habitats, including areas of seagrass, sand, algae and coral, and a range of water depths, from a shallow reef flat to a steeply sloping forereef. The objective behind the test environment is to collect multiple levels of image and field data with which to validate physical models, inversion algorithms, feature extraction tools and classification methods for subsurface aquatic sensing. Data collected from Enrique Reef currently includes airborne, satellite and field-level hyperspectral and multispectral images, in situ spectral signatures, water bio-optical properties and information on habitat composition and benthic cover. We present a summary of the latest results from Enrique Reef, discuss our concept of an open testbed for the remote sensing community and solicit other users to utilize the data and participate in ongoing system development.

## 17-11

**Remote Sensing Of Coral Reef Biogeochemistry Based On Optical Absorptance And Light-Use Efficiency**

**Eric HOCHBERG*[1]**, Marlin ATKINSON[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii, Honolulu, HI

We have developed a remote sensing technique for measuring coral reef benthic primary productivity based on light-use efficiency and optical absorptance. The model is GPP = $Ed A \varepsilon$, where GPP is gross primary production, $Ed$ is seafloor-incident irradiance, $A$ is seafloor absorptance, and $\varepsilon$ is the benthic community's light-use efficiency. Both $Ed$ and $A$ are derivable from various remote sensing data sources. Given appropriate values for $\varepsilon$, it is therefore possible to use remote sensing to determine GPP across spatial scales (meters to many kilometers) and in different reef environments (e.g., fore reef, reef flat). We demonstrate the utility of our approach for measuring the range and distribution of GPP across a reef system. Because reef calcification is inherently linked to photosynthesis, it is possible to define a separate light-use efficiency ($\varepsilon$calc) and thus remotely sense that rate, as well.

## 17-12

**An Investigation Into The Effects Of Coral Cover, Colony Size-Frequency Distribution And Clustering On The Classification Accuracy Of Simulated Reef Images.**

**Alan LIM*[1]**, Peter MUMBY[2], John HEDLEY[2], Chris ROELFSEMA[3], Ellsworth LEDREW[1]

[1]University of Waterloo, Waterloo, ON, Canada, [2]University of Exeter, Exeter, United Kingdom, [3]University of Queensland, Brisbane, Australia

Numerous studies have been conducted to compare the classification accuracy of coral reefs maps produced from satellite and aerial imagery at different spatial or spectral resolutions or from images processed to different levels. So far no work has been done that specifically looks at the differing spatial elements of the coral reef ecosystem and their effects on classification accuracy. In this study, we will examine how accuracy is affected by spatial elements of the reefscape by investigating the effects of colony size-frequency distribution, spatial aggregation of the coral colonies and the proportion of live coral cover at different spatial resolutions.

One of the main difficulties of such a study would be the acquisition of images that could be used to represent these different reef-scape scenarios. Additional difficulties in using actual imagery would include ensuring that improved accuracy in one instance was not the result of advantageous environmental conditions or on how well the accuracy assessment was carried out. Thus, in order to investigate these issues, we created simulated spectral reef images which could be manipulated to reflect the desired reefscapes. With simulated images, only those characteristics of the reef that were of interest would be allowed to vary, allowing us complete confidence in the results of the accuracy assessments.

The spatial elements determine the proportion of pixels in each class which are spectrally 'purer' due to lower amount of inter-class mixing. These factors will influence the number of 'purer' pixels such that images with higher coral cover, colony clustering and skew will have a greater proportion of 'purer' pixels. However, an increase in this proportion is not always related to increases in levels of accuracy. An analysis of the interactions between the various spatial elements provides an insight into how these spatial elements influence classification accuracy.

## 17-13

**Comparison Of in Situ Temperature Data From The Southern Seychelles With Sst Data: Can Satellite Data Alone Be Used To Predict Coral Bleaching Events?**

**Ben STOBART*[1]**, Nigel DOWNING[2], Raymond BUCKLEY[3], Kristian TELEKI[4]

[1]Marine Reserves, Spanish Institute of Oceanography, Palma de Mallorca, Spain, [2]Cambridge University Coastal Research Unit, Cambridge University, Cambridge, United Kingdom, [3]College of Ocean and Fishery Sciences, University of Washington, Seattle, WA, [4]International Coral Reef Action Network (ICRAN), Cambridge, United Kingdom

Degree-heating-weeks data derived from satellite sea surface temperature (SST) readings are increasingly being used to predict where bleaching is likely to occur, though predictions have not always been calibrated and corroborated by field observations. While SST can provide a good indication of water temperature, local oceanographic conditions will determine the depth to which satellite SST readings are representative. In 2003 the Aldabra Marine Programme initiated a temperature monitoring network, currently involving 40 temperature data loggers, in the southern Seychelles at Aldabra, Assomption, Astove and St. Pierre The annual temperature cycle in the region involves a shorter period of winter lows (min 23 ºC) between June and October, and extended high summer temperatures (max 30 ºC) between December and April. We compare SST temperature data from the four locations with *in situ* temperature measurements at 6m, 10m and 20m depth. *In situ* data is most similar to satellite SST during the winter period (typically not more than 1 ºC difference), and differs most during the summer period (up to 4 ºC difference). This seasonal difference is due to water column stratification during the summer, which is typified by calm weather with weak winds (though remaining a period of occasional cyclone activity). While during the winter rough weather fuelled by strong southeasterly winds reduces stratification. During the period of stratification *in situ* water temperatures are most similar to satellite data at 6m, followed less so by 10m and 20m depth. A combination of greater stratification during the summer period, along with periods of cool water upwelling, may in some cases reduce the reliability of satellite derived SST data for predicting bleaching events. We propose that during bleaching events exposure of coral communities at Astove, St Pierre and select sites at Aldabra to thermal stress may be reduced by local oceanographic conditions.

## 17-14

**New Ecological Insights From A 21-Year Coral Reef Temperature Anomaly Database**

**Kenneth CASEY*[1]**, Elizabeth SELIG[2], John BRUNO[3]

[1]National Oceanographic Data Center, NOAA, Silver Spring, MD, [2]Curriculum in Ecology, University of North Carolina - Chapel Hill, Chapel Hill, NC, [3]Department of Marine Science, University of North Carolina - Chapel Hill, Chapel Hill, NC

A wide range of new ecological insights has been enabled by advances in satellite remote sensing of the physical characteristics of the ocean. Dramatically improved algorithms coupled with advances in computational capabilities have resulted in new products with finer resolution, longer temporal coverage, greater accuracy, and better consistency. The Coral Reef Temperature Anomaly Database (CoRTAD), based on 21 years of AVHRR Pathfinder sea surface temperatures, is one such product that is yielding insights into the spatial and temporal characteristics of thermal stress and its influence on coral bleaching and disease. The development of the CoRTAD will be presented along with selected research highlights from its application to understanding thermal stress patterns, coral disease, and marine protected area design and effectiveness. In addition, information on how the extensive collection of information in the CoRTAD can be accessed and applied to global, regional, and local coral studies will be provided.

## 17-15

**A Methodology For Using Satellite-Based Temperature And Light Measurements For Predicting Coral Bleaching Severity And Mortality**

**William SKIRVING*[1]**, Roberto IGLESIAS-PREITO[2], Susana ENRIQUEZ[2], Tyler CHRISTENSEN[1], John HEDLEY[3], Mark EAKIN[1], Ove HOEGH-GULDBERG[4], Sophie DOVE[4], Scott HERON[1], Peter MUMBY[3], Alan STRONG[1], Gang LIU[1], Jessica MORGAN[1], Dwight GLEDHILL[1]

[1]NOAA Coral Reef Watch, Silver Spring, MD, [2]Universidad Nacional Autonoma de, Puerto Morelos, Mexico, [3]University of Exeter, Exeter, United Kingdom, [4]University of Queensland, St Lucia, Australia

The current NOAA Coral Reef Watch (CRW) suite of satellite products is designed to help coral reef managers monitor heat stress to better understand and predict mass coral bleaching. Although these products perform well when used to describe the onset of coral bleaching, they are not as accurate in describing the severity and mortality associated with mass coral bleaching events. The coral bleaching HotSpot and Degree Heating Week products are based purely on sea surface temperature (SST), yet coral bleaching is a physiological response that results from a combination of temperature and light. Here, we describe a potential major evolution of the NOAA CRW satellite products. A new methodology under development combines satellite-derived SST data with a new satellite-derived solar radiation product to better predict the severity and mortality of mass coral bleaching events. This new methodology is novel in that it goes beyond just examining the thermal stress, but actually combines thermal stress measurements of the existing CRW suite with light measurements from the Geostationary Environmental Satellites to provide a measure of the total photo-thermal damage.

## 17-16

**Producing A Satellite Sst Climatology – How Long Is A Piece Of String?**

**Scott F. HERON*[1]**, William J. SKIRVING[1], Gang LIU[2], Tyler R.L. CHRISTENSEN[2], C. Mark EAKIN[1], Jessica A. MORGAN[2], Dwight K. GLEDHILL[2], Alan E. STRONG[1]

[1]NOAA Coral Reef Watch, Silver Spring, MD, [2]IMSG at NOAA Coral Reef Watch, Silver Spring, MD

Coral reef ecosystem stress often occurs in response to abnormal environmental conditions (e.g., temperature, salinity, and light) rather than the absolute level of these. For example, corals in the Persian Gulf are accustomed to warmer summer conditions than corals off the coast of Brazil; as such, ocean temperatures of 30°C would be "comfortable" for the former but stressful for the latter. Identifying anomalous conditions requires good knowledge of the baseline of usual ("normal") conditions. Here we discuss whether the existing 22-year satellite sea surface temperature (SST) record is of sufficient length to calculate a long-term average (climatology) that can sensibly be used as a baseline for monitoring the health of corals. We also discuss issues related to global warming in determining this baseline and the relevance of adaptation by corals. At present, NOAA Coral Reef Watch uses near-real-time satellite temperatures to determine regions that experience thermal anomalies that have been linked to coral bleaching events. Inherent within the present operational process is a SST climatology that was defined using satellite SST data and which underpins the satellite-monitoring success.

## 17-17

**Fore-and Back-Reef Environments Interpreted from Airborne Laser Bathymetry: Northern Extension of the Florida Reef Tract Offshore SE Florida**

**Charles FINKL*[1]**, Jeffrey ANDREWS[1], William ROBERTSON[1], Beth FORREST[1]

[1]Coastal Geology & Geomatics, Coastal Planning & Engineering, Boca Raton, FL

The northern extension of the Florida Reef Tract (FRT) off SE Florida terminates in northern Palm Beach County at a southeast trending magnetic lineament known as the Bahamas Fracture Zone (BFZ). South of this morphostructural boundary, the FRT separates into a range of topologies that are based on interpretations of color-ramped imageries derived from airborne laser bathymetry (Laser Airborne Depth Sounding, LADS). LADS provided a contiguous data set in clear coastal waters to -70 m depth for 160 km of coast from onshore to about 6 km offshore. Enhancement of the LADS digital data permitted recognition of bathymetric patterns in the 600-km2 shelf survey area. Primary parabathic provinces include: (1) nearshore rocky zones dominated by limestones, (2) coral-algal reef systems (spur and groove topography, forereef rubble fields, back reef overwash deposits), (3) inter-reefal sediment troughs (partially infilled paleo mote systems) between barrier reef tracts, and (4) deep water marine terraces (paleo coral reefs) near the shelf break. Secondary sedimentary subprovinces include back reef shoreface sands, bar and trough systems, and reef gap ramps. Tertiary topographic features include drowned karst topography that was formed during glacio-eustatic lowering of sea level and subaerial exposure of reefs and limestone bedrock surfaces. Hierarchical organization of these bathymetric features is now possible due to the increased accuracy and density of bathymetric data in LADS format. Application of airborne laser bathymetric imagery for the first time permitted comprehensive differentiation of the world's third largest barrier reef environment along the southeast coast of the Florida Peninsula, separating the northern extension of the FRT from drowned beach ridge plains to the north and the Florida Keys to the south.

## 17-18

**Integrated Multi-Sensor Remote Sensing Of The Terrace Structure Of The Shallow Dry Tortugas Coral Reef Ecosystem**

**John BROCK*[1]**, Monica PALASEANU-LOVEJOY[1], Nayegandhi AMAR[1], C. Wayne WRIGHT[2]

[1]USGS, St. Petersburg, FL, [2]Wallops Flight Facility, NASA, Wallops Island, VA

Terraces have been recognized in many reef systems around the world and on last interglacial reefs this geomorphology has been linked to changes in sea level regimes. In parallel, many reef systems have an ecological zonation that correlates coarsely with geomorphology. Benthic habitat mapping of coral reef ecosystems is typically accomplished by the classification of multi-spectral images acquired from satellites or aircraft, an approach that omits the use of reef morphology in defining habitat boundaries. Aircraft lidar surveys can map fine scale reef structure, and enable the recognition of terraces on shallow coral reef ecosystems that may control the distribution of benthic communities.

The hypothesis that the shallow Dry Tortugas coral reef ecosystem is geomorphologically organized into terraces that act to control ecological zonation was evaluated. Following a NASA airborne lidar survey in August 2004 that resulted in a one-meter scale topographic map, the Wilcox signed rank test was used to verify the presence of terraces on Garden Key Bank, Pulaski Bank and Loggerhead Key Bank, the major geomorphic units of the shallow Dry Tortugas. Next, the boat-mounted Along Track Reef Imaging System (ATRIS) was used to collect voluminous observations of benthic class and topographic complexity to investigate correlation between the recognized terracing and the spatial structure of benthic habitats. A Jaccard dissimilarity analysis of interpreted ATRIS benthic images collected on transects across all three major banks of the Dry Tortugas revealed significant within and between bank differences in terrace benthic community composition.

## 17-19

**The View From Above -Are Reefs Fractal Because Of Neutral-Random Construction?**

**Samuel PURKIS*[1]**, Kevin KOHLER[1], Bernhard RIEGL[1]

[1]National Coral Reef Institute, Nova Southeastern University, Dania Beach, FL

Satellite remote sensing has shown numerous aspects of coral reef seascapes to be fractal. That is they display characteristics of scale-invariance and complexity. This property is pervasive and recognised in the geometries of both framework and lagoonal bedforms in reefal settings across the Pacific. To date, the interpretation of this curious scaling has been hampered by a lack of understanding as to why the morphometrics of reefs should be fractal. We investigate this property using high-resolution terrain models of the shallow Puerto Rico insular shelf built using bathymetric LiDAR soundings. We find that a computer-simulation model constructed using simple random processes is adequate to describe the intricacies of actual coral reef terrain. This model, based on fractional-Brownian motion (fBm), produces surfaces that are visually and statistically indistinguishable from natural seabeds, at spatial scales of 0.001 - 25 $km^2$. The conformity between model and nature prompts us to question whether the processes used in the simulation can provide insight into the construction of real-world reef platforms. Through this comparison we are able to identify simple natural processes that mimic the construction of the modelled terrains. We demonstrate that random settlement of coral colonies, followed by focused development of topographic highs, is sufficient to explain the production of fBm-like reef terrain. Importantly, this negates the requirement for secondary factors such as complex lateral interactions between habitat types, and/or the overprinting of landscape-altering processes such as sedimentation and erosion, to produce a fractal reef surface. By comparison, for terrestrial systems, such secondary processes have been identified as a necessary precursor for the creation of a fractal landscape. The findings of this study add weight to the hypothesis that the fractal property of reef terrain is the product of many simple random processes interacting at a variety of scales.

## 17-20

**Coastal Zone Classification Using Data Fusion Between Lidar And Hyperspectral Data**

**Jennifer WOZENCRAFT*[1]**, Christopher MACON[1], Grady TUELL[2], Joong Yong PARK[2]

[1]USACE - JALBTCX, Kiln, MS, [2]Optech International, Kiln, MS

Bathymetric lidar systems have been producing high resolution depth data since the late 90's.With developments in remote sensing technology and techniques the bathymetric depth map is just one of many products produced by the Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system. CHARTS is owned by the Naval Oceanographic Office (NAVO) and operated through the Joint Airborne Lidar Bathymetry Technical Center of Expertise (JALBTCX) with the U.S. Army Corps of Engineers (USACE).

The CHARTS system is a combination of multiple sensors including the Optech SHOALS-3000T20E ( 3 kHz bathymetric lidar, 20 kHz topographic lidar, and 1Hz RGB camera) and an Itres CASI-1500 hyperspectral imager. The CASI-1500 is programmable to collect between 4 to 288 spectral bands ranging from 380 nm to 1050 nm. The sensors share the same rigid platform allowing them to each use the same inertial navigation solution.

Since the integration of the CASI-1500 with the SHOALS-3000T20E, Optech International has been developing the Rapid Environmental Assessment (REA) processor. The REA processor fuses the lidar and hyperspectral image data at many levels to produce topographic land cover and bathymetric seafloor classifications with higher accuracy than previously possible. At the signal level, information extracted from the lidar waveform is used to invert the radiative transfer model for seafloor reflectance in the hyperspectral imagery. At the classification level, independent classifications based on lidar parameters like depth, bottom reflectance, and bottom roughness and on the hyperspectral bottom reflectance are merged using the Dempster-Schafer algorithm.

In January 2007, JALBTCX collected topographic, bathymetric, and hyperspectral data in and around Hilo Bay, Hawaii. Using these datasets and the Optech REA processor, JALBTCX has produced the first production level lidar and hyperspectral fusion derived seafloor classifications.

## 17-21

**A Comparative Assessment Of Lidar And Multibeam Sonar To Characterize Coral Reef Ecosystem**

**Timothy BATTISTA*[1]**, Bryan COSTA[1,2]

[1]National Ocean Service, NOAA, Silver Spring, MD, [2]National Ocean Service, NOAA, Silver Spring

A comparison of airborne LiDAR and ship-based mulitbeam sonar was conducted in southwest Puerto Rico to evaluate the efficacy of these systems in characterizing shallow-water coral reef environments (< 30 meters water depth). Multibeam sonar acquisition in shallow-water environments is prohibitive due to the relationship between swath width and water depth. The availability of comparable data products from airborne LiDAR (i.e., bathymetry and seafloor reflectance) provides an alternative to multibeam sonar surveys to collect seafloor characterization data. The test location, Abrir la Sierra conservation area, is comprised of a suitable diversity of topographic relief, geomorphological structure and biological cover types to test the utility of data derived from the respective remote sensing platforms. An evaluation was conducted to compare the efficiency, data integrity, and effectiveness of the LiDAR and multibeam sonar systems to discriminate meaningful landscape patterns. This analysis was conducted to allow resource managers and scientists to determine the most effective remote sensing platform to characterize shallow-water tropical marine environments.

## 17-22

**Statistical Comparison Of Single-Beam Acoustic Backscatter (38 And 418 Khz) With Lidar-Derived Coral Reef Benthic Habitat Class And Topographic Complexity**

**Greg FOSTER*[1]**, Walker BRIAN[1], Bernhard RIEGL[1]

[1]National Coral Reef Institute, Dania Beach, FL

Producing coral reef benthic habitat maps from acoustic backscatter has been hindered by uncertainties in interpreting the acoustic energy parameters E1 (roughness) and E2 (hardness), typically limiting such maps to sediment classification schemes. In this study acoustic interpretation was guided by high-resolution LADS (Laser Airborne Depth Sounder) bathymetry. The acoustic survey was conducted in Palm Beach County, FL, from inshore sand to outer reef slope, using a multiplexed echosounder (BioSonics DT-X at 38 & 418 kHz). E1 and E2 values, empirically normalized to mean depth, were compared to spatially-coincident values of a LADS-derived proxy for topographic complexity (Reef-Volume) and eight LADS-delineated benthic habitat classes. The 38 and 418 kHz E1 parameters were positively correlated with Reef-Volume, in agreement with the general empirical basis for bottom seabed classification. The opposite trend was observed for the 38 and 418 kHz E2 parameters, contrary to convention, which would predict an increasing trend of E2 from sand (soft, flat) to colonized pavement (hard, flat). Tukey HSD testing proved all four acoustic parameters capable of distinguishing between habitats; significant differences ranged from 25-27 of the k(k-1)/2=28 comparisons between the eight habitat categories. An *a posteriori* discriminant analysis of each frequency, pairing E1 and E2 as predictor variables, showed that the 418 kHz signal provided superior predictive accuracy for six (consolidated from eight) habitat classes (74.3 versus 68.2%). Consideration of all results reveals topographic complexity as the primary factor controlling both E1 and E2. The information encoded in the two frequencies is generally the same, with 418 kHz being better suited for discriminating between habitats of high complexity and 38 kHz for distinguishing between sand and sand-over-hardbottom. The LADS bathymetry proved useful for demonstrating that E1 and E2 values of single-beam echosounders can indeed produce meaningful coral reef benthic habitat maps.

## 17-23

**Measuring The Rough With The Smooth: Predicting Fish Species Richness Using Lidar Derived Surface Complexity**

**Simon PITTMAN*[1]**, Bryan COSTA[2], Tim BATTISTA[2]

[1]Biogeography Branch, NOAA & University of the Virgin Islands, St Thomas, Virgin Islands (U.S.), [2]Biogeography Branch, NOAA, Silver Spring, MD

Coral reef ecosystems exhibit complex vertical and horizontal structural heterogeneity at a range of spatial scales. This heterogeneity plays an important ecological role in influencing the distribution, abundance and behaviour of marine organisms. For example, more complex structures typically support higher species richness than less complex structures. Measures of surface complexity in the marine environment have been widely used to quantify structural heterogeneity, yet most studies have focused at relatively fine (<10 m) spatial scales and within single habitat types. Here we calculate several different measures of surface complexity at multiple spatial scales from LiDAR data collected from nearshore environments of southwestern Puerto Rico. We then evaluate their relative performance as predictors of fish species richness across topographically and compositionally complex mosaics of habitat types. The value of LiDAR data as a tool to support decision making in living resource management could be immense, if remotely sensed structural complexity can be linked effectively to biological patterns and processes.

## 17-24

**Remote Sensing For Studies Of The Local Spatial Distribution Of Coral Reef Fishes**

**Anders KNUDBY*[1]**, Candace NEWMAN[1], Ellsworth LEDREW[1]

[1]Department of Geography, University of Waterloo, Waterloo, ON, Canada

The local spatial distribution of fishes on a coral reef show that reef fish biodiversity is influenced by habitat variables including coral cover, depth, rugosity, and the distance to the reef edge. Commercially available satellite imagery can be used to map these habitat variables, and fish biodiversity can be estimated using the resulting habitat maps. We present a case study from two reefs in Zanzibar, Tanzania, based on high-resolution IKONOS imagery acquired concurrently with habitat and fish survey data from 2007. The influence of additional habitat variables, difficult or impossible to measure in-situ but mappable using satellite imagery, such as substrate beta-diversity and depth variability at a range of spatial scales, are also explored. We illustrate how accurately each habitat variable can be estimated using remote sensing, and how predictive each variable is for the local spatial distribution of fish biodiversity. We show a strong influence of the mapped habitat variables on fish biodiversity, and also show that the derived fish-habitat relationships change substantially between protected and unprotected areas. High-resolution satellite imagery is shown to have substantial value for spatial studies of fish biodiversity on coral reefs. Further research and/or future data sources are expected to improve estimation of several habitat variables, and thereby the accuracy of fish biodiversity maps.

## 17-25

**A Novel Model Framework For Predicting Organismal Distributions Across The Seascape Using Gis Topographic Metrics And Benthic Habitat Associations.**

**Brian WALKER*[1]**

[1]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Dania Beach, FL

Increased topographic complexity has been linked to increased species diversity and/or abundance in many ecological communities including coral reefs. Several topographic metrics can be measured remotely in GIS using high resolution bathymetry including elevation, surface rugosity, and seafloor volume within specified areas. Statistical relationships between these data and organismal distributions within mapped habitats can be used to make predictions across the entire bathymetric dataset. In this study a model framework is presented which determines statistically significant relationships between reef fish abundance and species richness and GIS topographic complexity measurements for samples within similar benthic habitats. Predictions from these relationships for each habitat were then projected to create GIS-based prediction maps of abundance and species richness for the entire seascape. Reef fish associations with GIS topographic metrics were significant and varied between habitats. Model evaluation showed that patterns in the measured data emerged in the prediction data. The results allow for viewing of data trends throughout the seascape, quantification of assemblages in non-sampled areas, and statistical comparisons of areas within the region to support and guide management related decisions. This model framework can be adapted to other communities (e.g. benthic organisms) and/or parameters (e.g. diversity) that relate to topographic complexity.

## 17-26

**An Investigation Of Reef Fish Community Modelling With Geostatistical Methods**

**Jeanne DE MAZIERES*[1]**, James COMLEY[2]

[1]School of Marine Studies, University of the South Pacific, Suva, Fiji, [2]Institute of Applied Science, University of the South Pacific, Suva, Fiji

The objective of this study was to determine the spatial distribution of reef fish communities according to the habitat types of the Coral Coast, Fiji Islands by using geostatistical analysis methods. The Coral Coast is located on the south coast of Viti Levu, Fiji's main island which is bordered by a fringing reef about 80 km long. The study area was divided into 22 geomorphological reef units where biological data were previously collected. Substrate cover and fish counts were obtained for a total of 312 transects. Data were processed and a spatial database was created including the location of the surveyed transects associated with quantitative and qualitative information on substrate cover, habitat type and fish family abundance. We worked with six classes of habitats (sand, rubble, bedrock, macroalgae, seagrass and live coral) which were distinguished according to thresholds of 20% for the biotic substrate and 50% for the abiotic. Nine fish families were selected due to their importance for the fisheries and as reef health indicators. We conducted batches of exploratory and multivariate statistical tests to identify distinct and significant patterns of fish assemblage distribution at both scales of the reef system and the reef unit. The overall results showed that sand, seagrass and live coral habitats hosted significantly different communities. We then determined the fish families which were characteristic of those habitats. Their distribution was predicted at the reef unit scale by using the cokriging geostatistical model which allowed multivariate interpolation and estimation of prediction error. It seemed that the quality of the estimations varied highly depending on the reef unit and the family. Used as a complement to the others available tools, this geostatistical model might provide a useful support for decision-making and management of the reef resources.

## 17-27

**Predictive Habitat Mapping Of Deep Or Turbid Coral Reefs Using An Ecological Modelling Approach With Multibeam Data**

**Ben RADFORD*[1]**, Kimberly VAN NIEL[1], Karen HOLMES[1,2], Gary KENDRICK[3], Jessica MEEUWIG[3], Euan HARVEY[3]

[1]School of Earth and Geographical Sciences, University of Western Australia, Perth, Australia, [2]Centre for Ecohydrology, University of Western Australia, Perth, Australia, [3]Botany, University of Western Australia, Perth, Australia

In the past coral reef mapping using forms of remotely sensed data (such as satellite imagery, aerial photography) has been largely been limited areas shallower 30 meters of water depth because of light availability. However in resent years this has changed with in the introduction of sensors that can collect high resolution "Multibeam" sonar data. Multibeam sonar provides the potential to map at broad scale by providing high resolution bathymetric and substrate information from water depths of 20 to over 60 meters, When combined with an ecological modelling approach, multibeam and towed video imagery provide the basis for mapping living coral on deep or turbid coral reefs.

Here we outline this approach integrating data capture with analysis methods and ecological theory. We demonstrate this mapping method using deeper coral reefs areas from the Abrolhos Islands, Western Australia. This mapping approach involved a number of stages: (1) collecting and processing of raw data, (2) extensive secondary modelling on primary data, such as bathymetry, to develop spatial surfaces which are relevant to both the physical (e.g. h) and biotic aspects of a site, (3) integrating spatial surfaces and in situ information, (4) the development of predictive habitat models, and (5) the spatial extension of the in situ data to the unknown areas using the predictive models. Each of these steps is essential to build realistic spatially explicit models of reef substrate and major biotic groups. Predictive modelling methods were used to explore the data and final predictions were developed using a novel approach of merging multiple biotic predictions. This framework facilitated development of high accuracy maps of hard coral distribution (and other important biotic groups) were traditional spectral remote sensing would fail.

## 17-28

**Seafloor Characterization Using Multibeam and Optical Data at French Frigate Shoals, Northwestern Hawaiian Islands**

**Jonathan WEISS*[1]**, Joyce MILLER[1], John ROONEY[1]

[1]Joint Institute for Marine and Atmospheric Research, University of Hawaii, and NOAA Pacific Islands Fisheries Science Center, Honolulu, HI

Multibeam bathymetry, backscatter, and optical data collected by NOAA's Coral Reef Ecosystem Division are used to create maps of seafloor habitats on the bank top at French Frigate Shoals in water depths ranging from <10-100 m. Supervised classification of backscatter and optical data with user-defined classes results in seafloor maps such as hard (rock, rubble, etc.) and soft (sandy) bottom that are useful. However, they suffer from a dependence on the optical data. Uncertainties in camera sled positioning, difficulty maintaining consistent tow depths, and user bias in the optical classification and supervised class definitions suggest an alternate approach may be necessary. Unsupervised classification of different combinations of bathymetry and backscatter derivatives uses the statistical separability of the data to define unique seafloor types. The optical data are then used to define and evaluate the accuracy of the classes. Habitat mapping using multibeam data in coral reef ecosystems presents unique challenges compared to other settings. A variety of methods are being evaluated and the resulting maps are being used to improve sampling techniques for long-term ecosystem monitoring, to guide future groundtruthing operations, and to identify coral-rich and species specific environments in the NWHI.

## 17-29

**Semi-Automated Classification Of Acoustic & Optical Remotely Sensed Imagery in The U.s. Caribbean**

**Bryan COSTA*[1]**, Tim BATTISTA[1], Charles MENZA[1]

[1]Biogeography Branch, NOAA/NOS/NCCOS/CCMA, Silver Spring, MD

Benthic habitat mapping supports ecosystem-based management objectives by contributing to the development of detailed species utilization models linking physical habitats with biological information. Marine habitats deeper than 30 meters have been successfully characterized by conducting heads-up digitizing of acoustic and optical remotely sensed imagery. These resulting maps, however, are subjective and ultimately irreproducible because they depend on the accuracy and interpretation of the person that is digitizing. Here we semi-automate the seafloor feature extraction and classification process using high-resolution MBES and LiDAR data as well as underwater images collected off the coast of western Puerto Rico. Alternative approaches were used to identify and extract seafloor features at relevant spatial and thematic scales. The accuracy of these mid to deep-water benthic habitat maps were validated using georeferenced underwater imagery. The ability to quickly and objectively create benthic habitat maps would allow scientists and resource managers to better quantify and assess the changing health of mid to deep-water coral reef ecosystems.

## 17-30

**Mapping Marine Habitats in The Largest Reef Area Of Southern Atlantic: The Abrolhos Bank, Brazil**

Daniel KLEIN[1], Alex BASTOS[2], **Guilherme DUTRA*[3]**, John MUSINSKY[4], Ruy KIKUCHI[5], Rodrigo MOURA[6]

[1]Marine Management Areas Science Program, Conservation International / UFBA, Caravelas, Brazil, [2]Laboratório de Oceanografia Geológica, DERN, UFES, Vitória, Brazil, [3]Marine Program, Conservation International Brazil, Salvador, Brazil, [4]CABS, Conservation International, Arlington, VA, [5]Centro de Pesquisas em Geofísica e Geologia, UFBA, Salvador, Brazil, [6]Marine Program, Conservation International Brazil, Caravelas, Bahia, Brazil

The Abrolhos Bank is the largest and richest coral reef area in the South Atlantic, covering 46,000 km$^2$ of shallow waters (up to 100 m deep) in the Northeastern Brazilian Continental Shelf. The region bears a mosaic of estuaries, mangrove forests and coralline reefs, as well as rodolith, grass, algae and muddy beds. Despite its importance, most of the bank remains unmapped in terms of the extension and distribution of its habitats, with the exception of emergent coralline reefs mapped in coarse scale with remote sensing (TM Landsat). This situation represents a major impediment for effective conservation planning, zoning and monitoring of marine managed areas. The project described herein is producing finer scale maps covering Abrolhos' main marine habitats with use of side scan sonar (Edgetech) surveys at two different scales: 1) East-West transects from shallow areas (20 m) to the shelf break, each transect spaced by 10 km (100 kHz); 2) finer scale mapping between the initial transects, in areas with hard bottom structures and higher habitat heterogeneity (500 kHz). Subsequent ground truth with targeted SCUBA dives, ROV (Remotely Operated Vehicle) and bottom grabbers are assisting habitat classification. Preliminary results are showing extensive areas of unmapped reefs (hard structures), as well as a great habitat diversity in inter-reefal areas. Paleochannels and other more isolated depressions were also recorded and observed along the Bank's plains. Habitats' maps resulting from these surveys will be critical for developing strategies for the sustainable use of the region's unique seascape.

## 17-31

**Single Beam Acoustic Remote Sensing For Coral Reef Mapping**

**Arthur GLEASON*[1]**, Pamela REID[1], Todd KELLISON[2]

[1]Marine Geology and Geophysics, University of Miami / RSMAS, Miami, FL, [2]NOAA Southeast Fisheries Science Center, Miami, FL

Coral reef habitats that cannot be mapped with optical techniques are both extensive and ecologically important. For example, over 55% of the Florida Keys National Marine Sanctuary (about 1540 square nautical miles) has not been mapped due to water depth or clarity limitations. Acoustic mapping systems are the natural solution to mapping optically deep water, and inexpensive commercial single beam seabed mapping systems are available. Several studies have used commercial single beam systems to map coral reefs, but basic questions about what substrates can be reliably distinguished and how consistent classification schemes are in different areas have not been systematically explored. We have used one commercial system, the Quester Tangent Series V (QTCV) to begin answering such questions. QTCV datasets from the Florida Keys, USA, the Bahamas, and Navassa Island reveal that rock and sediment are almost always reliably distinguished and that sediment grain size and high seabed relief are other factors captured by classification results. Moderate resolution (~100 m transect spacing) surveys in the Florida Keys are sufficient to delineate the extent of outlier reefs and to differentiate two distinct outlier reef morphologies: patches and linear ridges. Due to their low cost and portability, single beam systems can play a valuable role in coral reef mapping efforts, efficiently providing rapid reconnaissance and moderate resolution habitat maps of large areas.

## 17-32

**Characterization And Monitoring Of Insular Shelf Reefs in Optically-Deep Waters**

**Roy ARMSTRONG*[1]**, Maria CARDONA[1], Hanumant SINGH[2], Sara RIVERO[1], Fernando GILBES[1]

[1]University of Puerto Rico, Mayaguez, Puerto Rico, [2]Woods Hole Oceanographic Institution, Woods Hole, MA

Although remote sensing technology is a useful tool for monitoring shallow (<20 m depth) coral reefs present in clear oligothrophic waters, the large-scale assessment of reefs present in optically-deep waters require other approaches such as indirect methods or the use of *in situ* platforms for high-resolution optical and acoustic imaging. Optically-deep waters as those where the upwelling radiance received by the airborne or satellite sensor originates from the water column without any bottom signal contribution. These waters could be relatively shallow but mostly turbid or clear waters at depths of 30 m or more. For shallow reefs in clear to turbid areas we developed an indirect approach to infer coral reef community parameters based on the attenuation coefficient of photosynthetically-active radiation (Kd $_{PAR}$) of surrounding waters. Water optical measurements and coral reef surveys at 19 study sites along the south and west coasts of Puerto Rico were obtained. An inverse relationship ($R^2$ = 0.92) between Kd $_{PAR}$ and percent cover of living corals was found.

We used the Seabed autonomous underwater vehicle (AUV) for imaging mesophotic reefs, those present between 30 to about 100 m depth, using digital photo transects. Each transect was approximately 1 km in length and produced over 800 images, each about 3.1 m wide by 2.5 m long. These AUV transects have provided the first comprehensive data set of the deep coral reef habitat of Puerto Rico and the U.S. Virgin Islands. We found high coral cover at depths of 40-47 m at several sites south of St. Thomas and St. John (USVI), and between 35-40 m at Black Jack Reef, Vieques Island. These healthy and structurally-complex mesophotic reefs appear to be an abundant and ecologically-important habitat within the Puerto Rico-USVI geological platform.

## 17-33

**Geospatial Analysis: An Effective Tool For Simulating The Spatial And Temporal Dynamics Of Tropical Cyclone Disturbance Of Coral Reef Communities Across The Great Barrier Reef Region**

**Marji PUOTINEN*[1]**, Katharina FABRICIUS[2], Glenn DE'ATH[2], Terry DONE[2]

[1]School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia, [2]Australian Institute of Marine Science, Townsville, Australia

Tropical cyclones (hurricanes, typhoons) can cause major mechanical damage to coral reefs, which when repeated over time, can significantly affect the structure and function of reef communities such as those of Australia's Great Barrier Reef (GBR). Understanding the timing and frequency of these events (disturbance regime) requires mapping both the energy generated by each of a representative set of cyclones and the subsequent reef damage. However, direct measurements like these are rare in the GBR. For this reason, a meteorological model adapted to run in a GIS was used to reconstruct maximum wind speeds (as a proxy for wave heights) for 85 cyclones that passed near the GBR from 1969 to 2003. A comparison with limited field data of damage from cyclones Ivor and Joy (1990) and Justin (1997) was used to establish thresholds of maximum winds capable of damaging reefs. From these, a disturbance history was constructed. In 2005, severe tropical cyclone Ingrid crossed the Far Northern GBR, a region that had not been affected by major disturbances of any kind for several decades, and where benthic data had been collected before the event. This provided a unique opportunity to test the skill of the model in predicting reef damage and to refine the damage thresholds. An extensive field survey (82 sites on 32 reefs along the modelled wind gradient) showed that the types and intensity of damage were well explained by modelled maximum wind speed, and by spatial and biotic factors. For example, maximum winds <28 cm $s^{-1}$ for <12 hours inflicted only minor damage on any reef, but winds >33 m $s^{-1}$ and >40 m $s^{-1}$ caused catastrophic damage on inshore and offshore reefs, respectively. These results are being used to better understand both current and future (possible greater frequency / intensity) cyclone disturbance regime dynamics.

## 17-34

**Marine Integrated Decision Analysis System (Midas)**

**Suchi GOPAL*[1]**, Les KAUFMANN[1], Hrishi PATEL[1]

[1]Boston University, Boston, MA

Marine areas are critical regions on the Earth's surface as nearly two-thirds of the world's people live within 150 km of a coastline and are dependent on marine resources. Marine conservation has become seminal in this context. We present a spatial decision support system framework called MIDAS - Marine Integrated Decision Analysis System that integrates spatial and nonspatial data for marine management. The components of MIDAS are: (1) JIM (Java Interface for Managers) a graphic interface and JAVA code (programming) that allows a MMA manager to change parameters or conditions as a thought experiment and see outputs or consequences of a user-driven change in parameter states; (2) a GIS database that appears in map form, called JIM-Mapper, implemented using ArcIMS, that allows for dynamic GIS displays and spatial analysis; 3) a Bayesian Belief Networks (BBNs) to provide an appropriate method for developing predictive models of marine management effectiveness. The marine BBN's general structure is that of an integrated knowledge extraction/expert system. Knowledge is extracted from scientific literature as well as from experts for representing concepts as well as their relationships. BBNs represent information in the form of probabilities, enabling many different sources of data to be integrated and analyzed according to a common framework. We discuss the implementation of the three components of MIDAS for Belize and Brazil marine coastal management.

## 17-35

**A Procedure To Target Coral Reef Deterioration Using Ikonos Satellite Imagery, Zone Boundaries, And Coral Reef Use**

**Candace NEWMAN*[1]**

[1]Geography, University of Waterloo, Waterloo, ON, Canada

We have developed a procedure to identify specific locations of coral habitat that have a 'high probability of acute deterioration' caused by human impact. The procedure uses satellite imagery, coral zonal boundaries, and coral reef use by dive operators and fishermen. The procedure involves development of a habitat map, then overlaying zonal boundaries and reef use data in a GIS. Using a set of criteria, sites with a 'high probability of acute deterioration' are identified, and then validated using in-situ field survey data. The potential for this procedure to address local coral reef management issues is significant, and relevant to current management projects on Bunaken Island, Indonesia.

It is increasingly evident that context-relevant maps are essential to address acute coral reef degradation concerns in developing nations. On Bunaken Island, specific coral reef management projects are consistently undertaken, and many projects are focused on conflict resolution between coral reef resource user groups – dive operators and fishermen. Therefore, a challenge is to utilize remotely sensed information, combined with context-specific information, to contribute relevant and useful management information to these projects.

In this study, we develop a procedure to address this challenge. IKONOS satellite imagery was captured in 2001 and 2004 and has been integrated with zonal boundary data of Bunaken Island, which recognizes different coral reef use activities and coral reef use data by dive operator and fishermen groups. Following integration and analysis in a GIS, sites of 'high probability of acute deterioration' have been identified. Results were validated using field survey data, as well as contributions from Universitas Sam Ratulangi and local NGOs.

## 17-36

**The Coral Reef Landscape: Spatial Patterns Of Water Quality in The Florida**

**Daniel WAGNER*[1]**, Eric MIELBRECHT[2], Robert VAN WOESIK[1]

[1]Department of Biology, Florida Institute of Technology, Melbourne, FL, [2]Emerald Coast Environmental Consulting, Washington, DC

While we have some peripheral understanding of water-quality 'weather', which includes nutrients, salinity, temperature and turbidity, we know little about the coral-reef landscape 'climate' and the influences of that climate on coral-community structure. Determining the scales of the inherent variability of key environmental variables is clearly necessary. We use landscape-ecology techniques coupled with Geographic Information Systems (GIS) technologies to examine the spatial dynamics of specific water-quality parameters along the Florida Keys reef tract. The spatial distance at which temperature variance stabilized throughout the region was dependent on whether the samples were from the surface or near-substrate. Greater homogeneity was found for near-substrate temperatures, with patches at ≤ 1.075 km compared to ≤ 0.893 km for the surface. Salinity was more homogeneous at the surface (≤ 1.662 km) than near the substrate (≤ 0.234 km). Surface chlorophyll a showed greater homogeneity at ≤ 0.592 km while DIN patches were more homogeneous near the substrate (≤ 2.873 km) than at the surface (≤ 0.151 km). The greater variability of other parameters, including turbidity and total nitrogen, precluded accurate predictions at the applied spatial scale of sampling. This is not to say turbidity for example is not important, because it is, but we need to re-evaluate the sampling strategy to capture the inherent scale at which these parameters vary. Moreover, temperature variance decreased across the shelf from inshore zones to offshore as a function of distance from the shoreline. The significant difference between surface and near-substrate temperatures seriously questions the commonplace use of sea surface temperature data in evaluating direct influence on reef corals because it ignores the variability of the system due to the stratification of the water column.

## 18-1

**Stony Coral Status And Trends in Dry Tortugas National Park (Florida, Usa): 1975-2007**

**Douglas MORRISON*[1]**, Walt JAAP[2], Carl BEAVER[2], Michael CALLAHAN[2], Dustin JOHNSON[2], Jim KIDNEY[2], Selena KUPFNER[2], Shannon WADE[2], Jennifer WHEATON[2]

[1]Dry Tortugas National Park, USNPS, Key Largo, FL, [2]Florida Fish and Wildlife Research Institute, FFWCC, St. Petersburg, FL

Coral reefs are arguably the most important natural resource in Dry Tortugas National Park (DTNP). Stony coral abundance in DTNP has been monitored periodically since the mid-1970's using multiple methods. Live coral percent cover has been measured using photo quadrats and video transects at fixed stations. Larger scale assessments of coral spatial extent have been conducted using aerial and in-water surveys. There has been a substantial decrease in stony corals, especially *Acropora spp*., over the last 30 years. There were 479 hectares of *Acropora* dominated reefs (mostly *A. cervicornis*) in the park in 1976; but, there are currently only about four hectares of live *Acropora* thickets, a 99% loss. Furthermore, *Acropora* live cover is ≤5% on these existing reefs. Reef forming *Montastrea, Siderastrea*, and *Colpophyllia* coral species also have declined in abundance. Mean coral cover at a long term monitoring site dominated by *Montastrea spp*. and *Colpophyllia* decreased from 45% in 1975 to 10% in 2006. Stony coral abundance declined 25% at seven monitoring sites from 2005 to 2006, based on pooled means (6.3% cover in 2005 and 4.7% in 2006; $p<0.004$, Wilcoxon paired sample test). Most coral loss in the 1970's and 1980's was caused by hypothermic events (strong cold fronts) and disease. More recent coral loss has been due to disease and bleaching; and five hurricanes in a 14 month period in 2004 and 2005, an unprecedented occurrence in the 130 year history of Tortugas science. Coral decline is the most significant and challenging DTNP resource stewardship issue. U.S. National Park Service science and stewardship strategies addressing this issue are discussed.

## 18-2

**Status Of Florida Keys Coral Reefs Based Upon Multiple-Scale Sampling**

**Mark CHIAPPONE*[1]**, Dione SWANSON[2], Leanne RUTTEN[1], Steven MILLER[1]

[1]Center for Marine Science, University of North Carolina-Wilmington, Key Largo, FL, [2]Division of Marine Biology and Fisheries, RSMAS-University of Miami, Miami, FL

Large-scale coral reef benthic surveys in the Florida Keys utilizing a two-stage stratified random sampling design provide context to smaller-scale monitoring and experimental studies, and reveal a complex spatial and temporal pattern of reef status. Shallow, offshore reefs historically dominated by Acropora palmata are now, depending upon regional location, dominated either by Palythoa and Porites astreoides or by gorgonians and Millepora. Stony coral cover is currently low (< 10%) for most reefs, except those with existing A. palmata stands, where coverage is upwards of 25%. Patch reefs further inshore reveal a different spatial pattern, with greater coral species richness, colony density, size, and cover, especially by mounding corals, even though the Florida Keys inner shelf margin is closer to shore and experiences considerable environmental variability. Low-relief hard-bottom areas interspersed between higher relief reefs continue to exhibit dominance by turf algae and gorgonians, with very low coral abundance (< 5%). Deeper fore reef slope areas are intermediate in terms of coral species richness and abundance between the patch reef and shallow fore reef environments. Temporal comparisons since 1999 reveal a pattern of relative stability at multiple scales. Comparisons between no-fishing zones and corresponding reference habitats illustrate the non-random placement of 23 of these relatively small zones, as they were selected because of factors such as coral species richness and cover. Diadema antillarum densities are still well under 1 individual/m2 compared to pre-1983 values, although there is some indication that densities and sizes increased since 1999. Scleractinian coral disease prevalence is upwards of 2% of the Florida Keys coral colonies. Coral bleaching was relatively mild until 2005, when a moderately severe event impacted most species and ~25% of colonies, followed by a less severe episode in 2007.

## 18-3

**Shifting Dominance And Diversity On A Florida Forereef: Is The Ripple Effect Gaining Momentum?**

**Stephen GITTINGS*[1]**, Mitchell TARTT[1], Steven MILLER[2], Sarah FANGMAN[3], Patrick GIBSON[4], Lad AKINS[5], Mark CHIAPPONE[2], Dionne SWANSON[6], Allison WHITE[2]

[1]National Marine Sanctuary Program, NOAA, Silver Spring, MD, [2]University of North Carolina at Wilmington, Key Largo, FL, [3]National Marine Sanctuary Program, NOAA, Savannah, GA, [4]University of North Carolina, Chapel Hill, NC, [5]Reef Environmental Education Foundation, Key Largo, FL, [6]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

Since 1994, benthic cover and fish populations have been monitored between 20 and 30 m depth on Conch Reef, Florida Keys, to assess change in a deep fore reef community on the reef tract. Surface and saturation divers collected repetitive and random photographic data during four expeditions between 1994 and 2007, and counted fish, brittle stars, and sea urchins beginning in 1998. They measured coral, sponge, and algae cover, brittle star and sea urchin abundance, and fish richness and relative abundance. Our findings suggest that changes and impacts from declining environmental quality pervade this coral reef community. Cover data reflect a trend of increasing dominance by algae on Conch Reef. Invertebrate surveys show a lack of recovery of the long-spined sea urchin, Diadema antillarum, following the 1983 mass mortality of the species. The loss of this important herbivore has been linked to the proliferation of algae on the reef. An unexpected finding was the near absence of brittle stars inhabiting Conch Reef in 2007. A total of 360 individual surveys (visual inspections of the underside of rocks at three depths; 6m, 20m, and 30m) yielded only three individuals. Data from research published in the 1970s suggested abundances 250 times higher. This raises the concern that there may be widespread biodiversity loss among other taxa for which information is lacking. This would have significant implications on ecosystem integrity in a community that depends heavily on multi-species interactions, and represents a formidable challenge for marine protected area management.

## 18-4

**Ten Years And Counting: The Coral Reef Monitoring Project in The Florida Keys**

**James W. PORTER*[1]**, and Coral Reef Monitoring Team -[2]

[1]Odum School of Ecology, University of Georgia, Athens, GA, [2]-, -, FL

Coral reefs of the Florida Keys are the most studied, regulated, and protected tropical marine ecosystem in the world. Despite all of this attention, over the last decade, reefs of the Florida Keys have lost 50% of their living coral cover (falling from a survey-wide average of 12.1 % cover to 6.1%). In addition, 25% of all study sites have fewer species in them now than in 1996. Major reef-building corals, such as the iconic branching coral *Acropora palmata* and the massive monument coral *Montastraea annularis* have lost 85% and 33%, respectively, of their projected surface area. Coral loss (in terms of either reduced species number or coral cover) is greatest in the Upper Keys (off Key Largo) and in the Lower Keys (off Key West), and least in the Middle Keys (off Marathon). Bleaching and disease have contributed causally to these declines. *Diadema* density remains remarkably low, but has increased slightly from $0.0008/m^2$ in 1996 to $0.0033/m^2$ in 2006. Despite some inter-annual variation, neither octocoral nor marcolagal abundance has changed appreciably over the ten years of the project.

In the last half decade, coral loss in the Florida Keys has slowed considerably, perhaps providing a respite within which to enact stronger local (wastewater and stormwater master plans), state (wastewater treatment standards), federal (no-discharge zones, navigational aids, and tougher water quality standards), and international (green house gas) legislation to protect coral reefs.

## 18-5

**Coral Reef Habitat Around New Providence Island, Bahamas**

**Walter JAAP*[1]**, Jennifer DUPONT[2], Walter JAAP[1]

[1]Lithophyte & USF CMS, St. Petersburg, FL, [2]USF CMS, St. Petersburg, FL

In July 2006, the Academy of Natural Sciences of Philadelphia organized an expedition to New Providence Island, Bahamas. Sampling sites were based on the Böhlke and Chaplin's (1968) field notes and recollections of Gordon Chaplin (participant in the original studies). Coral species richness and cover, and reef surface rugosity were examined at three depth zones: 1.5 to 6.1 m (1), 6.2 to 7.6 m (2), 7.7 to 15.2 m (3) at Delaport Point (DP), Green Cay (GC), and Long Cay (LC). Greatest number of coral species (27) was observed at DP-2 and the fewest (14) at DP-3. Rugosity was greatest at GC-1 due to the spatial complexity of an *Acropora palmata* reef. Coral cover tracked well with rugosity index (RI); GC-1 with an average RI of 1.7 had coral cover (20.56%) superior to the other stations. Algae were the most abundant benthic cover component: mean= 50.99 ± 25.45% (SD) for all stations; stony coral cover ranged from 0.65 to 20.56%, and the mean was 6.72 ± 6.94%. Similarity (Bray Curtis coefficient) was greatest among GC stations and transects; weakest transect similarity occurred at DP-2. ANOSIM two-way crossed test documented that replicate transects at sampling stations were not different (Global R =0.066); however, site locations were different (Global R = -0.259). SIMPER analysis documented that when the algae genera were removed from the analysis, *Acropora palmata* contributed 20 to 30% of dissimilarity in setting GC-1 apart from other stations. Taxonomic Distinctness (□+) and Variation in Taxonomic Distinctness (Lambda+) evaluations reported that □+ is stable and Lambda+ shows strong variance.

## 18-6

**The Almost Total Loss Of Acropora Palmata From The Shallow Waters Off Barbados, West Indies, Initiated By Catastrophic Destruction Of A Major Bank-Barrier Reef Off The Southeast Coast**

**Ian MACINTYRE*[1]**, Peter GLYNN[2], Marguerite TOSCANO[1]

[1]Paleobiology, National Museum of Natural History, Smithsonian Institution, Washington, DC, [2]RSMAS - MBF, University of Miami, Miami, FL

The reef-building coral *Acropora palmata* has virtually disappeared from the shallow waters off the coast of Barbados. Only a few individual colonies are known to exist off the west coast. The abundance of *A. palmata*, which was a major reef-framework component of both Pleistocene and Holocene Barbados reefs, started to decline between 4,500 to 3,300 years ago as a result of the catastrophic destruction of a major bank-barrier reef off the southeast coast. This bank-barrier reef has never recovered to form reef framework since this period of destruction, and colonies of *A. palmata* have continued to disappear right up to modern times. Although the geologic loss of this coral was related to severe storm damage, in historic times stress factors related to human activity have brought this coral to a stage of almost total local extinction.

## 18-7

**Recent Regional Declines In Reef Relief Within The Caribbean**

**Lorenzo ALVAREZ-FILIP*[1]**, Jenny GILL[2], Nicholas DULVY[3], Andrew WATKINSON[1]

[1]School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom, [2]School of Biological Sciences, University of East Anglia, Norwich, United Kingdom, [3]Centre for Environment, Fisheries & Aquaculture Sciences, Lowestoft, United Kingdom

Habitat structure is a key factor influencing the abundance and diversity of organisms in all ecosystems. In tropical reefs, corals and other sessile organisms can provide a complex architecture that supports a wide array of species. The loss of this reef structure is therefore likely to result in a loss of biodiversity, with perhaps rapid loss of reef specialists and indirect, delayed consequences, for taxa with more generalist habitat preferences. Drastic declines in coral cover have been reported across the Caribbean in recent decades, as result of human activities, diseases outbreaks and climate change. Here we collate over 100 studies reporting reef rugosity (using the chain method) in the Caribbean Sea between 1969 and 2006, to explore the extent to which declines in coral cover have been mirrored by loss of reef structure, and the potential implications for reef biodiversity. There have been substantial changes in reef rugosity across the Caribbean throughout this time period, with studies in the 1970s reporting a wide range of values but recent studies consistently reporting low reef rugosity. These declines in habitat structure on reefs are likely to have very important implications for rates of change in reef biodiversity.

## 18-8

**Patterns Of Decline And Evidence For Resilience in Caribbean Coral Reefs**

**Virginia SCHUTTE*[1]**, Elizabeth SELIG[2], John BRUNO[1]

[1]Marine Sciences, UNC-Chapel Hill, Chapel Hill, NC, [2]Curriculum in Ecology and Marine Sciences, UNC-Chapel Hill, Chapel Hill, NC

Coral reefs are being degraded worldwide and the Caribbean basin is generally thought to include some of the world's most at-risk reefs. Building on several recent studies that described changes in Caribbean coral and macroalgal cover, we compiled and analyzed a database of quantitative reef surveys from eight Caribbean regions using data from peer-reviewed and grey literature and from several extensive monitoring programs. The database contains about 3,700 surveys from almost 2,000 reefs surveyed from 1971-2006. Yearly Caribbean-wide means show a 14.6% decline in absolute coral cover from 32% in 1971 to 17.4% in 2006. Most of this decline took place in the early 1980s. Coral cover has fluctuated between 12% and 18% since 1993, and has had an increasing trend from 2000 to 2006. There is significant variation in coral cover between regions, however. Average regional coral cover ranged from 6.9% to 50.3% in 2005. Some regions have even had a modest increase in coral cover from 2001 to 2005. In addition, most reefs have not undergone classic phase shifts. The majority of reefs have low coral and macroalgal cover, and only 5.6% of all surveys reported more than 50% macroalgal cover. Average macroalgal coverage on all reefs was only 12.9% in 2005, and ranged from a fraction of a percent to 71.9% on individual reefs. Our database yielded a much higher estimate of current coral cover and a much lower prevalence of phase shifts than previously reported. This suggests that Caribbean reefs are more resilient than expected, and that recovery may still be possible if we continue to invest in coral reef management.

## 18-9

**Long-Term And Large-Scale Trends in Caribbean Coral Reef Fish Populations**

**Michelle PADDACK*[1,2]**, Isabelle CÔTÉ[1], John REYNOLDS[1], Andrew WATKINSON[2]

[1]Biological Sciences, Simon Fraser University, Burnaby, BC, Canada, [2]School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom

Coral reefs worldwide have become severely degraded within the past several decades. This is particularly so in the Caribbean, where live coral cover across the region has declined by 80%, resulting in reefs with dramatically changed benthic community structure. Despite awareness that a fundamental shift in ecosystem structure has occurred, there is currently no quantitative estimate of temporal trends for other aspects of the coral reef community. Consequently, we have little understanding of how these organisms are responding to changes driven by increasing stressors. The aims of this project were to: (1) assemble, for the first time, all available abundance data on Caribbean coral reef fish communities, and (2) analyze these data to test predictions about how abundance and community composition respond to variation in both natural and anthropogenic stressors. Data from over 30 published and unpublished scientific surveys, spanning the entire range of years in which fishery-independent surveys have been conducted (1973 – 2007), and over 80 sites across the Caribbean were compiled and analyzed using meta-analytic techniques. Overall, there has been surprisingly little change in abundance of coral reef fishes over the past 34 years. However finer-scale examination reveals a mixture of significant declines and increases within specific guilds. These findings suggest that Caribbean coral reef fish community assemblages are experiencing shifts concomitant with changes in benthic structure, but that some groups of fishes may be less resilient than others to ecosystem-wide stressors.

## 18-10

**Population Status Of The Long-Spined Sea Urchin Diadema Antillarum in The Florida Keys 25 Years After The Caribbean-Wide Mass Mortality**

**Mark CHIAPPONE*[1]**, Dione SWANSON[2], Leanne RUTTEN[1], Steven MILLER[1]

[1]Center for Marine Science, University of North Carolina-Wilmington, Key Largo, FL, [2]Division of Marine Biology and Fisheries, RSMAS-University of Miami, Miami, FL

The 1983-84 Caribbean-wide mortality of the long-spined sea urchin Diadema antillarum Philippi was followed by a second mortality event in the Florida Keys in 1991. The demise of this once ubiquitous urchin is considered a key factor responsible for the changes observed on Florida and Caribbean reefs during the past 25 years, including increases in algal cover and declines in crustose coralline algae, reef coral abundance, and coral recruitment. Over an 8-year period from 1999-2007, we examined densities and test sizes of D. antillarum at over 800 sites spanning ~350 km of the southeast Florida shelf encompassing Biscayne National Park, the Florida Keys National Marine Sanctuary, and Dry Tortugas National Park. Visual surveys along belt transects were used to enumerate the number of individuals and test sizes in a two-stage stratified random sampling design that incorporated benthic habitat types, geographic regions, and no-fishing management zones. While pre-1983 densities in the Florida Keys were reported to be as high as 5 individuals/m2, surveys since 1999 at over 850 sites in a variety of hard-bottom and coral reef environments from < 1 m to 27 m depth reveal that current densities are still well below 1 individual per m2. During seven different annual sampling periods, the maximum site-level density was only 0.33 individuals/m2, with the highest densities of large (> 5 cm test diameter) individuals reported from shallow-water hard-bottom and reef sites in the Dry Tortugas and the upper Florida Keys. While the relative importance of larval survivorship, predation pressure, suitable recruitment sites, and reduced fertilization success are poorly known, these surveys provide baseline information from which recovery can be monitored across multiple habitat types, geographic regions, and managed areas.

## 18-11

**Was The 1998 Coral Bleaching in The Southern Seychelles A Catastrophic Disturbance? -1999-2006 Reef Fish Responses To Coral Substrate Changes**

**Raymond BUCKLEY*[1,2]**, Nigel DOWNING[3], Ben STOBART[4], Kristian TELEKI[5]

[1]College of Ocean and Fishery Sciences, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA, [2]Fish Program/Marine Resources, Washington Department of Fish and Wildlife, Olympia, [3]Cambridge Coastal Research Unit, Cambridge University, Cambridge, United Kingdom, [4]Marine Reserves, Spanish Institute of Oceanography, Mallorca, Spain, [5]International Coral Reef Action Network (ICRAN), Cambridge, United Kingdom

Responses of reef fish communities to massive losses of live coral habitat are influenced by pre-impact richness of corals and fishes, and by anthropogenic disturbances which can also confound determinations of natural responses. Aldabra Atoll, a protected UNESCO World Heritage site, and neighboring unprotected islands of Assomption, Astove and St Pierre, were coral-rich sites prior to the 1998 bleaching-event loss of up to 50% of live coral. Hard coral recovery has been minimal except for significant increases at St. Pierre. Multivariate comparisons are made of fish populations at 10m and 20m depths at Aldabra (1999-2006; Sites 1-8), Assomption (2002-2006), Astove (2002-2005), and St Pierre (2002-2005). Aldabra fish abundances by species were not different between years and sites, except at Sites 2 (10m), 4 (20m), and 7 (20m), where between year differences were driven by high annual variability in schooling, reef-resident planktivores (Serranidae 5 species, Labridae 1 species, Pommacentridae 5 species). Removing these species from analyses eliminated differences at Sites 2 and 4, but Site 7 remained different, likely due to storm-induced inundation by sand that caused habitat changes. Assomption, Astove and St. Pierre fish abundances by species were not different between years, and were similar to high fish counts at Aldabra Site 6. These results support earlier analyses that post-bleaching reef fishes at Aldabra represent pre-bleaching community structure, and abundance changes appear to be within the natural ecology of the system. Similar responses at neighboring unprotected islands suggest that any local harvest primarily affects non-reef-resident species. The massive1998 losses of live coral habitat in these rich coral and reef fish communities do not appear to represent catastrophic disturbances that changed the basic structure of the reef fish assemblages.

## 18-12

**Spatiotemporal Trends in Biodiversity And Coral Reef Communities Structure At A Decade Scale (Reunion Island; Southwest Indian Ocean)**

**Lionel BIGOT*[1]**, Bruce CAUVIN[2], Emmanuel TESSIER[2], Pascale CHABANET[3], Vianney DENIS[1]

[1]ECOMAR, University of Reunion Island, St Denis, Reunion, [2]APMR - Reunion Marine Reserve, St Leu, Reunion, [3]IRD La Réunion, Ste Clotilde, Reunion

Since 1998, the GCRMN standardised methodology (LIT) has been used to assess the coral reefs and fishes in Reunion Island through a monitoring survey realized each year. Fourteen stations have been surveyed on the reef flats and the outer reef slopes at St Gilles / La Saline, St-Leu, Etang Sale and St Pierre reef complexes. Spatio-temporal trends of benthic community structure and fishes were studied in the context of the BIOCOR and PAMPA scientific project related to the implementation of the new Marine Reserve. The first results on St Gilles / La saline reef show that 75 species of corals have been recorded during the 10 last years and highlight the dominance of the "habitat" factor on the time (year) factor. Main trends in benthic community structure show that algal coverage became dominant after 2000 on reef flat and reef slopes. On the outer reef slopes, temporal trend is associated with a decrease of coral cover (from 56 to 32 % in 2007) and coral diversity (from 29 in 1998 to 15 species in 2006), and a progressive shift of coral communities. St Leu outer reef slope are characterized by the highest live coral coverage and diversity and a moderate temporal changes in benthic communities between 1998 and 2007.

Overall, fish densities increase after 2002 on all sites that could be due to a massive recruitment. Moreover, results on trophic structure highlight important fluctuations through time of herbivore groups while carnivorous group remains at a very low level, results probably related to overfishing.

All these results displayed contrasting spatial and temporal situations of Reunion Island coral reef ecosystems that are subjected to several natural disturbances (cyclone, bleaching) surrounding the chronic anthropogenic pressures affecting coral reef communities according to their degree of resilience.

## 18-13

**Response Of High Latitude Hermatypic Coral To The Rising Sea Water Temperature At Daya Bay, South China's Guangdong Province**

**Hui HUANG*[1]**, Jiansheng LIAN[1], Jianhui YANG[2], Xiubao LI[1]

[1]LMB, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, China, People's Republic of, [2]South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, China, People's Republic of

Daya Bay is a semi-enclosed subtropical bay located in the southeast of the south China's Guangdong Province. Its latitude is 22.5°N-22.9°N, covering an area of about 550 km$^2$. The water exchange with the ocean is low and the residence time of seawater is about 1 or 2 months. Two Nuclear Power Stations, situated in the mid-part of west coast of the bay, began in commercial operation in the 1994 and 2003 respectively. The cooling water plume flows into the bay and accumulatively elevates the sea water temperature of the bay by about 1.1 degree Celsius, which is about the temperature rise of IPCC 2007's projection for 2050. This provides a unique "in situ experiments" to explore the response of hermatypic coral to the rising sea water temperature. Change of temperature scheme is very sensitive because the distribution of hermatypic corals in Daya Bay is near their north limit.

The percent cover and community structure of hermatypic corals in Daya Bay was surveyed using line transect methods in 2007. Comparing the historical survey records in 1983~84, 1991, and 2002, a great change was observed. The live coral cover was 70% in 1983~84, then stabilized at ~30% after 1991, and slightly increase to 33~35% after 2005. The dominant species was *Acropora* spp. in 1983~84 and theretofore, which was replaced by *Favia* spp. after 1991. The percent cover of *Acropora* spp. and the total species number was also increased after 2005.

The annual growth rates were estimated using X-radiography technique with coral samples of *Porites lutea*. We found that the growth rates of the coral influenced by the cooling water were 0.8mm/a greater than those unaffected.

Our results suggested that increasing sea water temperature may favor the growth and development of hermatypic corals in high latitude area like Daya Bay.

## 18-14

**A Ten-Year Study On Dynamical Structure Of A Sub-Tropical Coral Community in Hong Kong Sar, China**

**Tze-wai TAM*[1]**, Put O. ANG[1]

[1]Marine Science Laboratory, Department of Biology, The Chinese University of Hong Kong, Hong Kong, Hong Kong

A long term monitoring programme of a sub-tropical coral community has been set up in A Ma Wan, Tung Ping Chau Marine Park, Hong Kong and has been on going since May 1997 with nine fixed position 40 m long transects and 0.5 m x 0.5 m permanent quadrats laid at every 5 m interval along each transect. The study is to provide the first-hand information for understanding the natural variation of Hong Kong corals towards physical disturbances and to serve as an important baseline for objective assessment of human impacts on the local coral communities. At the beginning of the study, a total of 40 scleractinian coral species from 20 genera (12 families) was recorded. Over the ten-year study (1997 - 2006), the coral community was subject to repeated physical disturbances caused by tropical cyclones. Within the period from 1997 to 1999, the site experienced the highest frequency of severe tropical cyclones and the strongest cyclone to hit Hong Kong in the last 23 years (1984 - 2006). The coral cover was reduced significantly after the cyclone impacts and the community never recovered to its original state ever since. *Cyphastrea serailia*, *Goniopora lobata*, *Montipora peltiformis* and *Pavona decussata* were the dominant species most highly affected by the cyclone impacts. Significant shift in the coral community structure from *Platygyra-Goniopora* dominant community to *Pavona-Platygyra* dominant community was also observed after the cyclone impacts. Overall, the coral community was relatively stable and resistant towards short-term but not long-term repeated disturbances. The community may also have low resilience towards more severe disturbances in the future. Preserving the resilience of coral communities/species in Tung Ping Chau should be one of the main goals of coral conservation strategies for the island marine park.

## 18-15

**Decadal Scale Changes in Coral Reefs in Quintana Roo, Mexico**

**Thaddeus NICHOLLS*[1]**, W. David LIDDELL[1]

[1]Geology, Utah State University, Logan, UT

The east coast of Quintana Roo, Mexico is bordered by the barrier-fringing reefs of the Mesoamerican reef system. Spanning over 1126 km from the tip of the Yucatan Peninsula south to the Bay Islands off the Honduran coast, this reef system is the largest in the Atlantic, and the second largest in the world. The Caribbean coast of Quintana Roo was covered by semi-humid tropical rainforest until 1970, when coastal development including road and resort construction broke ground. Sixty percent of this area had been cleared by 1988 for the "megaproject" known as the "Cancun-Tulum Touristic Corridor," or "Mayan Riviera." The long term impact of this development on the coral reefs of this area had not been quantified. In 1992 data on community composition were collected from two areas, Akumal and Chemuyil, ranging from 4.8-33.5m depth. These areas were revisited in 2005 and data were collected in the same fashion and at the same depths as in 1922 to determine if coastal development has had a significant impact on the coastal reefs. Chi squared analysis determined that the community composition data collected in 1992 are significantly different from those data collected in 2005 (alpha value 0.05). Coral cover in Chemuyil at 33.5m declined from 44.1% to 33.3%. Algae (including macro algae, filamentous algae, and erect coralline algae) coverage at the same site increased from 29.1% to 46.7%. Similar trends are observed at accompanying sites. Anecdotal accounts suggest that the trends exhibited by the reefs are due to nutrification by septic water flowing through the highly porous karst limestone of the Yucatan Peninsula since there were few signs of damage to the reefs other than a very high percentage of algae coverage. Furthermore, fish populations appeared to be relatively healthy.

## 18-16

***pocillopora* Recovery At Devil's Crown, Galápagos Islands, Ecuador, Following Extirpation Associated With The 1982-83 El Niño-Southern Oscillation**

**Joshua FEINGOLD*[1]**, Peter GLYNN[2]

[1]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Fort Lauderdale, FL, [2]Department of Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

In 1982-83 a severe El Niño-Southern Oscillation (ENSO) event killed 95% of the scleractinian corals in the Galápagos archipelago. Over 99% coral mortality occurred at the Devil's Crown study site located within the flooded (2-4m depth) center of a small (156 x 100m), emergent, dormant volcanic cone off the north coast of Floreana Island. Also at this site, a structural reef composed primarily of the branching coral *Pocillopora* spp. was lost from contrary wave action combined with primary and secondary biological disturbances associated with ENSO. For the subsequent 11 years *Pocillopora* was not observed there, however 5 colonies were seen in May, 1995. Since then the number and size of colonies were monitored approximately annually. Coral colony surface areas were determined following two methods: direct measure during snorkel surveys to determine maximum width and length (1995-2003), and digital photography to obtain 2-D images (2004 & 2007). These images were converted to projected surface area using the program CPCe. The numbers of *Pocillopora* colonies increased from 5 in 1995 to 154 in 2007, with total colony surface area increasing from 849 cm2 to 37,772 cm2 (3.8m2) over the same period. Colonies initially appeared via sexual recruitment, probably from source populations located upcurrent, and now larger colonies are fragmenting and forming localized aggregations. This long term (25y) monitoring reveals slow initial recruitment from 1995 to 2002 followed by recent accelerated increases in *Pocillopora* colony number and surface area. This suggests that *Pocillopora* may once again attain population densities sufficient to form reef structures, an unusual prospect considering the widespread reports of coral loss worldwide.

## 18-17

**Status Of The Mesoamerican Reef System**

Miguel GARCIA SALGADO[1], Marydelene VASQUEZ[1], **Gabriela NAVA MARTÍNEZ*[2]**, Noel JACOBS[3]

[1]MBRS project, Belize City, Belize, [2]Oceanus, A.C., Chetumal, Quintana Roo, Mexico, [3]MBRS project, Belize city, Belize

A synoptic monitoring program was established in the Mesoamerican Barrier Reef System (MBRS) region since 2004, with the objective of gather information about the status of the reef ecosystems and other associated ecosystems such as seagrasses and mangroves. This MBRS project comprises a four countries initiative: Mexico, Belize, Guatemala and Honduras.

The establishment, operation and maintenance of this environmental monitoring program in the long term will provide a synoptic vision of de MBRS health. At the same time, a Regional Environmental Information System was created and uploaded to the www to facilitate the capture of the data on line and results analysis information in the regional level.

The information generated allowed the establishment of a baseline with data from 2004-2005.For Coral Reef Ecosystem, the MBRS region has an average of 23.47% live coral cover, and 35.38% of algal cover for the region. The main live components (sponges, octocorals, stony corals, encrusting coralline algae and Millepora) were compared to algae in order to develop a baseline that can be used by later studies to determine any trends in change to the benthic reef community. The baseline mean ratio of MLC to algae in the MBRS region was of 1.19 meaning that typical reefs in this region are not overrun with algae.

This information is now analyzed in a temporal trend at each site to determine changes in the Mesoamerican Reef. This tool has been useful for comparisons of impacts from human activities and natural disasters that influence directly in the sustainable use and conservation of the MBRS.

## 18-18

**The Decline Of Crinoids On The Reefs Of Curaçao And Bonaire, Netherlands Antilles**

**David L. MEYER*[1]**, Elizabeth A. DAME[1,2], Peter B. LASK[1]

[1]Geology, University of Cincinnati, Cincinnati, OH, [2]Geology, University of Cincinnati, Cincinnati

Comatulid crinoids were abundant on the leeward fringing reefs of Curaçao and Bonaire until the 1990s, but since 1996 have declined drastically in population size and diversity. Prior to this decline, five species inhabited the forereef slope from depths of 6 to over 30 m: *Nemaster grandis, Davidaster rubiginosa, D. discoidea*, an undescribed species of *Davidaster*, and *Ctenantedon kinziei*. Of these, *D. rubiginosa* and *D.* n. sp. were common along the edge of the forereef slope from about 6 to 15 m depth, and *D. discoidea* was common below about 15 m. *N. grandis* and *C. kinziei* were found in lower abundance at about 30 m depth. Transect data from Bonaire showed that a drastic decline in numbers of the *Davidaster* taxa occurred between 1989 and 1996. Transects in Curaçao in the late 1990s through 2001 documented a similar decline. In 2007, transects following the AGRRA protocol in Curaçao showed that sites where species of *Davidaster* were formerly common are now practically devoid of crinoids. In particular, *D. discoidea*, once the most numerous crinoid in these islands, has all but disappeared. The cause of this decline is unknown. It is noteworthy that the decline affected both Bonaire and Curaçao, even though Bonaire has about one-tenth the human population of Curaçao, very little industrialization, and protected reefs, while a much higher level of development impacts the reefs of Curaçao. It is possible that heating associated with the severe coral bleaching event of 1995 also affected the crinoids. As far as we are aware, reef crinoid populations elsewhere in the western Atlantic region have not shown a similar decline. However, the loss of these passive suspension-feeding echinoderms from one of the centers of high reef diversity of the region is a cause for concern and requires ongoing monitoring.

## 18-19

**Brazilian National Coral Reef Monitoring Program: Status And Perspectives.**

**Beatrice FERREIRA*[1]**, Mauro MAIDA[1], Ana Lidia GASPAR[2], Caroline FEITOSA[1], Sergio REZENDE[1], Eduardo MACEDO[1], Fabio NEGRAO[3], Ana Paula PRATES[4], Clóvis CASTRO[5], Débora PIRES[5], Andreza PACHECO[1], Iara SOMMER[6], Liana MENDES[7], Joao Marcello CAMARGO[2]

[1]Oceanography Department, Federal University of Pernambuco, Recife, Brazil, [2]Instituto Recifes Costeiros, Tamandare, Brazil, [3]Instituto Recifes Costeiros, Caravelas, Brazil, [4]NZCM, Ministry of Environment, Brazilia, Brazil, [5]UFRJ, Tamandare, Brazil, [6]APA Guadalupe, Tamandare, Brazil, [7]UFRN, Natal, Brazil

The coral reefs of Brazil represent the only coral reefs in the south Atlantic and include a large proportion of endemic species. Since 2002 the Ministry of Environment is funding an initiative to monitor Brazilian coral reefs using a methodology compatible with the global protocol Reef Check. Between 2002 and 2007, surveys were conducted in eight representative regions of Brazilian reefs, between latitudes 3° and 18°S, including reefs inside protected areas of both full protection (4) and sustainable use (5) categories as well as areas of general use (2) or protected areas with no enforcement (1). Those included coastal reefs, shelf reefs and reefs in oceanic waters. Analysis of data indicated that fishery indicators at all trophic levels are significantly more abundant on fully protected areas (no fishing). Sustainable use areas were no different of general use or protected areas without enforcement, except those that include special no take zones. Fishing has moved down the food chain and impacts are no longer restricted to large predatory groups (serranids, lutjanids and sharks) with larger scale fisheries now also directed to herbivorous fishes (scarids and acanthurids) as well as Haemulids. Within each region, abundance of indicators was related to fishing pressure directed over the specific resource. Higher hard coral cover was inversely related to land based pressures, mostly sedimentation, regardless of coral diversity or species composition. Low proportion large scale bleaching, across 2000 kms, was detected twice, in 2003 and 2005, with low effect on the apparently resilient Brazilian coral reef fauna. Conservation and recovery of Brazilian coral reefs depend on effective fishing regulation as well as protected areas establishment/ enforcement, but, in the case of the extensive coastal reef formations, also on coastal and riparian recovery and protection.

## 18-20

**Long-Term Changes in Taxonomic Distinctness And Trophic Structure Of The Reef Fishes At Cabo Pulmo Reef, Gulf Of California**

**Hector REYES-BONILLA*[1]**, Lorenzo ALVAREZ-FILIP[2]

[1]Departamento de Biología Marina, Universidad Autonoma de Baja California Sur, La Paz, Mexico, [2]School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom

Cabo Pulmo is the most septentrional coral reef in the Tropical Eastern Pacific, and although many aspects of the reef have been described, there is a lack of the temporal studies that addresses the change that this marginal ecosystem has suffered in the last decades. In this context the present study evaluates the changes in community structure and average trophic level of the 13 most important reef families, from 1987 to 2006. In this period the reef has suffered several perturbations, such as ENSO events, hurricanes strikes and the increase of the coastal development, and at the same time the efforts for its protection has increased as the area was declared a National Park in 1995. In each year we performed at least 18 stationary censuses in observation cylinders of 5 m radius, and calculated the taxonomic distinctness index as well as the trophic level. The results show that community composition did not differ between seasons (warm and cold), in clear contrast to what occurs in other areas of the Gulf of California. However, when the comparison was made among years, the ordination analysis shows that ichtyofaunal composition differs between 1987 and the rest of surveys. The taxonomic distinctness gradually declined between 1987 and 2006 but at the same time, the trophic level of the assemblages increased through the years. In conclusion these results suggest that the establishment of the National Park might have had a positive effect on the fish community, as shown by the increase in the trophic level. However the simultaneous decrease in taxonomic distinctness probably indicates that a large number of carnivores has depleted the abundance of herbivores and omnivores; this way, the conservation efforts have reached a goal but at the same time produced unexpected consequences in the ecological function of the area.

## 18-21

**Socio-Economic Monitoring (Socmon) As A Tool In The Management Of Marine Protected Areas: Participatory Process And Initial Results In Palawan Province, Philippines**

**Michael PIDO*[1]**, Sheila VERGARA[2], Melissa MACASAET[3], John Francisco PONTILLAS[4], Marissa PONTILLAS[1], Eva Marie PONCE DE LEON[1], Delia MARTINEZ[3], Filomeno RACUYA[4]

[1]Palawan State University, Puerto Princesa City, Philippines, [2]Conservation International-Philippines, Quezon City, Philippines, [3]City Government of Puerto Princesa, Puerto Princesa City, Philippines, [4]Palawan Council for Sustainable Development Staff, Puerto Princesa City, Philippines

Methodological tools in the assessment of bio-physical parameters in marine protected areas (MPAs) have been fairly standardized. The same level of consensus is not yet reached in assessing the human dimension's socio-economic and governance variables. Socioeconomic Monitoring (SocMon) is a standardized set of guidelines on how to conduct socio-economic monitoring for collecting and analyzing basic socio-economic data useful for coastal management As a methodological tool, SocMon was employed to assess the awareness of people's dependence on marine resources, perceptions of resource conditions, threats to marine resources, use levels, and status of governance of two locally-managed MPAs in Puerto Princesa City, Palawan Province, Philippines. Preliminary results show that there is an almost equal number of male and female residents; almost half of the population are 20 years and below; few adults (barely 10%) belong to a stakeholder organization; a quarter reached high school level; and the migrant population now comprise nearly three quarters. They generally perceive the natural resources' status to be either good or very good. Male and female respondents share similar positive attitudes towards non-market and non-use values of resources. Coastal communities are aware of temporal benefits of marine resources and they would put a higher value on future benefits (such as bequest values) rather than on current needs. In the order of decreasing importance, threats to resources identified were: rampant cutting of mangroves; destructive fishing activities for corals; and pollution for beaches. Overall, the method was found very useful in providing basic socio-economic information and has huge potential for between and across sites comparison to better inform management decisions, including communication with stakeholders, and to form a baseline for current socio-economic conditions of MMAs and coral reef areas. Methodologically, SocMon has potential for large-scale use in the Philippines and Southeast Asia by virtue of its ease in field application and data analysis.

## 18-22

**Socio-Economic Status Of Communities Dependent On Coral Reefs in The Western Indian Ocean**

**Innocent WANYONYI*[1]**, David OBURA[2], Delphine MALLERET-KING[1]

[1]socmon Wio, Cordio Ea, Mombasa, Kenya, [2]corals, Cordio Ea, Mombasa, Kenya

Coral reefs form the basis of the livelihoods of hundreds of thousands of people in the region. Numerous poor coastal households depend very highly on marine resources often as a last economic resource for food and income, through extractive uses such as fishing. Climatic change, destructive fishing, sand mining, pollution etc threaten coral reefs in the Western Indian Ocean (WIO) region. To manage resources effectively, it is essential to understand the context within which marine resource users live, their livelihood constraints and opportunities. It is increasingly recognised in the region that for resource management to be effective in the long term, MPA and fisheries management need to adapt and respond to changes in marine resource users' socio-economic context. The Socio-economic Monitoring Initiative for Coastal Managers of the Western Indian Ocean (SocMon WIO) aims to increase coastal manager's capacity to understand and incorporate the socio-economic context into coastal management programmes. SocMon WIO is a regional programme that builds on local-level monitoring systems. SocMon approach is based on community members' participation, it is implemented locally at site level by relevant projects, marine protected area authorities, local area management authorities, fisheries officers or community groups. The SocMon WIO sites include eight managed as MPAs, three ICM/Co management sites and four are either fisheries management or co-management as well as Eco-region sites of regional importance within the East Africa Marine Eco-region (EAME). The SocMon WIO network expanded to 15 sites across the region in 2007. The Results are presented here for pioneer SocMon WIO sites as sample monitoring data collected by the various sites to address their respective management needs. Diani-Chale site had 66% of households that undertook marine related livelihood activities and 25% households involved in fisheries alone.

## 18-23

**Lessons Learned from Socio-economic Monitoring (SocMon) and Marine Protected Area Management Effectiveness (MPA-ME) Evaluation in the Caribbean**

**Maria PENA*[1]**, Patrick MCCONNEY[1]

[1]Centre for Resource Management and Environmental Studies (CERMES), The University of the West Indies, Cave Hill Campus, Barbados, Bridgetown, Barbados

*Socio-economic Monitoring at Negril Marine Park (NMP), Jamaica*, was implemented from 2004 to 2006 aimed at obtaining sound socio-economic information useful for decision-making. The assessment was linked to the simultaneous formulation of the first fisheries management plan for the NMP. The application of the *SocMon Caribbean* methodology to this project was informally evaluated by the Centre for Resource Management and Environmental Studies (CERMES), University of the West Indies (UWI) in Barbados. The project followed the SocMon methodology reasonably well, and the methods used were largely successful in achieving intended outcomes. The major deficiency in the project was lack of institutional capacity to undertake some tasks.

*CERMES Regional Project on Enhancing Management Effectiveness at Three Marine Protected Areas in St. Vincent and the Grenadines, Jamaica and Belize* was implemented from 2005 to 2007 to evaluate management effectiveness of MPAs at these sites. The project utilised methods set out in the guidebook *"How is your MPA doing?"* for evaluating management. The process of evaluating management effectiveness in order to implement adaptive management was new to all study sites and therefore was a learning process. Primary lessons learned included an appreciation for evaluating management; the need for management agencies to undertake evaluation tasks based on available resources; the need for stronger science training for evaluation; the importance of presentation and validation of results and an awareness of stakeholder perceptions of management efforts.

This paper reports on the practical lessons learned from applying the *SocMon Caribbean* methodology to socio-economic monitoring at the NMP; and biophysical, socio-economic and governance assessment outlined in *"How is your MPA doing?,"* for evaluating MPA management effectiveness at specific MPAs in the Caribbean.

## 18-24

**Status And Trends in Socioeconomic Factors Affecting The World's Coral Reefs**

**Christy LOPER*[1]**, Robert POMEROY[2], Patrick MCCONNEY[3], Arie SANDERS[4], Gaya SRISKANTHAN[5], Khulood TUBAISHAT[6], Innocent WANYONYI[7], Sheila VERGARA[8], Caroline VIEUX[9]

[1]NOAA, Washington, DC, [2]University of Connecticut, Groton, CT, [3]University of the West Indies, St. Michael, Barbados, [4]University of Zamorano, Tegucigalpa, Honduras, [5]IUCN- The World Conservation Union, Colombo, Sri Lanka, [6]PERSGA- Regional Organization for Conservation of the Environment of the Red Sea and Gulf of Aden, Amman, Jordan, [7]CORDIO East Africa, Mombasa, Kenya, [8]Conservation International- Philippines, Manila, Philippines, [9]SPREP- South Pacific Regional Environment Programme, Apia, Samoa

This presentation aims to address two primary questions: (1) What are the current status and trends in socioeconomic factors affecting the world's coral reefs? and (2) How have socioeconomic monitoring programs contributed to coral reef research, conservation and management? In coral reef conservation, understanding socioeconomic factors is critical to the success of management tools used to conserve coral reefs.

Since 2000, the Global Socioeconomic Monitoring Initiative for Coastal Management (SocMon) has facilitated socioeconomic monitoring in approximately 40 sites in six regions: Caribbean, Western Indian Ocean, Southeast Asia, Pacific, Red Sea, and South Asia. A critical gap in this data collection has been a coordinated review and analysis of socioeconomic information at the global and regional levels. Moreover, most of the data that has been collected has not previously been accessible to coastal managers, decision makers or donor agencies.

By working with global partners to synthesize individual SocMon site assessments, this study has delineated trends in factors such as regional and global awareness of people's dependence on coral reefs, perceptions of reef conditions, threats to coral reefs, use levels, and status of governance around the world. Access to all of this data is now provided through a Global Socioeconomic Database, a web-enabled resource developed by WorldFish Center in Malaysia.

This is a seminal study in the understanding of socioeconomic factors impacting coral reefs. Never before has a comprehensive survey of socioeconomic assessments of coral reef areas been undertaken. The results fill a critical need by advancing a global and regional understanding of human interactions with and dependence on coastal resources.

## 18-25

**Status Of Coral Reefs in South Asia (Bangladesh, India, Maldives, Pakistan, Sri Lanka And Chagos (Biot))**

Jerker TAMELANDER[1], **Arjan RAJASURIYA*[2]**, JK PATTERSON EDWARD[3], Sarang KULKARNI[4], Rohan ARTHUR[5], Alasdair HARRIS[6], Terney PRADEEP KUMARA[7], Vineeta HOON[8], Zahirul ISLAM[9], Hussein ZAHIR[10], M.F.M. FAIROZ[7], K. VENKATARAMAN[11]

[1]Global Marine Programme, IUCN - The World Conservation Union, Dar es salaam, Tanzania, [2]NARA, Colombo, Sri Lanka, [3]SDMRI, Tuticorin, India, [4]Oceaeco, Mumbai, India, [5]NCF, Mysore, India, [6]Blueventures, London, United Kingdom, [7]University of Ruhuna, Matara, Sri Lanka, [8]CARESS, Chennai, India, [9]Marinelife Alliance, Dhaka, Bangladesh, [10]MRC, Male, Maldives, [11]NBA, Chennai, India

Coral reef recovery in South Asia over ten years since the 1998 coral bleaching and mortality event has been highly variable. Some severely bleached reefs such as in the Chagos archipelago and at locations in the western atoll chain of the Maldives have returned to pre-bleaching coral cover and are making gradual progress towards pre-bleaching population structure. However, although coral cover is increasing at most sites in the Lakshadweep islands, recovery is limited on several atolls. Localized and seasonal bleaching has been observed annually in the region since 1998, but bleaching related mortality has been very low. For example, reefs on the Indian side of the Gulf of Mannar exhibited annual bleaching around May but usually with full recovery within weeks-months. The impact of the Indian Ocean tsunami 2004 was comparatively low, with the exception of areas affected by tectonic activity in the Andaman and Nicobar Islands, and recovery predictions are mostly good. However, direct anthropogenic stress hampers recovery and is the main driver behind reef degradation in many areas. Surveys show reef status and recovery is better in areas where human interference and anthropogenic stress is low. Direct anthropogenic stress and poor management of coral reef areas, including many MPAs, is further expected to reduce the ability of many areas to adapt to climate change, a synergistic effect that threatens to drastically change reefs in some parts of the region over the coming years to decades. Natural resource dependence and a shortage of livelihood options leaves many communities highly vulnerable. Efforts underway seek to address this through improved reef monitoring that increasingly incorporates social and economic aspects, strengthening the research agenda and supporting uptake into management and policy through development of tools and communication and capacity building initiatives.

## 18-26

**Patterns Of Coral Community Recovery in The Maldives Following Mass Bleaching in 1998**

**Hussein ZAHIR*[1]**

[1]Ministry of Fisheries Agriculture and Marine Resources, Marine Research Centre, Male, Maldives

The recovery in one of the world's largest oceanic atoll reef systems following a catastrophic coral bleaching is reported. Increased sea surface temperature during the 1998 El Niño Southern Oscillation event caused extensive coral bleaching and widespread coral mortality throughout the Indian Ocean including the reefs of the Maldives. Live coral cover was reduced from pre-bleaching estimates of 40-60% to less than 3% in shallow waters assessed soon after the bleaching. Virtually no living *Acropora* species were recorded at the study sites during these assessments in late 1998. Changes during the last 7 years at 15 selected reef sites throughout the Maldives from almost 7° N to almost 1° S are presented and discussed. Trends in coral cover both between sites within atolls and between atolls are presented, as is the generic diversity of the live coral community and its development since the bleaching. Patterns of coral settlement on tiles and recruitment to natural substrates were assessed at 6 sites in the central atolls to see whether recruitment rates were related to recovery. Same site comparisons using settlement plates to study potential availability of coral larvae and *in situ* monitoring of coral recruits to assess those surviving to a few mm in diameter provided useful information on the availability of coral larvae for recruitment and replenishment of denuded coral reefs. The recovery was very variable from site to site; coral taxa that were most susceptible to bleaching (acroporids and pocillorids) have shown the largest increase in cover since 1998; while the more resilient groups that survived the bleaching (e.g. agariciids and poritids) show a relative decrease in cover. The patterns and rates of coral recovery on these reefs suggest that recruitment was not a limiting factor for reef recovery in the Maldives.

## 18-27

**Status Of Coral Reefs in Southeast Asia – 2008**

Karenne TUN[1], Loke Ming CHOU[1], **Thamasak YEEMIN*[2]**, Nguyen VAN LONG[3], Dr SUHARSONO[4], Cleto NANOLA JR[5], David W LANE[6], Affendi YANG AMRI[7]

[1]Biological Sciences, National University of Singapore, Singapore, Singapore, [2]Faculty of Science, Ramkhamhaeng University, Bangkok, Thailand, [3]Institute of Oceanography, Nha Trang, Vietnam, [4]COREMAP, Jakarta, Indonesia, [5]College of Science, University of Philippines, Marine Science Institute, Diliman, Quezon City, Philippines, [6]Universiti Brunei Darussalam, Brunei Darussalam, Brunei Darussalam, [7]Marine Biology Unit, University of Malaya, Institute of Biological Sciences, Kuala Lumpur, Malaysia

The coral reefs of Southeast Asia have not seen major change in the past four years; many reefs continue to remain under threat, mainly from anthropogenic impacts, although encouraging signs of improvement are emerging in many areas resulting from better monitoring and management initiatives. The 2004 Asian Tsunami did not cause widespread damage to the coral reefs of Southeast Asia, with only localized impacts reported in Indonesia, Thailand and Malaysia. Long-term monitoring programmes are still ongoing in many countries, while expanding in Peninsular Malaysia with the formal establishment of Reef Check Malaysia. However, the status of coral reef monitoring in Cambodia and Myanmar remain largely unknown.

## 18-28

**Status of Coral Reefs in Post-Tsunami Period in Andaman & Nicobar Islands (India)**

**Alok SAXENA*[1]**

[1]Department of Environment & Forests, Government of India, Port Blair, India

Andaman & Nicobar Islands, located in the Bay of Bengal off the eastern coast of India, are one of the four major sites of coral reefs. Coral reefs found in these islands are mostly fringing types. The survey carried out by the UNDP team along with experts from India in 2001 recorded 197 species only in Andaman group of Islands as against 179 species reported earlier by Pillai (1983) for the entire Andaman & Nicobar Islands. The survey was based on satellite data interpretation and field survey of 13 sites. It also projected that the actual number of coral species may be as high as 400. The survey done by Kulkarni and Saxena (2002) for 21 coral reef sites identified under coral reef monitoring action plan showed not only the distribution of corals, but also the status of health and mortality. Tsunami that struck these islands on 26th December 2004 led to vast destruction of coral reefs mainly due to geo-morphological changes resulting in uplifting and exposure of reefs in the northern islands and submergence in the southern islands A rapid assessment done by the Reef Watch, an NGO in 2005 showed that there was overall 20% mortality in Andaman group of Islands while in Nicobar group of Islands, up to 80% mortality was observed. The report however indicated recovery processes in some coral reef sites particularly those in shallow reefs. The present study is based on the survey being carried out at different coral reef sites to monitor recovery processes. The initial results show not only recovery but also changes in the distribution pattern of corals at the selected sites.

## 18-29

**Extent And Timing Of Disturbances: Comparison Between Australia's Great Barrier Reef And The Caribbean Region**

**Hugh SWEATMAN*[1]**

[1]Australian Institute of Marine Science, Townsville, Qld 4810, Australia

Australia's Great Barrier Reef (GBR) province and the greater Caribbean region include similar areas of coral reef. In recent decades, the major cause of losses of coral cover on the GBR has been *Acanthaster planci*, the crown-of-thorns starfish. Three well-documented waves of outbreaks have passed southwards along the central GBR in the past 40 years, with an independent pattern of outbreaks on the Swain Reefs in the south and less-well documented waves of outbreaks travelling northward in the remote northern region. At any point in time, 1-3 discreet regions are affected, each adjoining areas where the reefs are recovering or are yet to be affected. Published reports from the Caribbean suggest that impacts on coral in the Caribbean, notably coral diseases, are much more widespread at any time. One salient example is the fatal disease of *Diadema* that spread through the entire region in 1983 and 1984. Such differences in the extent and timing of major disturbances may influence replenishment and hence the processes of recovery.

## 18-30

**Patterns Of Reef Fish Utilization And The Consequence Of Human Population Growth On Fish Density And Community Composition in American Samoa**

**Marlowe SABATER*[1]**

[1]Department of Marine and Wildlife Resources, American Samoa Government, Pago Pago, American Samoa

Long-term time-series data from fishery-independent underwater surveys and fishery-dependent surveys were examined and analyzed alongside prehistoric and current utilization patterns of reef fish populations in order to assess the status of coral reef fish populations and the fishery. Underwater surveys showed overall density of coral reef fish has been increasing over the past three decades due largely to a significant increase in parrotfish populations. Concurrent with this increase in fish density was a significant decrease in subsistence fishing effort and a non-significant decrease in commercial effort over time. Catch landings showed no long-term trend with highs recorded from 1994-2001 and lows prior to and after these years. Rapid population growth on the main island of Tutuila is seen as a threat to coral reef resources. One major impact that is often assumed is that increases in human population will lead to increases in fishing pressure. However, despite the rapid significant increase in human population on Tutuila, fishing effort has continually decreased over the last three decades. Population growth had a negative relationship with fishing effort (subsistence and commercial) due possibly to the society's shift from subsistence to a cash-based economy since the early 1900's. Present catch composition and reef fish assemblage is statistically similar to prehistoric periods dating 1500-3000 years ago. Recent interviews of 425 respondents in Tutuila has shown preference for surgeonfish, groupers, squirrelfish, and parrotfish which again follows the same proportion as the prehistoric records and significantly correlates with the present day fish assemblage. This preference may have existed since prehistoric times despite advances in fishing technology or may have been driven by what was abundant and easily available in the fishery. These findings indicate that the fishery was sustainable from the prehistoric times and the fish population shows signs of improvement in the recent past.

## 18-31

**Ten Years Of Volunteer Science**

**Gregor HODGSON*[1]**, Cori KANE[1], Craig SHUMAN[1]

[1]Reef Check Foundation, Pacific Palisades, CA

In 1997, Reef Check began as the first attempt to survey the world's coral reefs using a standard method, carried out by volunteer recreational divers trained and led by marine biologists. Reef Check has expanded into an international non-profit organization, the Reef Check Foundation, with thousands of volunteers in 90 countries and territories and with a mission of protection and rehabilitation of reefs (including temperate reef ecosystems in California). The initial assumption was that trained volunteers could collect reliable data and catalyze marine conservation activities. The ten-year coral reef database shows that overfishing remains the most important problem affecting coral reefs, with most high-value indicator species missing from most coral reefs. The results show that on a global scale, both reef corals and reef fish are relatively resistant to perturbation from bleaching events and recovered during the period. The rapid declines in coral reefs during the 1980s and 1990s have not continued. Numerous conservation projects have been triggered by the actions of volunteer Reef Check teams in all tropical seas including the creation and improvement of several Marine Protected Areas. By involving recreational divers in scientific monitoring, Reef Check has helped build a better educated constituency that will support coral reef conservation activities throughout the world.

## 18-32

**The Response Of Caribbean Coral Reefs To Repeated Stress Events.**

**Loureene JONES*[1]**

[1]Integrated Watersheds and Coastal Zone Management Branch, National Environment and Planning Agency, Kingston 5, Jamaica

In recent times, coastal ecosystems and specifically coral reefs have been experiencing varying degrees of stress from several sources. The incidence of natural phenomenons such as hurricanes and bleaching events has increased to the point where one or both of these events are guaranteed to occur annually. Coupled with terreginous run-off and poorly planned coastal developments, the reefs of the region are constantly bombarded with less than ideal conditions. At present coral cover is still low at most sites assessed and has been for a long while.

In Jamaica Reef Check assessments indicated coverage ranging between 2% and 37% were recorded between 2001 and 2006. Results from bleaching assessments conducted during and after the 2005 event depicted up to 75% bleaching in some countries and varied levels of recovery. Data from long-term monitoring sites in Jamaica also produced results, which indicate that the reefs are to an extent able to survive and recover from the stress events. Given the increased frequency of stress events it is still unsure what level of recovery will be realized and the duration.

## 18-33

**Agrra Data Can Distinguish Chronic From Acute Impacts To Wider Caribbean Reef Communities And Provide Baselines To Assess Future Changes**

Robert GINSBURG[1,2], Philip KRAMER[3], Judith LANG[2,4], **Kenneth MARKS*[2,5]**, Patricia RICHARDS KRAMER[6], Robert STENECK[7]

[1]Marine Geology & Geophysics, RSMAS, University of Miami, Miami, FL, [2]Ocean Research and Education Foundation, Coral Gables, [3]The Nature Conservancy, Sugarloaf Key, FL, [4]Independent, Ophelia, VA, [5]Independent, Boca Raton, FL, [6]Perigee Environmental, Big Pine Key, FL, [7]School of Marine Sciences, Darling Marine Center, University of Maine, Walpole, ME

Standardised AGRRA coral health indicators *(e.g.,* >5% recent mortality of outer colony surfaces) have quantified the immediate impacts of acute perturbations like mass bleaching and outbreaks of disease. The program's reef-community condition indicators *(e.g.,* old mortality of coral colony surfaces, live coral cover, abundance of benthic algae, AGRRA fish data) have assessed the effects of chronic stressors acting on longer (multi-months to multi-annual) time scales. Collectively the AGRRA data are a regional baseline of reef community status for the early 21st Century against which future changes can be compared. This baseline augments previous evidence for widespread reef decline at <20 m in much of the wider Caribbean, even though the average live coral cover of 19% on 468 surveyed fore reefs was higher than expected. For example, at some sites small, non-framework building corals have replaced large, massive species in a change that may not be evidenced in coral cover. Macroalgae have clearly increased in abundance and biomass on many reefs. Given their regional importance as reef framework constructors, significant declines in the *Montastraea annularis* complex after both the 1998 and 2005 mass bleaching events are cause for much concern.

The online database (www.agrra.org) has data on the benthos at some 812 sites spread over the Caribbean, Gulf of Mexico, Florida and the Bahamas and, for the AGRRA fishes, at 689 of the same sites. It is the only comprehensive, standardized dataset for the wider Caribbean. However, because the collection of data spanned almost a decade, there is a need to revisit representative areas in a shorter period to determine changes that have occurred since the initial assessments.

## 18-34

**The Status Of Coral Reefs Of The World: 2008**

**David SOUTER*[1]**, Clive WILKINSON[1]

[1]Global Coral Reef Monitoring Network, Townsville, Australia

The condition of coral reefs in most regions of the world has progressively declined during the past 3 to 4 decades. Initial damage was largely caused by human activities, such as over- and destructive fishing, inappropriate coastal developments and land-use causing sedimentation and nutrient pollution, and outbreaks of coral and fish diseases and predators such as the crown-of-thorns starfish; all of which might have been exacerbated by human activities. However, since the first recognised mass bleaching event in 1982/83, there has been growing concern about the influence of climate on coral reefs. Unfortunately, these concerns have been vindicated by the increasing frequency and intensity of mass coral bleaching events, particularly in 1998 when approximately 16% of the world's reefs were functionally destroyed, in 2002 when reefs across the western Pacific were affected, and in 2005 when severe bleaching and coral disease caused up to 50% mortality in many areas of the Caribbean. Caribbean reefs were also subjected to 26 named storms, including 13 hurricanes in 2005. There is also growing recognition that increasing concentrations of atmospheric $CO_2$ threaten the structural integrity of reefs by reducing the rate of calcification in corals. Assessments by the GCRMN, WRI, Reef Check, CORDIO, AGRRA, ReefBase and many NGOs show considerable damage to reefs in Eastern Africa, mainland South Asia, Southeast Asia and the wider Caribbean, although there are signs that the condition of reefs is improving in well managed areas and where there are major national, and international initiatives by governments and NGOs to conserve coral reefs, particularly when the community and stakeholders are deeply involved. The results of 80 national status reports highlight that the events of the past decade clearly indicate that there must be unified action to halt and reverse the impacts of climate change on the world's coral reefs.

## 18-35

**Coral Reef Monitoring in The South West Pacific 2007**

**Kenneth MACKAY*[1]**, Cherie WHIPPY-MORRIS[2]

[1]Institute of Marine Resources, University of the South Pacific, Suva, Fiji, [2]Institute of Marine Resources, University of South Pacific, Suva, Fiji

The GCRMN Southwest Pacific Node of Fiji, Nauru, New Caledonia, Samoa, Solomon Islands, Tuvalu and Vanuatu, is coordinated by the Institute of Marine Resources, University of the South Pacific.

Monitoring is carried out by scientists, students, dive guides and communities. Country monitoring sites have been mapped and will feature in the WorldFish Center Reebase Pacific online database. Results show reefs are in good condition but under increasing pressure from anthropogenic impacts (over-fishing, sedimentation, and coastal development) as well as climate events (cyclones, tsunamis and coral bleaching). Coral cover has recovered in Fiji since the bleaching events of 2000 and 2002. Solomon Islands experienced an earthquake and tsunami in 2007 with deep sites damaged by underwater landslides while one island was uplifted 3m. Recent monitoring there shows little impact on the fish assemblage but future monitoring will determine the long-term impacts. Recognition of anthropogenic impacts has led to establishment of Marine Protected Areas (MPA) by communities. Coral health and fish populations are increasing in some MPAs.

A network of temperature loggers has been established in Fiji and is being expanded to other countries to collect long-term data and its relationship to bleaching. A reef crisis framework has been developed to provide information on reef recovery and resilience.

IMR has coordinated workshops: on monitoring, in-country networking and data analysis and report preparation to increase in-country capacity. Priority for future work will be specific in-country database and measuring effectiveness of MPAs.

A report on the 2004 Status *has* just been published while the 2007 report will be less inclusive but published more timely. .

The value of long-term monitoring has been shown but on-going resources are required to allow predictions of responses of coral reefs to anthropogenic and climate change stresses.

## 18-36

**Rapid Recovery From Bleaching Events -Fiji Global Coral Reef Monitoring Network Assessment Of Hard Coral Cover From 1999-2007**

**Edward LOVELL*[1]**, Helen SYKES[2]

[1]School of Marine Studies, University of the South Pacific, Suva, Fiji, [2]Marine Ecology Consulting Fiji, Suva, Fiji

Long-term biological and water temperature monitoring of reef sites across the Fiji Islands was carried out over an eight year period which included mass coral bleaching events. Data was contributed by many organisations, including scientists, tourism operators, non-governmental and community members. All used point intercept transects from which the percentage of hard coral cover was used for regional comparisons over-time. Benthic data was generally recorded as coral life-form categories. In-situ temperature loggers were placed on sites where biological surveys were made, and compared with NOAA sea surface temperature (SST) records. High SST's in 2000 and 2002 led to large-scale coral bleaching events with hard coral mortality of 40 – 80%. In both cases, temperatures remained above the observed bleaching threshold (29ºC) for over 3 months. Though variable, substantial recovery to pre-bleaching levels was seen within 5 years in many areas. Fiji's reefs show great diversity, and are spread over a large geographical area. Though mass bleaching events were expansive, they did not affect the entire country's reef systems at one time. Some habitats appear to be conducive to minimising the effects of bleaching. This allowed for the repopulating of affected areas more swiftly than may occur in more isolated reefs. A high level of resiliency of the Fiji reef system as a whole is indicated, and is a cause for optimism.

**It Depends On Where You Look: The Status Of Coral Reef Ecosystems in The United States And Pacific Freely Associated States**

**Alicia CLARKE*[1]**, Jeannette WADDELL[1]

[1]Center for Coastal Monitoring and Assessment, Biogeography Branch, National Oceanic and Atmospheric Administration, Silver Spring, MD

U.S. states, territories, commonwealths and affiliated states that contain coral reef ecosystems span more than half the globe from the U.S. Virgin Islands to Palau. T*he State of Coral Reef Ecosystems of the United States and Pacific Freely Associated States: 2008,* a NOAA publication, pools monitoring data from 15 jurisdictions to provide a comprehensive assessment of the condition of the nation's coral reefs in an effort to broadly summarize key threats, present monitoring activity results in three primary categories, and describe current management actions taken at both local and national levels to conserve coral reefs. Data from the U.S. Virgin Islands, Puerto Rico, Navassa Island, Southeast Florida and the Florida Keys, the Flower Garden Banks and other banks of the NW Gulf of Mexico, Hawaii, the Northwestern Hawaiian Islands, American Samoa, the Pacific Remote Island Areas, the Commonwealth of the Northern Marianas, Guam, the Republic of the Marshall Islands, the Federated States of Micronesia and the Republic of Palau are presented. Information from jurisdictional chapters written by teams of scientists, academics, coastal managers, and state and federal agencies is used to develop the National Summary chapter which describes trends in ecosystem condition. This chapter of the report also presents key biotic and abiotic variables that are currently the focus of monitoring efforts, spatial and topical data gaps, and a qualitative assessment of the perceived impact of 13 key threats identified in the U.S. Coral Reef Task Force's National Coral Reef Action Strategy. The 2008 report is the third in a series of reports intended to deliver the most comprehensive and up-to-date information to a wide audience, including members of the U.S. Congress, scientists, managers and the general public. Results from the 2008 report will be released and presented during the ICRS.

## 18-38

**The Status And Trends Of Coral Reef Ecosystems in The Hawaiian Archipelago**

**Eric BROWN*[1]**, Greta AEBY[2], Russell BRAINARD[3], Kathy CHASTON[4], Athline CLARK[5], Alan FRIEDLANDER[6], Jean KENYON[3], Petra MCGOWAN[7], Tony MONTGOMERY[5], William WALSH[8], Ivor WILLIAMS[8], Wendy WILTSE[9]

[1]Kalaupapa NHP, U.S. National Park Service, Kalaupapa, HI, [2]Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kaneohe, HI, [3]Pacific Islands Fisheries Science Center, Coral Reef Ecosystem Division, NOAA, Honolulu, HI, [4]Dept. of Natural Resources & Environmental Management, University of Hawaii at Manoa, Honolulu, HI, [5]Division of Aquatic Resources, Hawaii Department of Land and Natural Resources, Honolulu, HI, [6]Biogeography Branch and The Oceanic Institute, NOAA, Waimanalo, HI, [7]Division of Aquatic Resources, NOAA, Honolulu, HI, [8]Division of Aquatic Resources, Hawaii Department of Land and Natural Resources, Kailua-Kona, HI, [9]Pacific Islands Contact Office, U.S. Environmental Protection Agency, Honolulu, HI

Coral ecosystems in the Hawaiian archipelago range from poor to excellent condition and are geographically split into the remote Northwestern Hawaiian Islands (NWHI) and the populated Main Hawaiian islands (MHI) in the southeast. Archipelago-wide stressors include large waves, increasing temperature (0.8°C since 1956), diseases, ship groundings, and marine debris. MHI-specific stressors add coastal development, pollution, increasing tourism, shifting fisheries, the commercial aquarium fishery, and invasive species.

Resource condition assessment indicated that overall quality of Hawaii's waters is good with impaired coastal waters in the MHI around harbors and protected embayments. Benthic habitats had moderate coral coverage (20.0%) across 1746 sites in the archipelago. Coral cover was highest in the southern portion of the archipelago and lowest in the north. Trends at long-term (>10 yrs) MHI sites showed that the majority (70%) experienced a decline in percent coral cover. Fish biomass was highest on islands with low human populations and this pattern appears consistent since 2000. Oahu with the highest human population had the lowest overall fish biomass and apex predators were virtually absent. Assessments for 55 fish species targeted in all fisheries found that nearly three-quarters of the species are depleted.

In 2006, the NWHI were designated a Marine National Monument, the largest fully protected marine conservation area in the world, encompassing nearly 3,626,000 $km^2$ (100%). In the MHI no-take MPAs comprise only 2.2 $km^2$ (0.4%) of nearshore waters with an additional 19.4 $km^2$ (3.6%) in partially protected areas, and 35.0 $km^2$ (6.5%) in areas with no or restricted access. Studies have shown that the MHI are in poor condition compared with the NWHI and even small protected areas in the MHI do not adequately protect the full complement of species or interactions found in the NWHI.

## 18-39

**Healthy Algal-Dominated Reefs On Remote Pacific Islands?**

**Peter VROOM*[1]**, Kimberly PAGE[1], Jean KENYON[1], Russell BRAINARD[1]

[1]Coral Reef Ecosystem Division, NOAA Pacific Island Fisheries Science Center, Honolulu, HI

Reefs surrounding remote, uninhabited islands in the central Pacific Ocean have been regarded as "predominantly healthy and at low threat risk" by leaders of tropical reef research. To gain multidisciplinary understanding of such healthy reefs under U.S. jurisdiction, NOAA, PIFSC's Coral Reef Ecosystem Division began synergistic surveys of fish, coral, macroinvertebrates, and algae coupled with oceanographic surveys in 2000. Baseline research presented here showcases percent cover of benthic organisms at a functional group level from eight of the most isolated islands monitored, including reefs from the Northwestern Hawaiian Islands (NWHI), the U.S. Phoenix Islands (USPI), the U.S. Line Islands, American Samoa, and the Commonwealth of the Mariana Islands. Although localized patches of dense coral cover occurred in select habitats at all of these top-predator-dominated islands, average coral cover ranged from 7.1% to 32.7%. Algal functional groups (macroalgae, turf algae, and crustose coralline red algae) were 2.0 to 12.0 times more abundant than corals around islands when all habitat types were considered together, with fleshy macroalgae occupying more substrate than corals at 46% of sites examined. This unexpected finding is forcing scientists to reevaluate the definition of reef health at remote tropical Pacific islands. Can the same parameters used to gauge reef health in one ecosystem be transferred to other ecosystems in different geographic areas? For instance, the subtropical NWHI are dominated by turf algae and the meadow-forming green alga, Microdictyon, whereas the USPI contain very little turf algae but high abundances of crustose coralline red algae. Should low coral cover automatically be considered alarming if no evidence of a recent phase-shift is evident? Is a high abundance of macroalgae always indicative of decreased reef health?

## 18-40

**Pacific Reef Assessment And Monitoring Program (Ramp): Integrated Ecosystem Observations Of Coral Reef Ecosystems Of The U.s. Pacific Islands**

**Russell BRAINARD*[1]**, and Research COLLEAGUES[1,2]

[1]Coral Reef Ecosystem Division, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [2]Joint Institute for Marine and Atmospheric Research, University of Hawaii, Honolulu

In an effort to provide scientific information needed to support ecosystem approaches to management of coral reefs in the U.S. Pacific Islands region, a multi-institutional team of scientists led by NOAA's Coral Reef Ecosystem Division has been collaborating to implement the Pacific Reef Assessment and Monitoring Program (RAMP): an integrated ecosystem observing system to map, assess, and monitor the coral reef ecosystems across the Pacific region. With support from NOAA's Coral Reef Conservation Program, Pacific RAMP has conducted multidisciplinary baseline assessments and biennial monitoring around 50 island/atoll ecosystems in the Hawaiian and Marianas Archipelagos, American Samoa, and the remote U.S. Line and Phoenix Islands. Monitoring efforts include rapid ecological assessments of corals, other invertebrates, fish, and algae to species or genus level using multiple methods; spatial towed-diver surveys of benthic composition and the abundance and distribution of ecologically and economically important macroinvertebrate taxa and large fish; mapping of shallow and moderate depth benthic habitats using multibeam acoustic systems, optical systems, and satellite imagery; passive acoustic monitoring of biotic and anthropogenic sounds; and multi-platform oceanographic and water quality monitoring using shipboard surveys, moored instrument arrays, drifters, and satellite remote sensing. A subset of these multidisciplinary ecosystem observations have been integrated into the *Coral Reef Ecosystem Monitoring Report for American Samoa: 2002 – 2006*, the first in a series of comprehensive reports for each of the four U.S. Pacific Island regions. Use of consistent multidisciplinary methods across this vast region allows an unprecedented opportunity to perform biogeographic and ecological comparative analyses across diverse ecological, environmental, oceanographic, and socioeconomic gradients. Patterns of variability of reef fish biomass, coral cover and disease prevalence, and other reef metrics across the Pacific Islands are examined.

## 18-41

**Observer Variability And Deployment Effect With Reef Check Data In Australia: Implications For Management**

**Jos HILL*[1]**, Andrew HARVEY[1], Laura FANTOZZI[2], Craig SYMS[3]

[1]Reef Check Australia, Townsville, Australia, [2]James Cook University, Townsville, Australia, [3]Marine Biology and Aquaculture, James Cook University, Townsville, Australia

In Australia there is a role for community-based coral reef monitoring programs to supplement government datasets. Reef Check Australia (RCA) volunteers have surveyed 48 sites in the GBR Marine Park since 2001. A well-documented limitation of community-collected data is lack of precision due to the use of multiple observers who have limited levels of training and experience in coral reef monitoring. A key question for reef managers is how well do the data reflect real patterns, and is data resolution sufficient to reveal important changes in reef status? The objective of this study was to determine the level of precision of data collected by RCA participants in order to better inform managers on how the data should be interpreted and where RCA can best value-add to other datasets on coral reef status and trends. We compared data from randomly deployed transects that were surveyed by a sample of trained RCA volunteers. Precision was high for hard corals, with only 6.7% of the random variation due to observer effects. Precision was lower for less abundant substratum types including rubble and recently killed coral. Differences in precision were due to a combination of the percent cover of different substratum types, and the level of substratum categorisation. These results suggest that RCA data can identify temporal trends in cover of important substrata such as hard coral, and that between-observer variability can be minimised in volunteer divers. This enables RCA to make informed recommendations to managers and other stakeholders, with a clear confidence interval on the RCA results. We will discuss the relevance of this study for a successful marriage between the general community and coral reef managers in Australia.

## 18-42

**Assessment Of Resilience in *montastrea Faveolata* Inside And Outside Of A Marine Park**

**Erich MUELLER*[1]**

[1]Perry Institute for Marine Science, Jupiter, FL

Wound healing was used as a proxy for assessing organismal resilience in the coral, *Montastrea faveolata*. In addition, potential effects of wounding on quantum yield determined by PAM fluorometry were examined. Cores (2.5 cm diameter) were extracted from parent colonies cultured at least two years in an open seawater system at Lee Stocking Island (Exumas, Bahamas). In a mesocosm experiment, surface lesions (~0.5 cm2 x 2 mm deep) were imaged daily over 15 days to develop healing curves. Quantum yields were obtained daily using a PAM fluorometer (2 mm fiberoptic) at four locations 5 mm away from the lesion and 10 mm away. Results demonstrated that 50% healing occurred in 5-6 days. To examine whether wound healing (i.e. resilience) differed in the Exuma Cays Land and Sea Park from a control location near Lee Stocking, additional cores were removed from parent colonies (N=6) and deployed to one of three field arrays at each site. Lesions, images and PAM measurements were made on day 0 and again 5-7 days later. These procedures were repeated in the winter, spring and summer of 2007. There were no seasonal differences in healing rates or between genotypes. No consistent effects of site, time of year or wounding were seen on quantum yields of surrounding tissue, however, newly formed tissues had significantly lower yields than measured in undamaged tissues. Healing was significantly greater at the Park site in the winter of 2007 but there were no site differences in spring or summer. This Marine Management Area Science (Conservation International) study has developed a simple and inexpensive method to assess coral resilience. It will be further developed examining known stressors and with colonies *in situ* to provide researchers and resource managers with a tool to identify colonies and reef areas particularly susceptible to decline.

## 18-43

**Occupancy Models For Estimating The Size Of Reef Fish Communities**

**M. Aaron MACNEIL*[1]**, Timothy R. MCCLANAHAN[2]

[1]National Research Council, NOAA Panama City Laboratory, Panama City Beach, FL, [2]Wildlife Conservation Society, Bronx, NY

Reef fish surveys conducted using underwater visual census (UVC) have the potential to introduce substantial downward bias in species richness estimates when cryptic, mobile, or rare species are prevalent. In particular, heterogeneity in the detection of reef fish species can inflate or distort trends in community composition through time, compromising the quality of data collected and degrading our ability to link observations with processes. Using a suite of models for repeated observations through time, we develop a framework for estimating the number and composition of species in a reef fish community that can be readily applied to conventional survey data. Estimation of community-level quantities are made from model-based estimates of occurrence that incorporate imperfect detection of individual species. We suggest that occupancy models should be routinely used in monitoring programs, particularly in threatened or recovering areas.

## 18-44

**Evaluating The Health Of The Mesoamerican Reef**

**Melanie MCFIELD*[1]**, Nadia BOOD[2], Ana FONSECA[3], Alejandro ARRIVILLAGA[4], Albert FRANQUESA RINOS[5], Rosa María LORETO VIRUEL[6]

[1]Smithsonian Institution, Belize City, Belize, [2]Worls Wildlife Fund, Belize City, Belize, [3]Universidad de Costa Rica, San Jose, Costa Rica, [4]The Nature Conservancy, Guatemala City, Guatemala, [5]Amigos de Sian Kaan, Puerto Morelos, Mexico, [6]CONAP, Cancun, Mexico

Like most of the world's reefs, the health of the Mesoamerican Reef (MAR) has declined in the last decades. The1998 coral bleaching event and Hurricane Mitch caused widespread bleaching and significant coral mortality, particularly in Belize. Large-scale bleaching affected most reefs within the MAR in late 2005, although resulting coral mortality was lower than in previous bleaching years. The active 2005 storm season damaged reefs, mainly in Mexico, but may have also contributed to greater mixing of oceanic waters and prevented 'doldrum conditions' associated with more severe bleaching events. The bleaching and hurricanes in 2005 may have further delayed potential recovery from the bleaching-related losses of 1995 and 1998, as coral cover throughout the region remains moderately low (just over 10%), with little to no overall recovery from the 1998 losses. The 2006 Rapid Reef Assessment sponsored by TNC and WWF was the largest reef study ever conducted in the MAR and aimed to evaluate reef recovery from these disturbances and provide a comprehensive, representative assessment of reef health throughout the region. The results are also being used by a variety of partners for different management and research purposes. These data are also being combined into an Integrated Reef Health Index, as one component of a new ecosystem report card for the Mesoamerican Reef being developed by the Healthy Mesoamerican Reef Ecosystem Initiative. The findings from Belize are similar to the other countries: Only 3.7% of over 5000 colonies assessed showed any signs of coral bleaching by summer 2006. Average disease infestation was also low (<2% of colonies). Mean recent coral mortality for was less than 1.5%, with no difference among habitats. Although the 2005 bleaching event did not cause significant mortality it may have contributed to the continued lack of recovery recorded on these reefs.

## 18-45

**New Insights Into The Exposure And Sensitivity Of Coral Reefs To Ocean Warming**

**Patrick BOYLAN*[1]**, Joanie KLEYPAS[1]

[1]Institute for the Study of Society and Environment, National Center for Atmospheric Research, Boulder, CO

Increases in coral bleaching events over the past 20 years are correlated with increases in sea surface temperature (SST). While SSTs have increased everywhere in the tropics, and coral bleaching events have occurred in all coral reef provinces, the frequency and intensity of coral bleaching events have varied considerably from region to region. Unless these patterns are random, we can derive useful information about why some reefs have been less vulnerable to increasing SST, and use this information to guide conservation efforts. Coral reef vulnerability to bleaching is a function of exposure to some stress (elevated SST), sensitivity to that stress, and the capacity of the reef to adapt to the exposure. To better characterize differences in coral reef vulnerability to increases in SST, we analyze temperature and coral bleaching records from reefs in select regions for differences in exposure (nature of the SST increase at multiple temporal scales) and sensitivity to the SST increase. These refined relationships between temperature and bleaching allow us to create region-based bleaching thresholds that allow better predictions of future bleaching events.

## 18-46

**Mesophotic Reefs Of The Puerto Rican Shelf: Physical Processes, Resistance To Climate Change, Cryptic Mortality, And Future Trajectories**

**Tyler SMITH*[1]**, Richard NEMETH[1], Jeremiah BLONDEAU[1], Jacqulyn CALNAN[1], Elizabeth KADISON[1]

[1]Center for Marine and Environmental Studies, University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.)

Mesophotic coral reefs (MPR) are some of the least studied and most poorly understood reefs systems in the world. Available data for the Caribbean and extrapolation from bathymetric data suggest that these environments are extensive between 30 and 100 m. MPR south of St. Thomas (US Virgin Islands) have been under investigation for the last five years. A study to understand the resources within a full no-take marine reserve, the Red Hind Marine Conservation District (MCD, 41 $km^2$), using technical SCUBA and closed circuit rebreather, has revealed 25 $km^2$ of coral reefs, and expanded estimates of coral reef structure from multi-beam/side-scan data by ~110%. Surveys show that coral cover is unusually high for modern Caribbean reefs, and often surpasses 40%. Furthermore, a community of commercially important fish species, including rare high trophic level carnivores, is both abundant and in large biomass. Both exploratory dives and inspection of regional bathymetry strongly suggest that similar MPR are extant in a large (300 $km^2$+) region near St. Thomas, a fact that has not been previously appreciated. Studies on the health of these coral reefs have revealed important information on their potential to withstand climate related thermal disturbance. During a mass bleaching event (2005) MPR suffered relatively little bleaching compared to all shallow reefs (5% bleaching prevalence vs. 70%), but still experienced high mortality (27% cover lost vs. 36%). Surveys in 2007 revealed that within the matrix of the MCD a large (8 $km^2$), spatially explicit cryptic coral mortality event occurred (42% of sites at 45% prevalence), that was decoupled from trends in shallow reefs. The spatial extent of mortality suggests a large common driver. Clearly, further ecological, geological and oceanographic investigations are needed to fully understand the role that MPR play within the interconnected reefs systems of the Caribbean and the world.

## 18-47

**Recurrent Large-Scale Disturbances, Recovery Trajectories, And Resilience Of Coral Assemblages On A Coral Reef in The South-Central Pacific**

**Mehdi ADJEROUD*[1]**, François MICHONNEAU[1], Peter J. EDMUNDS[2], Yannick CHANCERELLE[3], Lucie PENIN[1], Jérémie VIDAL-DUPIOL[1], Bernard SALVAT[1], René GALZIN[1]

[1]Biologie et Ecologie Tropicale et Méditerranéenne, Université de Perpignan, Ecole Pratique des Hautes Etudes, UMR 5244 CNRS-EPHE-UPVD, Perpignan, France, [2]Department of Biology, California State University, Northridge, CA, [3]Centre de Recherches Insulaires et Observatoire de l'Environnement, Moorea, French Polynesia

Temporal variability in coral community structure on the outer reef at Tiahura, Moorea (French Polynesia) was investigated between 1991 and 2006 to test for the effects of major disturbances. During the study, the reef was impacted by one cyclone (1991) and four bleaching events (1991, 1994, 2002, 2003). The cyclone and bleaching of 1991 had the greatest impact, and caused a rapid decline in coral cover from 51.0 % in 1991 to 24.2 % in 1992. In contrast, the three successive bleaching events had little effect on coral cover, even though the thermal anomalies causing these events were similar to the conditions leading to the 1991 bleaching. By 2001, coral cover returned to the 'pre-disturbance' levels of early 1991, but the trajectories of change differed among genera. *Acropora* was affected by the disturbances of 1991, but subsequently showed a high rate of recovery; *Montipora* was affected by most disturbances and showed no sign of recovery; *Pocillopora* was affected by the disturbances of 1991, and showed a partial recovery by 1995; and *Porites* was not affected by any disturbances, but increased in cover throughout the study. Our results demonstrate that large-scale disturbances are not always associated with a phase-shift from coral- to algal-dominated communities, but instead show that coral cover can recover rapidly after dramatic declines. To our knowledge, our study is the first contemporary analysis to demonstrate rapid recovery of coral cover, despite the effects of ongoing disturbances, although importantly this trend was achieved through a shift in the relative abundance of coral genera. Thus, coral communities at Tiahura appear to be characterized by ecological resilience to disturbances in terms of coral cover, but fragility in terms of generic composition.

## 18-48

**Multiple States Of Coral Reefs In Human Shaped Environments**

**Albert NORSTRÖM*[1,2]**, Magnus NYSTRÖM[1,2], Jerker LOKRANTZ[1,2], Carl FOLKE[2,3]

[1]Systems Ecology, Stockholm University, Stockholm, Sweden, [2]Stockholm Resilience Centre, Stockholm, Sweden, [3]The Beijer Institute, Royal Swedish Academy of Sciences, Stockholm, Sweden

Coral ecosystems worldwide are facing large-scale degradation that is often associated with phase shifts: modifications of their functions and feedback mechanisms to a new regime. The most well documented type of phase shift on coral reefs involves a decrease in the abundance of scleractinians coupled with an increased abundance of large, fleshy macroalgae. However, there are numerous reports of coral reefs becoming dominated by other organisms following a disturbance but they have largely been ignored in coral phase shift literature. An ISI search with the keywords "phase shifts AND coral" revealed that only 2 out of 152 research articles mention other possible regimes. We search the literature for evidence of transitions from coral dominance to community assemblages other than macroalgae and argue that four other types of phase shifts seem to occur on coral ecosystems: coral to soft coral, coral to corallimorpharian, coral to sponge and coral to urchin barrens. We place our findings in the context of the current phase shift discourse, and discuss whether these transitions constitute alternative states, as opposed to transient alterations in local community structure. We assess processes and mechanisms behind their manifestation, emphasizing human induced drivers. We conclude that the mix of different human-induced drivers (like excess nutrient runoff, sedimentation, overexploitation) in different coastal and marine contexts create attractors of reef development that lead to the existence of a multiple set of alternative regimes.

## 18-49

**A Global Assessment Of The Threat Of Extinction For Reef-Building Corals**

**Kent CARPENTER*[1]**, Suzanne LIVINGSTONE[1], Muhammad ABRAR[2], Greta AEBY[3], Richard ARONSON[4], Andy BRUCKNER[5], Charles DELBEEK[6], Lyndon DEVANTIER[7], Graham EDGAR[8], Alasdair EDWARDS[9], Doug FENNER[10], Hector GUZMAN[11], Bert HOEKSEMA[12], Gregor HODGSON[13], Danwei HUANG[14], Ofri JOHAN[15], Al LICUANAN[16], Edward LOVELL[17], Jennifer MOORE[18], David OBURA[19], Domingo OCHAVILLO[20], Bill PRECHT[21], Miledel QUIBILAN[22], Clarissa REBOTON[23], Zoe RICHARDS[24], Alex ROGERS[25], Jonnell SANCIANGCO[1], Anne SHEPPARD[26], Charles SHEPPARD[26], Jennifer SMITH[1], Muhammad SYAHRIR[2], Emre TURAK[27], Ernesto WEIL[28], Elizabeth WOOD[29], Dana ZEBROWSKI[1]

[1]Global Marine Species Assessment, IUCN - World Conservation Union, Norfolk, VA, [2]The Indonesian Coral Reef Foundation, Jakarta, Indonesia, [3]Hawaii Institute of Marine Biology, Honolulu, HI, [4]Dauphin Island sea lab, Dauphin, AL, [5]NOAA, Boston, ME, [6]Waikiki Aquarium, University of Hawaii at Manoa, Honolulu, HI, [7]Australian Institute of Marine Science, Brisbane, Australia, [8]Conservation International, Perth, Australia, [9]Newcastle University, Newcastle, United Kingdom, [10]Dept Marine & Wildlife Resources, American Samoa, United States Minor Outlying Islands, [11]Smithsonian Institute, Panama City, Panama, [12]Naturalis, Amsterdam, Netherlands, [13]Reef Check, Los Angles, CA, [14]National University of Singapore, Singapore, Malaysia, [15]Research Center for Aquaculture, Jakarta, Indonesia, [16]DeLa Salle University, Manilla, Philippines, [17]University of the South Pacific, Fiji, Fiji, [18]NOAA, Tampa, FL, [19]CORDIO East Africa, Nairobi, Kenya, [20]Reef Check Philippines, Manilla, Philippines, [21]Reef Resources, Miami, FL, [22]Conservation International, Manilla, Philippines, [23]Marine Laboratory Silliman University, Manilla, Philippines, [24]James Cook University, Townsvillle, Australia, [25]Institute of Zoology, Zoological Society of London, London, United Kingdom, [26]University of Warwick, Warwick, United Kingdom, [27]AIMS, Paris, France, [28]University of Puerto Rico, Mayagüez, Puerto Rico, [29]Marine Conservation Society, Peterbourgh, United Kingdom

The continuing decline and growing threat facing the world's coral reefs motivated the IUCN Species Survival Commission to conduct a series of workshops under the Global Marine Species Assessment initiative to evaluate the zooxanthellate scleractinian coral species of the world against the categories and criteria of the IUCN's Red List of Threatened Species. This is the first attempt to globally assess the threat of extinction for reef-building corals at the species level. A high proportion of species were listed in threatened categories based on habitat decline of recently destroyed and critically declining reefs and life history traits related to species resilience to threats. In addition to habitat loss estimated from published reef assessments and monitoring data, major threats were identified as bleaching, disease, acidification and other climate-related phenomenon, coastal destruction, over-harvesting for the curio and aquarium trade and other human disturbance. This global taxonomic group represents one of the richest and most important ecosystems in the ocean, and the IUCN Red List assessment highlights that the threat off loss of marine biodiversity is comparable to that of terrestrial environments.

## 19-1

**Nutritional Exchange in The Anemonefish/anemone Symbiosis: Photosynthetically-Fixed Carbon Is Translocated To Host Fish**

**Ann CLEVELAND*[1]**, Alan VERDE[1], Raymond LEE[2]

[1]Corning School of Ocean Studies, Maine Maritime Academy, Castine, ME, [2]School of Biological Sciences, Washington State University, Pullman, WA

The relationship between anemones and anemonefish is an oft-cited and endearing example of a mutualistic symbiosis. Current research on mutualistic symbioses suggests these relationships are more commonplace and have greater import at the ecosystem level on nutrient dynamics and evolutionary processes than previously thought. Our research examines the flow of nutrients between resident anemonefishes *Amphiprion clarkii* and *A. perideraion* and their host anemone *Heteractis crispa*; this study provides the first direct evidence of nutritional transfer from zooxanthellae to resident fish. Specifically we traced 1) the flow of photosynthetically-fixed carbon from zooxanthellae to resident fish and 2) the flow of ingested carbon and nitrogen from anemones to resident fish. In the photosynthetic study, anemones were incubated in seawater with 13CO2; in the carbon/nnitrogen study, anemones were fed pellets containing both 13C and 15N. After isotopic exposures, anemones were transferred to individual aquaria equipped with running seawater and paired with a resident fish. Prior to placing each fish in an aquarium and at 2, 4, 8, 16, and 24 hr after exposure to labeled anemones, the epidermis of each fish was wiped with GFC filters; after a 12 d exposure to the labeled anemones, tissue samples were collected from each fish. Filters and fish tissues were analyzed for 13C and 15N using a mass spectrometer. 13C was detected in the filters at the 2 hr timepoint and both 13C and 15N were present in fish tissue samples. Although isotopic label is transferred directly from anemone to fish epidermis via direct contact, the only mechanism for the fish tissues to accumulate the labels is by ingestion. The data suggest that fish are directly ingesting zooxanthellae expelled by the anemone and that photosynthetically-fixed carbon may be an important supplement to anemonefishes.

## 19-2

**Continuous Measurements Of Productivity Over An Algal Reef Flat Using A Modified Eulerian Approach**

**James FALTER*[1]**, Ryan LOWE[2], Marlin ATKINSON[1], Stephen MONISMITH[3], Daniel SCHAR[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI, [2]School of Environmental Systems Engineering, University of Western Australia, Perth, Australia, [3]Civil and Environmental Engineering, Stanford University, Stanford, CA

We made continuous measurements of the flux of dissolved oxygen over an algal-dominated reef flat community on the Kaneohe Bay Barrier Reef, Hawaii as a proxy for the instantaneous net community production (NP) of organic carbon. Fluxes were calculated from measurements of dissolved oxygen and current profiles taken from moored oxygen sensors and acoustic Doppler current profilers (ADCPs) located at points defining the vertices of a triangular control volume 250 m in length on each side. We also used conventional Lagrangian methods of estimating NP by following drifters and dye patches. Comparison with conventional Lagrangian methods of estimating NP were excellent when tracking water with dye patches, however, the use of surface drogues over-predicted NP. Continuous measurement of daily integrated Production (P) and integrated community Respiration (R) reveal that R varies with P on short time scales in response to changing light conditions; thus indicating the predominance of autotrophic respiration in this plant-dominated reef community. At seasonal time scales, P and R are well matched in late fall and winter, however, P:R become significantly greater than 1 in summer. In addition, light utilization efficiencies were significantly greater in summer than late fall.

## 19-3

**Nitrogen Dynamics on a Post-bleaching Reef**

**Glen HOLMES*[1]**, Ron JOHNSTONE[1]

[1]The University of Queensland, St Lucia, Australia

Understanding the dynamics of coral reef nutrients, particularly nitrogen, following a coral mortality event is imperative for the prediction of further possible changes on the impacted reef as well as for the identification of potential management interventions. This is particularly pertinent in view of the continued trend towards the increased frequency and geographic extent of coral mortality events. This study investigated the dynamics of nitrogen associated with microbial communities that develop on coral skeletons following bleaching induced mortality using both the acetylene reduction and isotopic nitrogen techniques. The results show that nitrogen fixation activity increases dramatically in the initial three months following coral mortality with fixation rates as much as an order of magnitude higher than those observed on hard substrate material throughout the study sites. Rates of ethylene conversion up to 705 µmol.m-2.hr-1 were observed on *Montastrea faveolata* skeletons while nitrogen fixation rates using 15N of up to 144 µmol N2.m-2.hr-1 were observed on *Acropora aspera* skeletons. These rates are higher than previously reported for coral reefs. Nitrogen fixation activity was found to be influenced by environmental parameters such as nutrient loading and light levels. The results also suggest that the microbes persisting from the pre-bleached coral may influence the dynamics of the microbial community developing on the newly dead coral skeletons. The observed rates of nitrogen fixation following bleaching induced coral mortality may potentially be sufficient to singularly direct an affected ecosystem towards a phase change from a coral to algal dominance.

## 19-4

**Nitrogen Fixation in Coral Reef Environments**

Coral reefs are sites of high nitrogen fixation activity. Marine cyanobacteria are major contributors of nitrogen fixation in coral reefs. In coral reefs cyanobacteria can be found in very diverse environments: in the water column, in the sandy bottom, on coral gravels as endolithic and epilithic forms, or forming microbial mats. The high diversity of cyanobacteria in coral reefs shows their adaptative capacity to live in these nutrient limited environments. The purpose of the present research is to evaluate N2 fixation rates in different environments of the coral reefs and their contribution to the primary production of the total ecosystem. Two different fringing coral reef sites were studied: Sesoko at Okinawa, Japan and La Reunion at the Indian Ocean. N2 fixation and primary production rates were measured using 13C and 15N fixation techniques. Time series incubations were done in order to asses N2 fixation during the night (dark period) and day time. Measurements were done in sandy bottom, coral gravels and cyanobacteria mats. N2 fixation in sandy bottom varied from 2 to 8 µmol N/mg Chl-a with 2.5 to 12% contribution to the primary production. In coral gravels it ranged from 0.5 to 12 µmol N/mg Chl-a with 6 to 26% contribution to primary production, while in cyanobacteria mats it varied between 9 to 240 µmol N/mg Chl-a with contributions of 5 to 21% to the primary production. Differences in N2 fixation rates between daytime and nighttime were found in all the studied environments. Moreover the presence of both heterocystous possessing and non-heterocystous possessing cyanobacteria indicates that N2 fixation and primary production were separated in time (day and night) and space (presence of heterocystous) due to oxygen sensitivity of the nitrogenase enzyme.

## 19-5

**Cyanobacteria Mats in Two Shallow Coral Reef Ecosystems: La Reunion (Sw Indian Ocan) And Sesoko (Okinawa, Nw Pacific Ocean)**

**Charpy LOIC*[1]**, Casareto BEATRIZ[2], Langlade MARIE JOSÉ[3], Suzuki YOSHIMI[4], Palinska KATARZYNA[5], Golubic STJEPKO[6]

[1]IRD, Marseille, France, [2]Laboratory of Aquatic Science and Consultan, Tokyo, Japan, [3]IRD, Marseille, France, Metropolitan, [4]Shizuoka University, Shizuoka, Japan, [5]University of Oldenburg, Oldenburg, Germany, [6]Boston University, Boston, MA

Various types of microbial mats are present in Okinawa and La Reunion coral reef ecosystems. The heterocystous Nodularia and non-heterocystous Leptolyngbya cyanobacteria were present in the two ecosystems. Many mats contained a mixture of different morphotypes. Using the acetylene reduction technique, nitrogenase activity was observed in all the tested mats. The conversion ratio of ethylene to N (C2H2:N2) calculated from 15N2 method ranged between 1.1 and 5.8. Nitrogen fixation by Nodularia, Hydrocoleum lyngbyaceum and Hydrocoleum cantharidosmum mats were particularly high at Sesoko compared with literature data. Nitrogen fixation represented between 5% (Leptolyngbya ) to 21% (Hydrocoleum cantharidosmum ) of that required for primary production measured using 13C uptake and C:N ratio.

## 19-6

**Functional Role Of Crustose Coralline Algae in Nutrient Dynamics Of Coral Reef Ecosystem**

**Yeong Shyan YUEN*[1]**, Seitaro S. YAMAZAKI[1], Takashi NAKAMURA[1,2], Hideo YAMASAKI[1]

[1]Faculty of Science, University of the Ryukyus, Okinawa, Japan, [2]Amakusa Mar. Biol. Lab., Kyushu University, Kumamoto, Japan

Coral reefs worldwide, especially those located near the coastline are constantly being subjected to anthropogenic nutrient input. This anthropogenic nutrient input generally increases the nitrogenous compound concentrations in seawater. This is in contrast with the paradigm that coral reefs thrive best in oligotrophic waters. Accordingly, the study of biogeochemical of nitrogen cycle in reef ecosystems should consider this increasing eutrophication phenomenon. In addition, crustose coralline algae (CCA), a main reef-builder, have been overlooked when it comes to the study of organisms involved in the major nitrogen cycle processes. CCA is well known for its important role in reef-building, inducer for invertebrates' larval settlement and metamorphosis as well as primary producer. In this study, we consider CCA as a combination of the algal component and its calcium carbonate substratum. Here, we report the $NH_4^+$ and $NO_3^-$ uptake activities by CCA and the organisms involved in these activities. Laboratory experiments on the nutrients uptake involved the incubation of CCA in seawater containing a spike of nutrient and monitor its depletion. Organisms involved in nutrients uptake was identified using molecular biological approach. Our results show that microbial consortium residing in the substratum plays a major role in nitrogen cycle processes in the CCA system. The substratum covered by CCA would create a low oxygen concentration environment as well as anoxic environment, which is ideal for the growth of various microbes. Our finding leads us to conclude that CCA is an important functional group involved in the nutrient dynamics in coral reef ecosystems.

## 19-7

**Nitrogen Dynamics in Symbiotic Relationships in Corals**

**Kazuyo SHIROMA*[1]**, Yoshimi SUZUKI[1], Kazuhiro DAIGO[1], Sylvain AGOSTINI[1], M.F. M. FAIROZ[1], Beatriz E. CASARETO[1,2]

[1]Shizuoka University, Shizuoka, Japan, [2]Laboratory of Aquatic Science, Tokyo, Japan

Symbiotic systems in corals are found to be complex and diverse today. The components are not only corals and zooxanthellae but algae and bacteria also have important roles in/on corals. The systems sustain coral symbiosis with nitrogen cycling in oligotrophic environment.

Empirical data have demonstrated imbalance of nitrogen budget that contributed in the symbiotic relationships with measurement such as nutrients in seawater and nitrogen isotope in corals. These studies found that besides external resources, internal resources are used in coral symbiosis.

Isotope technique enables determination of external resource usage or translocation of nitrogen from symbionts to corals without facing to nitrogen conservation issues. However, the calculation used today overestimate uptake rate by coral symbiosis since only uptake but not excrete rates are considered. If the assimilation of ammonium only contribute 10 % of nitrogen required by zooxanthellae, nitrogen cycle in corals are underestimated. Here, we propose possible methods to evaluate internal and external nitrogen cycles found in symbiotic systems in corals.

By introducing C and N stable isotopes into seawater simultaneously, we found that uptake ratios fluctuate, possibly caused by variation in internal resource availability to coral symbiosis. In the future, mathematical model is built to develop as a tool to predict nitrogen dynamics in coral reefs with environmental data. Construction of mathematical model of the symbiosis become useful tool to predict fluctuations of symbiotic relationships in corals those are vulnerable to environmental changes.

## 19-8

**Dissolved Organic Carbon Dynamics and Microbial activity in Tropical and Sub-tropical Coral Reefs**

**Fairoz M F M *[1]**, Forest ROHWER[2], Yoshimi SUZUKI[1], Beatriz CASARETO [3]

[1]Global Biogeochemistry Lab, Shizuoka University, Japan, Shizuoka, Japan, [2]Biology Department, San Diego State University, U.S.A., San Diego, CA, [3]Laboratory of Aquatic Research and Consultants (Pvt) Ltd., Tokyo, Japan, Tokyo, Japan

The marine microbial food web is supported by dissolved organic carbon (DOC). Yet very few measurements of DOC have been made on coral reefs and the relationship between DOC, microbial activity, and macro-organisms in reef environment is not well understood. In previous studies we have shown that additions of labile DOC kill corals. In this study, DOC, nutrients and coral reef characters were measured on Sri Lankan reefs and compared with similar measurements from the Caribbean, Line Islands, Bermuda, and Japan. The water chemistry analysis and reefs surveys were performed using JGOFS and Reef Check protocols, respectively. On the northern Sri Lanka coral reef, the DOC levels were high with low nutrient levels. These conditions correlated with higher coral and lower algae cover. DOC levels were lower and nutrient levels were higher at reefs in southern region, which had low live coral and higher algae cover. However, this is significant variation in the general trends. We suggest that the biogeochemical origin and fate of labile fraction of DOC in coral reef will be important to describe the interactions between microbial activity and coral stress.

## 19-9

**A Role Of Organic Matter In Chemical Symbiosis At Coral Reef**

**Yoshimi SUZUKI*[1]**, Beatriz CASARETO[1], Sylvain AGOSTINI[1], M.F.M FARIOZ[1], Kazuyo SHIROMA[1], Loic CHARPY[2]

[1]Graduate School of Science and Tecnology, Shizuoka University, Shizuoka, Japan, [2]Cyanobacteria Lab., IRD, Marseille, France

Bleaching of corals and damages of the symbiotic zooxanthellae are presently believed to result largely from elevated temperature of the seawater and the increase of UV radiation. Mild or moderate bleaching is commonly followed by recovery, but the long-term effects of high temperature of seawater will end in an irreversible bleaching and massive death of corals. Due to the impact of rising up seawater temperature, corals receive a strong stress, and as a result, corals release high amounts of organic matters (mucus) and ammonia. This means that organic matters in dissolved (DOM) and particulate (POM) forms might play an important role for the fate of corals and coral ecosystem, especially in the food web. The production of organic matters by corals can act as a mechanism for defence but also it is used in feeding for particles capture strategy. High amount of ammonia in the reefs surrounding waters can enhance the growth of pico-phytoplankton, which acts as main food source for benthic community. However organic matters may enhance the growth of certain bacteria, which are known to infect corals and induce bleaching and diseases. Therefore the understanding of organic matters dynamics is of extremely importance for the evaluation of coral health. In this paper, the behaviour of dissolved and particulate organic matters such as concentration, distribution and changes in its characteristics (composition such as amino acids, carbohydrate and molecular weight) at the field and during incubation experiments are reported.

We discuss also the significance of chemical symbiosis in coral reef communities.

## 19-10

**Stimulation Of Coral-Derived Organic Matter Release During Bleaching**

**Wolfgang NIGGL*[1]**, Martin GLAS[1], Christoph MAYR[2], Christian LAFORSCH[3], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, Munich, Germany, [2]GeoBio-Center & Department of Earth and Environmental Science, Ludwig-Maximilians-Universität München, Munich, Germany, [3]Department Biology II, Ludwig-Maximilians-Universität München, Munich, Germany

Corals continuously release mucoid exudates in order to clean their surfaces. But recent research also showed that this coral-derived organic matter acts as an energy carrier and particle trap, thus plays an important ecological role for recycling of matter and conservation of nutrients for the oligotrophic reef ecosystem. Some environmental stressors such as air exposure, high sediment loads and turbidity are known to increase mucus production. But although it is a common statement in the literature, scientific data verifying increased mucus release rates during temperature-induced bleaching events (loss of symbiotic zooxanthellae from the coral host) are lacking. This is critical as coral bleaching is the most extensive coral disease world-wide, and bleaching-induced changes in organic matter release potentially have far reaching consequences for reef functioning. In this study, we induced a bleaching event and determined release of particulate organic carbon (POC) and particulate nitrogen (PN) by corals. A new methodology involving several centrifugation steps was introduced in order to separate released zooxanthellae from the coral-derived organic matter. Microscopical counting revealed that at least 99 % of released zooxanthellae could be removed. Our results show that during bleaching on average 50 % more POC is released whereas PN release rates almost doubled compared to the unstressed controls. This is the first experimental evidence that coral bleaching has consequences for organic matter release and ensuing element cycles in tropical reef ecosystems.

## 19-11

**Bacterial Degradability Of The Organic Matter Released From Symbiotic Coral Colonies**

**Yasuaki TANAKA*[1]**, Toshihiro MIYAJIMA[1], Yu UMEZAWA[2], Isao KOIKE[3], Takeshi HAYASHIBARA[4], Hiroshi OGAWA[1]

[1]The University of Tokyo, Tokyo, Japan, [2]Research Institute for Humanity and Nature, Kyoto, Japan, [3]University of the Ryukyus, Naha, Japan, [4]Seikai National Fisheries Research Institute, Ishigaki, Japan

The organic matter released from corals is well known to be utilized by bacteria and stimulate the bacterial growth. However, degradability of the organic matter has not been investigated in a long-term perspective and therefore it is still not understood what % of the released organic matter can actually be mineralized by bacteria. To investigate the long-term degradability, the reef-building corals *Acropora pulchra* and *Porites cylindrica* were first incubated in a normal submerged condition or a stressful condition (air exposure), and released organic matter to the ambient seawater. After taking out of the corals, the incubation seawater containing organic matter was put under dark over 1 year to follow bacterial decomposition of dissolved and particulate organic matter (DOM and POM). The results showed that the concentrations of DOM and POM rapidly decreased within the first 1 week and the remaining organic matter was gradually decomposed much more slowly, suggesting that the coral-derived organic matter had two different fractions in bacterial degradability. The labile organic matter (L-OM) had turnover time of 3.2-9.1 d (average 6.2 d) for DOM and 5.6-9.1 d (average 7.4 d) for POM. The L-OM could be easily mineralized within or around the reef ecosystem. The stressful condition increased the ratio of degradable to bulk organic matter. On the other hand, a part of the coral-derived organic matter was not mineralized even after 1 year, suggesting that it was very recalcitrant to bacterial decomposition. The corals might routinely release such refractory organic matter to the ambient seawater for defense against pathogens.

## 19-12

**Uptake Of Dissolved Organic Matter By The Scleractinian Coral Stylophora Pistillata**

**Renaud GROVER*[1]**, Jean-François MAGUER[2], Denis ALLEMAND[1], Christine FERRIER-PAGÈS[1]

[1]Centre Scientifique de Monaco, Monaco, Monaco, [2]Laboratoire de Chimie Marine, Institut Universitaire Européen de la Mer, PLOUZANE, France

In this work, we investigated the importance of dissolved free amino acids (DFAA) as an organic nitrogen source for the scleractinian coral *Stylophora pistillata*. For this purpose, 15N-enriched DFAAs were used and %15N enrichments were measured separately in both symbiotic zooxanthellae and animal tissue after incubation of the entire coral colonies at different DFAA concentrations and light levels. As previously observed for urea, which is another organic nitrogen source for corals, DFAA uptake is carrier mediated for concentrations below 3 µM and diffusive for higher concentrations. Our results showed that corals are well adapted to in situ DFAA concentrations, since they are able to take up DFAAs at very low concentrations (ca. 0.5 µM) and their Km, that represents the carrier affinity for the substrate was also very low. When normalized to skeletal surface area, uptake rates were ca. twice higher in the animal tissue than in the zooxanthellae and were enhanced by light exposure. The contribution of DFAA as a nitrogen source for tissue growth in the coral *Stylophora Pistillata* was compared to other nitrogen sources such as ammonia and nitrate for the inorganic part, as well as urea for the organic part. It ensues that inorganic sources constitute 75% of the daily nitrogen needs against 24% for the organic sources, and that all dissolved nitrogen sources can supply almost 100% of the nitrogen needed for tissue growth.

## 19-13

**Water Quality Monitoring Along The Florida Reef Tract: Assessment Of Dissolved Organic Matter Sources And Compositional Variations**

**Youhei YAMASHITA*[1]**, Joseph BOYER[1], Diane WILLIAMS[1], Rudolf JAFFE[1]

[1]Southeast Environmental Research Center, Florida International University, Miami, FL

The characterization of DOM can contribute to understanding its ecological roles in diverse aquatic environments. This carbon pool is highly reactive and influences ecosystem function through many biogeochemical reactions and is known to fuel the microbial loop, particularly in oligotrophic environments. Thus in addition to its quantity it is important to determine its source and characteristics (i.e. quality) in large scale and long term water quality monitoring programs. DOM in coastal regions is derived from a variety of sources, including autochthonous planktonic as well as allochthonous terrestrial and anthropogenic sources and its quality has been found to strongly depend on sources and physical and biological processes. This study reports on preliminary data on DOM quality along the Florida Keys reef tract. The concentration of dissolved organic carbon (TOC) and dissolved organic nitrogen (DON) in addition to optical properties of DOM were determined at over 100 field stations ranging from the upper Florida Keys to the Dry Tortugas National Park in the Gulf of Mexico on a quarterly schedule. DOM quality was determined through excitation emission matrix (EEM) fluorescence in combination with parallel factor analysis (PARAFAC). Results show that the DOM associated with the South Florida coral reef community is derived from a combination of sources including autochthonous microbial sources as well as terrestrial and anthropogenic sources, both from the Florida Keys as well as through water exchange with Florida Bay and the Florida Shelf. The spatial variability confirmed potential source assignments of the DOM.

## 19-14

**Organic Matter Cycling in Tropical Coral Reef Ecosystems: The Role Of The Reef Framework And Its Biota, Dominated By Encrusting Sponges.**

**Jasper M. DE GOEIJ*[1,2]**, Joost W. VAN DAM[1,2], Hubèrt EIJKELENBOOM[1,2], Eric H.G. EPPING[3], Fleur C. VAN DUYL[1]

[1]Department of Biological Oceanography, Royal Netherlands Institute for Sea Research, Den Burg, Netherlands, [2]Caribbean Research & Management of Biodiversity, The CARMABI Foundation, Willemstad, Netherlands Antilles, [3]Department of Marine Chemistry & Geology, Royal Netherlands Institute for Sea Research, Den Burg, Netherlands

The coral reef framework is a major sink of organic matter. The removal of organic carbon by framework cavities, with volumes ranging from 50-250 $dm^3$, in reefs of the Berau area, East-Kalimantan, Indonesia and in the reefs of Curaçao, Netherlands Antilles were in the range, or even exceeded the estimated average gross primary production of a coral reef ecosystem. Dissolved organic carbon removal rates by coral cavities were on average 1 to 2 orders of magnitude higher than particulate organic carbon removal rates. A mass balance for carbon (C), nitrogen (N) and phosphorus (P) was constructed for Curaçaoan coral reef framework cavities. The major fate of C was assimilation, suggesting a rapid turnover of matter for a net increase in biomass close to zero. Relative to C and N, P was selectively retained from the reef water flushing the coral cavities. To directly link the nutrient cycling within the reef framework with the cryptic biota, the organic carbon fluxes were determined for the four dominant communities: (1) Sponge, (2) calcareous algae, (3) sediment, and (4) bare substrate – together accounting for, on average, 88% of the surface of the cavities. Evidently, sponges play a key role in the carbon cycling within the reef framework. Sponges, with an average cavity surface cover of approximately 25%, represented approximately 75% of the total organic carbon flux by coral cavities. Dissolved organic carbon accounted for more than 90% of the total organic carbon removal rate by encrusting sponges. We conclude that the coral reef framework is an important habitat for decomposition and (re)cycling of - to large extent dissolved - organic matter within the coral reef ecosystem. The nutrient cycling is mainly accounted for by a thin veneer of, mostly encrusting, sponges.

## 19-15

**Seasonal Carbon Production And Topographic Features in Sesoko Beach Reef, Okinawa, Japan**

**Hiroyuki FUJIMURA*[1]**, Takashi FUKUNAGA[1], Kyouhei ISHIKAWA[1], Koujiro SHIMADA[1], Tomihiko HIGUCHI[1], Tamotsu OOMORI[1], Yoshikatsu NAKANO[2], Tatsuo NAKAI[3], Beatoriz CASARETO[4], Yoshimi SUZUKI[5], Takuji ITO[6]

[1]Department of Chemistry, Biology and Marine Science, University of the Ryukyus, Okinawa, Japan, [2]Sesoko Station Tropical Biosphere Research Center, University of the Ryukyus, Okinawa, Japan, [3]Kokushikan University, Tokyo, Japan, [4]Laboratory of aquatic science consultant (LASC), Tokyo, Japan, [5]Shizuoka University, Shizuoka, Japan, [6]Mitsubishi corporation, Tokyo, Japan

Owing to the global warming and environmental change, coral reefs have been under a serious threat of degradation in the world. In order to understand the present state of coral reefs and predict the future changes, it is important to study a seasonal variation of community carbon metabolism and topographic features in coral reefs. We observed the community carbon metabolism of photosynthesis and calcification every month in Sesoko Beech reef in northwestern part of Sesoko Island, Okinawa, Japan. Most of the corals damaged by mass coral bleaching in 1998 and has not recovered yet. Topographically and biologically different sites were selected as representatives of the reef community in Sesoko. We took water samples every 30min for pH, dissolved oxygen and total alkalinity during slack water periods when the shallow lagoon water (< 80cm) was isolated from offshore. Only two narrow channels is existed and small portion of inside water is flowing out to offshore during low tide. Organic and inorganic carbon productions were estimated from the change in total alkalinity ($A_T$) and total dissolved inorganic carbon ($C_T$) with time. $C_T$ was calculated from pH and total alkalinity using a carbonate equilibrium in seawater. Gross primary production was 300-400 $mmol/m^2/d$ and respiration was 150-300 $mmol/m^2/d$. P/R ratio varied 1.3-1.9, indicating the high photosynthesis rate of fringing reef in Ryukyu Islands. While the high organic carbon production, inorganic carbon production of calcification was 45-55 $mmol/m^2/d$ which is lower value than the other reefs of Okinawa reported before the bleaching. This suggests that the Sesoko coral reef has significantly degraded since coral bleaching in 1998. Further observations are needed to detect the early change in recovery or more additional degradation in the future.

## 19-16

**Temporal Variations in Dissolved Inorganic Nitrogen, Dissolved Gas And Volatile Organic Matter Fluxes Resulting From Sponge Respiration And Microbial Transformations On Conch Reef, Florida Keys (Usa)**

**Christopher MARTENS*[1]**, Niels LINDQUIST[2], Howard MENDLOVITZ[3], James HENCH[4], Richard CAMILLI[5], Anthony DURYEA[6], Brian POPP[7], Patrick GIBSON[3], Melissa SOUTHWELL[3,8], Jeremy WEISZ[9], Nyssa SILBIGER[3]

[1]Marine Sciences, UNC-Chapel Hill, Chapel Hill, NC, [2]Institute of Marine Sciences, UNC-Chapel Hill, Morehead City, NC, [3]UNC-Chapel Hill, Chapel Hill, NC, [4]Stanford University, Stanford, CA, [5]Woods Hole Oceanographic Institution, Woods Hole, MA, [6]Monitor Instruments Company, Cheswick, PA, [7]University of Hawaii at Manoa, Honolulu, HI, [8]UNC-Wilmington, Wilmington, [9]Old Dominion University, Norfolk, VA

High nutrient element fluxes from sponges resulting from rapid respiration rates of dissolved and particulate organic matter likely dominate dissolved inorganic nitrogen (DIN) cycling on the Florida Keys reefs and should be dominant in coral reef ecosystems around the world featuring significant sponge biomass. The barrel sponge *Xestospongia muta* accounts for approximately 60% of sponge biomass in a 600m2 area on Conch Reef off Key Largo, and generates net DIN fluxes exceeding 10 mmol/m2/day, far greater than fluxes from coral substrate and sediments. Respiration by *X. muta* generally results in a 5-15% oxygen drawdown in the huge volumes of ambient water pumped through its tissues. This sponge and many other plentiful species have a single exit point for all exhaled water, allowing for rigorous in situ quantification of filtration rates and net chemical fluxes utilizing a variety of underwater instrumentation. During two 2007 missions utilizing the NURC/UNCW Aquarius Reef Base undersea observatory, chemical transformations and fluxes resulting from *X. muta* respiration were quantified continuously for periods of hours to weeks by coupling chemical sensor measurements with acoustic Doppler velocimetry (ADV) pumping rate measurements. Three different instrument arrays, including a newly designed, in situ membrane inlet mass spectrometer (MIMS), were utilized to continuously measure dissolved gases including O2 (mass 32), N2 (28), Ar (40) and CO2 (44,45) plus a variety of volatile dissolved organic molecules. The stoichiometries of O2 consumption, CO2 production and DIN release were utilized to quantify the role of barrel sponges in reef respiration and C and N cycling and to identify potential biogeochemical transformations such as the uptake of dissolved organic matter, N2 fixation and denitrification. The new capability to measure fluxes of volatile organic molecules from sponges using MIMS should provide novel insights into the chemical interactions of sponges with other reef ecosystem inhabitants.

## 19-17

**Biochemical Symbiotic System in Corals : Role Of The Vitamin $B_{12}$ Produced By Coelenteric Bacteria**

**Sylvain AGOSTINI*[1]**, Yoshimi SUZUKI[1], Beatriz CASARETO[2], Kazuyo SHIROMA[1], Kazuhiro DAIGO[1], Hiroyuki FUJIMURA[3], M. F. M. FAIROZ[1]

[1]Shizuoka University, Shizuoka, Japan, [2]Laboratory of Aquatic Science, Shizuoka, Japan, [3]University of the Ryukyus, Shizuoka, Japan

Vitamin B12, cyanocobalamin and other analogues, is an essential factor for numerous phytoplankton. Croft et al., Nature 2005, showed that 25 species of Dinoflagellates were vitamin B12 dependent out of 30 studied . Until now all Animalia were found vitamin B12 dependent. Even if Cnidaria were not specifically studied we can suppose that they require it too. Vitamin B12 is known to be only produce by bacteria and is found at very low level in seawater. Thus it is controlling the primary production in some oceanic area. Unfortunately the levels, the role of vitamin B12 in Coral Reefs and the requirement of the genus *Symbiodium* were never studied. The source of vitamin B12 in coral reefs was investigated in Sesoko, Okinawa, JAPAN. Vitamin levels were measured in surface water, pore water and coelenteric fluid of *Galaxea fascicularis*, sampled using a novel technique. The measurement was done using radioassay (SimulTrac SNB) which was optimized for analysis in seawater and in some case by HPLC. The highest concentrations were found in the coelenteric fluid : 200-400 pmol l-1 against 10-20 pmol l-1 for the surface water and the pore water. On the other hands high bacteria abundances (108 cells l-1) were found in the coelenteric fluid. Thus the hypothesis that vitamin B12 required by the zooxanthella was acquired through a symbiotic relation with the coelenteric bacteria was made. In order to confirm this hypothesis, the impact of an enrichment of vitamin B12, the requirement of zooxanthella and the possibility of a translocation of the vitamin between the bacteria and the zooxanthella were investigated. The different results precised the integration of the coelenteric bacteria in a biochemical symbiosis with corals and zooxanthella.

## 19-18

**Terrestrial Organic Matter Contribution in Surface Sediment Of Northern Mid Reef, Ishigaki Island, Japan**

Yumi KOTAKE[1], **Yutaka TATEDA*[2]**

[1]Tokyo College of Medico-Pharmaco Technology, Tokyo, Japan, [2]Environmental Science Research Laboratory, CRIEPI, Abiko Chiba, Japan

To evaluate the origin of organic matter being sedimented in the fringing reef environment, normal alkanes from $C_{12}$ to $C_{36}$ were analyzed in the reef surface sediments to identified the origin of the end member of organic matter loading from adjacent mangrove ecosystem. Marine biota originated $C_{15,17}$-alkanes peaks were obvious in the reef sediment, while the common signal of the terrestrial vegetation $C_{31}$ alkane peak were also detected, indicating some reef areas receive significant organic matter loading from terrestrial organic matter especially of mangrove. The straight chain n-alkanes detected in reef surface sediments at Ishigaki northern mid reef area, Okinawa, Japan were estimated to reflect the input of marine biota originated organic matter to be 39 -64 %, mangrove leaf originated organic matter to be 31 - 61 %, upstream riverside soil originated organic matter to be 3 - 9 %. The result of field decomposition experiment using terrestrial leaf indicated that turn over rates of terrestrial organic matter in reef sediment environment were within a range of 3 - 12 months. The overall result indicated that n-alkanes ratio of the end members: marine, mangrove, upstream soil n-alkanes are regarded as a good fingerprints to estimate the contributions of organic matter loading into the reef sediment, suggesting its usefulness for estimate how the stability of coral reefs linked to the biogeochemical cycles keeping the health of coral reef ecosystem, and also for the estimation of upstream land-derived soil loading to reef area under future land use planning.

## 19-19

**The Role Of Mucus Flocs in The Biogeochemical Cycle On Intertidal Coral Reef**

**Yu TAMURA*[1]**, Makoto TSUCHIYA[2]

[1]Graduate school of Engineering and Science, University of the Ryukyus, Ginowan-shi Okinawa-ken, Japan, [2]Faculty of Science, University of the Ryukyus, Naha-shi Okinawa-ken, Japan

On intertidal reef flats, thin films consisting of fine sand, algae and detritus often form on the water's surface during the flooding tide. When drifted by wind, these films develop into thick mucus flocs (MF). MF are transfered by the flooding tide, and are either deposited to the sediments after the gas bubbles inside it disappear, or are dispersed in the water. The organic matter, lipid and carbon hydrate content were higher in MF than in surrounding sediments. These substances seem to be produced by microorganisms like benthic diatoms that are abundant in MF. Therefore, migration of MF may affect the spatial and temporal distribution of nutrients in the oligotrophic coral reef environment.

The objectives of this study were to evaluate the contribution of MF as a food source for deposit feeders and to assess the role of MF in the biogeochemical cycle within the coral reef. We show that MF occur in sandy, exposed areas at the lagoon's edge, and are then carried down wind to the reef flat. The developmental process of MF were classified into 4 to 6 stages based on observations. Then, weight per unit area of each stage was determined, and the occurrence areas of each stage were measured to estimate total MF amount in one tidal cycle within the study area. As MF were produced in larger quantities in July, the amount of nutrients supplied to the reef flat from the lagoon's edge may fluctuate depending on the season. In addition, to investigate the contribution of MF as a food source for deposit feeders, we estimated the food consumption of the *Ophiocoma scolopendrina* population, which is one of the most dominant deposit and MF feeders in the intertidal.

## 19-20

**Coral Mucus Creates A Short-Linked Energy And Nutrient Cycle Via Particle Trapping in Fringing Reefs Of The Northern Red Sea**

**Florian MAYER*[1]**, Andreas HAAS[1], Malik NAUMANN[1], Riyad MANASRAH[2], Jonathan M JESCHKE[3], Christoph MAYR[4], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany, [2]Marine Science Station, Yarmouk University, Jordan, Aqaba, Jordan, [3]Dept. Biology II, Evolutionary Ecology, Ludwig-Maximilians-Universität München, Martinsried-Planegg, Germany, [4]Department of Earth and Environment, GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany

Mucoid exudates of hermatypic corals are known to play an essential role as energy carrier and particle trap in reef ecosystems. The mucus trap mechanism prevents loss of essential elements and facilitates fast recycling of organic matter within the oligotrophic system. Compared to platform and atoll reefs where mucus is quickly detached from the coral due to strong tidal currents, coral mucus produced in Red Sea fringing reefs remains significantly longer attached to the coral. Therefore, the mucus trap mechanism is increasingly initiated on the coral surface. Consequently, this suggests the existence of a short-linked nutrient cycle via coral-derived organic matter in fringing reefs. We conducted a series of interconnected investigations during two expeditions to the Northern Red Sea to understand the relevant processes underlying this potential cycle. Highly contaminated mucus strings were attached to 14.6 % of all inspected coral colonies (n= 733). Organic matter enrichment in mucus strings was determined by high temporal resolution sampling. This revealed mean enrichment rates for particulate organic carbon (POC) of up to 5.0 g $h^{-1}$ $L^{-1}$ of exuded mucus. After detachment from the coral, more than 95 % of the highly contaminated mucus aggregates descended to the reef floor within a distance of less than 5 m to the originating coral colony. In-situ and laboratory investigations for planktonic and benthic microbial degradation of collected mucus aggregates showed high organic C turnover rates. This confirms fast recycling of this material and a concomitant release of regenerated nutrients essential for reef productivity. This study therefore indicates that short-linked nutrient cycles via coral mucus importantly contribute to reef ecosystem functioning in the Red Sea.

## 19-21

**Coral Mucus Stable Isotope Composition And Labelling**

**Malik NAUMANN*[1]**, Christoph MAYR[2], Ulrich STRUCK[3], Christian WILD[1]

[1]Coral Reef Ecology Work Group (CORE), GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany, [2]GeoBio-Center & Department of Earth and Environmental Science, Ludwig-Maximilians-Universität München, München, Germany, [3]Museum für Naturkunde, Humboldt Universität zu Berlin, Berlin, Germany

Recent research showed that mucus released by reef corals functions as a carrier of energy and nutrients to the reef community, thereby importantly contributing to the conservation and fast recycling of organic matter and nutrients in oligotrophic reef ecosystems. However, food web processes involved in the uptake, assimilation and degradation of this material are poorly understood. Staining techniques involving different dyes proved to be inefficient tools in order to label coral mucus. This study now aims to elucidate the usefulness of stable isotopes in order to study the fate of coral mucus. Natural C stable isotope signatures (δ13C) of coral mucus (-25.5 ± 1.0 ‰) were similar to those of particulate organic matter (POM) suspended in reef waters (-23.6 ± 0.4 ‰), whereas N stable isotope signatures (δ15N) of coral mucus (+1.2 ± 0.3 ‰) were comparably lower than those of POM (+15.9 ± 4.1 ‰). For experimental investigations, where larger differences in δ13C and δ15N are required, a technique involving label addition to the coral incubation water was developed. This produced δ13C values of up to +122 ‰ and δ15N values of up to +2280 ‰ for mucus exuded by hermatypic corals of the genera *Fungia* and *Acropora*, indicating fast transfer of assimilated C and N as labelled compounds from the endosymbiotic dinoflagellates to the coral host under light conditions. The usefulness of this technique was demonstrated by laboratory experiments with labelled coral mucus addition. Another potential advantage of stable isotope labelling is that such a non-noxious methodology can be used in-situ. This was confirmed by benthic chamber experiments on coral reef sands revealing fast advective transport of labelled coral mucus from the water column into the sediment surface layer.

**Biogeochemical Constraints On Ecology Of Coral Reefs**

**Marlin J ATKINSON*[1]**

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI

Biogeochemistry is the study of rates of input, production and consumption of compounds that are involved in biological and geological processes. The fluxes and chemical kinetics of these compounds often set limits to ecosystem-metabolism and directly control organism-metabolism. The biogeochemistry of coral reefs is sufficiently well understood that we can delimit a number of basic rate processes, but we are just beginning to link biogeochemistry with ecological processes. Basic parameters in biogeochemistry are light, temperature, concentration (hence water residence time), water motion, waves, surface roughness or bottom drag, and community structure. The combinations of these variables often set limits for biomass accumulation, nutrient input, community metabolism, zonation of metabolism, herbivory, and food chain dynamics. This talk review will briefly review the concepts and approaches for biogeochemical constraints for the above ecological processes.

## 19-23

**Diurnal And Seasonal Nutrient Dynamics Associated With A Nuisance Macroalgae Bloom in The Permeable Coastal Margin Of Kihei, South Maui**

**Iuri HERZFELD*[1]**, Francis J. SANSONE[1], Celia M. SMITH[2]

[1]Department of Oceanography, University of Hawaii, Honolulu, HI, [2]Botany Department, University of Hawaii, Honolulu, HI

Nutrient regimes on coral reefs are dynamic and driven by forces acting on multiple spatial and temporal scales. We explored nutrient dynamics over time-scales ranging from days to seasons associated with a coastal fringing reef on the island of Maui, Hawaii. Studies were performed at Waipuilani Beach Park, Kihei, a site that is experiencing chronic nuisance blooms of the macroalgae Ulva fasciata and Hypnea musciformis. In an attempt to elucidate the mechanisms affecting nutrient concentrations in the water column, multiple 48-hour diurnal multi-parameter surveys of reef water-column and sediment porewater dissolved nutrients (N, P, Si, and Fe) and carbonate chemistry, water physics (tides, waves, currents), and wind speed were performed in 2005-2007 during both dry and wet seasons. Sampling was conducted over different tidal phases and amplitudes in order to decouple the effects of light and tides on nutrient supply and demand. Preliminary results indicate that diurnal nutrient concentrations in the water column and sediment porewater are affected by changes in the kinetic energy being dissipated by the system (wave height and near bottom current velocity), indicating an enhanced remineralization of organic matter. Over seasonal time-scales, nutrient concentrations in the water column are affected by a combination of fresh groundwater inputs, and recirculated brackish groundwater that is actively being altered by sediment diagenesis. We conclude that water column nutrient dynamics at our study site are the result of an intricate interplay between the hydrologic cycle and the atmospheric and gravitational forces that enhance porefluid flow in this permeable coastal margin.

## 19-24

**Dual-Carbon Sources Fuel The Deep Reef Community, A Stable Isotope Investigation**

**Kenneth SULAK*[1]**, James BERG[2], Michael RANDALL[1], George DENNIS III[3], Robert BROOKS[4]

[1]Florida Integrated Science Center, U.S. Geological Survey, Gainesville, FL, [2]ENSR International, Westford, MA, [3]Vero Beach Ecological Services Office, U.S. Fish and Wildlife Service, Vero Beach, FL, [4]ENSR International, St. Petersburg, FL

Surface marine phytoplankton is considered the sole carbon source for the OCS deep reef community (>60 m), the endpoint of one vertically-intergrated, surface to substrate ecosystem. Accordingly, community structure on deep reefs may be directly tied to phytoplankton carbon, channeled via benthic particulate consumers. We tested the hypothesis that phytoplankton carbon is the sole fuel of the deep-reef community, and an alternative hypothesis that terrestrial carbon may contribute secondarily. Our objective was to define trophic structure on, off, and above, northeastern Gulf of Mexico deep reefs via analysis of carbon and nitrogen stable isotopes. We analyzed 114 entities (carbon sources, sediment, fishes, and invertebrates). Carbon signatures supported surface phytoplankton as the primary fuel for the deep-reef community. However, unexpectedly, a second non-terrestrial carbon source was identified as important to the reef food web. This is the pelagic macroalgae Sargassum and the associated macroalgal epiphyte Cladophora liniformis. Macroalgal carbon signatures were detected among 23 consumer species. Most notably, macroalgae contributed 45 % of total carbon to the 13C isotopic spectrum of the particulate-feeding reef-crest gorgonian Nicella. Terrestrial carbon from coastal rivers was not detected. Nitrogen signatures revealed a 4-step trophic chain from particulate organic matter through apex macrovores. Eleven trophic guilds fell into four 15N-defined trophic levels, and three 13C consumer groups. Trophic enrichment in d15N per trophic step was 1.67 ‰, in d13C, 2.0 ‰, both departing from the classical 3.0-3.4 ‰, and 1.0% per step, respectively. In contrast to ubiquitous phytoplankton, the secondary macroalgal carbon source is spatially heterogeneous in surface waters. The spatial distribution of some key particulate-feeding sessile reef invertebrates may depend on carbon fallout from spatially discontinuous surface macroalgae, providing novel insight into the spatial heterogeneity of key colonial reef invertebrates.

## 19-25

**Mangrove-Exported Nutrient Incorporation By Sessile Invertebrates On Adjacent Coral Reefs**

**Elise GRANEK*[1]**

[1]Environmental Sciences and Resources, Portland State University, Portland, OR

Understanding the consequences of the declining global cover of mangroves necessitates consideration of how mangrove-derived nutrients contribute to threatened coral reef systems. We sampled potential sources of organic matter and a suite of sessile reef invertebrate consumers from six sites in Bocas del Toro, Panama in the Caribbean Sea to conduct stable isotope analyses using $\delta^{34}S$ or $\delta^{13}C$. Using IsoSource mixing models we determined the range of potential contributions to consumers from the various organic matter sources in the system. Mangrove organic matter contributed substantially to most filter feeders ranging across sites from 11-53% for sponges, 18-44% for file clams, and 29-51% for feather duster worms. Mangroves contributed 7-31% of the organic matter to coral species. To examine how mangrove contribution varied with distance from mangrove source we conducted a transplant experiment. Results indicated that the mangrove contribution to invertebrate species declined with increasing distance from shore. These results provide the first evidence that mangrove inputs of organic matter to sessile invertebrate species are substantial and offer an indication of the magnitude of incorporation. Thus, removal of mangroves from tropical shores can potentially generate a deficit in the organic inputs to reef organisms, with as yet unknown ecological consequences for the integrity and persistence of reefs.

## 19-26

**Habitat-Dependent Diet in Zooplanktivorous Fishes: Implications For Trophic Connections With Coral Reef And Oceanic Food Webs**

**Kate HANSON*[1]**, James LEICHTER[1]

[1]Scripps Institution of Oceanography, La Jolla, CA

The import and export of zooplankton from reef systems is an important pathway by which coral reefs exchange organic matter, energy and nutrients with adjacent open ocean ecosystems. Understanding the dynamics of this exchange requires knowledge of the trophic pathways through which zooplankton enter the reef system. This study examines the relative importance of oceanic versus reef-associated resources for site-attached reef planktivores. We utilize gut-content and stable isotope analyses to examine intra-specific spatial variability in the diet of zooplanktivorous reef fishes. Muscle tissue was collected from individuals of the damselfish species *Dascyllus flavicaudus* inhabiting three reef zones at 6 sites surrounding the island of Moorea, French Polynesia. Carbon isotope values measured from fish inhabiting deep forereef sites are depleted relative to values measured from shallow lagoon and fringing reef conspecifics by ~ 3 ‰, with corresponding differences in nitrogen isotope values of up to 1.5 ‰. Similar results were found for a second planktivorous species, *Chromis viridis*. Isotope values of forereef *Dascyllus flavicaudus* are less variable through time than are values of fringing reef individuals. Together with the results of gut-content analysis, comparison of isotope values sampled from fish with those obtained from bulk zooplankton tows suggests that forereef individuals rely on oceanic zooplankton while lagoon and fringing reef individuals may be increasingly dependent on reef-associated zooplankton such as larval decapods.

## 20-1

**The Comparative Demographic Of Two Scleractinian Corals On A Shallow Caribbean Reef**

**Peter EDMUNDS*[1]**

[1]California State University, Northridge, Northridge, CA

In light of the consequences of anthropogenic disturbances for coral reefs, considerable effort has been expended to understand the mechanisms by which such phenomena result in coral death, and how affected populations change over time. There has been less attention however, to the question of which corals might endure the adverse conditions, and to what extent might their populations increase in size? This study focused on two Caribbean corals that have survived better than most on shallow reefs (<8 m) in St. John, US Virgin Islands, and the objectives were to use demographic models to explore the responses of these species to disturbance, and elucidate their trajectories of change over the next 25 years. The study species were Porites astreoides, which is well known for its weedy life-history characteristics, and Diploria strigosa, and the approach utilized population censuses from 1994 to 2007, and a tag-and-resurvey procedure repeated annually between 1999 and 2007. The empirical data were used to parameterize size-based matrix models, and bootstrap resampling was used to attach confidence intervals to population parameters and projections. In contrast to the population trajectories of the historically dominant corals in St. John and elsewhere in the Caribbean, the intrinsic rate of population increase (?) rose gradually for both species between 1999 and 2007, and ended the study >1 showing that the populations were growing independent of the input from recruitment. Over the next 25 years, population projections suggest that both species will increase in abundance, regardless of the effects of catastrophic disturbances or periodic recruitment failure. Both P. astreoides and D. strigosa appear to have characteristics favoring high adult survival and successful fission under contemporary environmental conditions, both of which contribute to population growth in an era when most corals are declining in abundance.

## 20-2

**Simulating the Growth and Spread of Key Macroalgae in Florida Reefs**

**Aletta YÑIGUEZ*[1]**, John MCMANUS[2]

[1]National Center for Coral Reef Research (NCORE)/ Marine Biology & Fisheries (MBF), RSMAS, University of Miami, Muntinlupa City, Philippines, [2]National Center for Coral Reef Research (NCORE)/ Marine Biology & Fisheries (MBF), RSMAS, University of Miami, Key Biscayne, FL

The growth patterns of macroalgae can provide important information regarding the environments in which they live, and insights into changes that may occur when those environments shift. To decipher these patterns and their attendant mechanisms and influencing factors, a spatially-explicit model was developed. Using the three-dimensional agent-based model SPREAD (SPatially-explicit REef Algae Dynamics), which incorporates key morphogenetic characteristics of clonality and morphological plasticity, the influences of light, temperature, nutrients and disturbance on how the dominant macroalgae in the Florida Reef Tract grow and occupy space were investigated. At the individual level, SPREAD yielded several morphological types for *Halimeda tuna*, *Halimeda opuntia*, and *Dictyota* sp. under a large range of light, temperature, nutrient and disturbance levels. These morphological types approximated those measured for individuals in two inshore patch reefs and two offshore spur and groove reefs, and were formed in conditions similar to the environmental (light, nutrient and disturbance) conditions in the field sites. At the macroalgal population level, increasing disturbance in SPREAD such that the fragment pool was increased, but not enough so that fragments could not survive, led to the highest potential for space capture. Enabling fragmentation also allowed for comparable abundances in the three species between the model and the actual study sites, and, for *Halimeda* spp., captured the observed disparity in abundances between the sites. The variation in growth and disturbance conditions, as well as each species' capacity for success with fragmentation, seemed to play a strong role in the distinct differences in macroalgal abundances between inshore patch and offshore reef study sites. These mosaics of scenario-running and empirical studies have enabled us to tease out potential mechanisms and factors responsible for the growth patterns observed in reality at different levels.

## 20-3

**Recovery Dynamics Of *diadema Antillarum* And The Potential For Active Rebuilding Measures**

**Alice ROGERS*[1]**, Kai LORENZEN[1]

[1]Biology, Imperial College London, London, United Kingdom

In recent decades, Caribbean coral reefs have suffered a shift in community structure from a healthy coral-dominated state to a less resilient and less productive macroalgae-dominated state. This shift is believed to be related in part to the functional extinction of the previously dominant grazer of macroalgae, the sea urchin *Diadema antillarum* following a mass mortality event in 1983.

*Diadema antillarum* has failed to recover to pre-mortality densities in many locations. In light of recent studies suggesting that large scale recovery of *Diadema antillarum* could reverse community change and improve the health of Caribbean coral reefs, interest has arisen around the potential for active rebuilding measures such as hatchery enhancement to aid and increase population recovery.

We developed a size- and spatially structured, combined population dynamics and grazing impact model for *D. antillarum*. The model accounts for compensatory density-dependence in recruitment and individual growth, and depensatory density effects mediated by fertilization success, the possible refuge function of adults for juveniles, and 'cultivation' of settlement habitat by grazing. Results show that the population can exist in two distinct states, i.e. a low-abundance equilibrium associated with high macroalgal cover, and a high-abundance equilibrium associated with low macroalgal cover.

In order to 'kick start' recovery and switch from the low to the high abundance state the population needs to overcome multiple depensatory processes. This may require both, prior reduction in algal cover by other herbivores or human intervention, and a high recruitment event based on dispersal from recovered populations or the stocking of hatchery-reared *D. antillarum*. Hatchery releases could contribute effectively to recovery, but this would require stocking densities that are high relative to the natural population and may result in substantial ecological and genetic interactions with the natural population.

## 20-4

**Spatial Dynamics Of Herbivory And Coral Growth: Implications For Reef Conservation And Recovery**

Dylan MCNAMARA[1], **Stuart SANDIN*[2]**

[1]Duke University, Atlantic Beach, NC, [2]Scripps Institution of Oceanography, La Jolla, CA

Competition for space is a critical dynamic affecting patterns and rates of growth of sedentary organisms both on land and in the sea. Understanding the aggregate impact of spatial dynamics on competitive hierarchies along shared margins is important for gaining insight into large-scale systematic shifts, such as catastrophic phase shifts within coral reefs. Predictive insights are fundamental for both understanding conditions leading to coral loss and, perhaps more importantly, for designing strategies for restoring coral populations.

To explore this question, we have constructed a cellular automata model for coral reefs to mimic the dominant dynamics of coral reefs. State transitions are governed by probability-driven rules based on dynamics of growth, death, succession and recruitment. Explicit spatial dynamics are depicted both through size-dependent patterns of growth in corals and autocorrelated patterns of foraging for some herbivores. These assumptions are based on two main field observations: (i) small corals are more susceptible to overgrowth by macroalgae than larger colonies, and (ii) patterns of herbivory are distinct between fishes and urchins, especially in reference to the level of spatial autocorrelation of foraging. We find that algal dominated reefs are particularly stable because coral recruitment is severely reduced in the presence of macroalgae. Although clonal growth allows adult corals to increase in size even in the presence of high macroalgal cover, only in the presence of significant herbivory is coral recruitment facilitated. Additionally, because urchins open larger contiguous sections of benthos from algal coverage than do fishes, coral recruitment will be particularly facilitated in the presence of herbivorous urchins. The wide-spread mortality of both fast-growing corals (e.g., acroporids) and herbivorous urchins in the Caribbean, the dynamic attractor of macroalgal domination is particularly stable. These model predictions mimic closely a growing number of empirical observations from across the Caribbean.

## 20-5

**Agent-based Simulation of a Recreational Coral Reef Fishery: Linking Ecological and Social Dynamics**

**Jennifer SHAFER*[1]**

[1]University of Hawaii, Honolulu, HI

In this agent-based simulation, the ecological dynamics of a simple coral reef ecosystem are linked to the social dynamics of a recreational fisher community. The simulation captures the interaction and dynamic feedback between the ecological and social systems and how these affect fish stocks and fisher behavior. The analysis reveals the complex nature of how system-level dynamics emerge from localized individual-level behaviors. Empirically based parameter estimates and behaviors drive the energetics and ecology of the reef's three trophic levels from the bottom-up through individual-based mechanistic rule-sets: photosynthetic turf algae grows, herbivorous fish graze while schooling and avoiding predation, and roaming piscivores hunt herbivores and patrol the reef edge. These simple individual behaviors give rise to the more complex ecological phenomena of fish schooling, carrying capacity, and population cycles. At the same time, a community of recreational fishers interacts with each other and the physical and biological components of the reef. Individual fishers assess risk and pay-off in deciding when to go fishing, find appropriate locations on the reef to set gear, and attempt to catch fish. Simple individual choices made in the dynamic reef environment result in the emergent sociological phenomena of localized resource depletion, diffusion of information and cooperation. Under a community-based management scenario where fishers have the choice to form self-organized coalitions to establish and enforce catch restrictions, the resource dilemma associated with overfishing can be overcome under certain conditions. This research provides proof-of-concept for using agent-based simulation as a versatile and powerful modeling tool for coupling biophysical and sociological processes and evaluating alternative management scenarios.

## 20-6

**Models of Coral Reefs with And without Macroalgae Indicate Differential Resilience to Fishing And Anthropogenic Nutrients**

**Tak FUNG*[1]**, Robert SEYMOUR[1], Craig JOHNSON[2]

[1]Department of Mathematics, University College London, London, United Kingdom, [2]School of Zoology, University of Tasmania, Hobart, Australia

A dynamic model of a generic coral reef ecosystem is constructed using differential equations. Three benthic groups (corals, turf algae and macroalgae), three fish groups (herbivorous and small and large piscivorous fish) and one invertebrate group (sea urchins) are modeled.

The model is parameterized for a pristine (no fishing) generic reef with and without macroalgae using data from the Caribbean and Indo-Pacific. Three scenarios are examined, *viz*. increased a) fishing pressure, b) nutrients, and c) fishing and nutrients. Nutrients increase the growth rates of both macroalgae and turf, but can have a much bigger impact on reefs with macroalgae, since macroalgal patches grow laterally over other benthic groups.

For the reef without macroalgae, increased fishing pressure can give a continuous phase shift from high coral cover to high cover of turf algae. The reef with macroalgae can exhibit both continuous and discontinuous phase shifts to dominance by algae (turf and macroalgae) as fishing pressure increases. Increased nutrients also promotes algal cover, and for reefs which exhibit a discontinuous phase shift as grazer biomass decreases, nutrients can increase both the hysteresis effect (which slows recovery of coral cover) and the grazer biomass at which such a phase shift occurs. Fishing and nutrients can interact synergistically, such that a heavily fished reef with high nutrients can have high algal cover where in the presence of either factor alone, it would have low algal cover. However, in some cases, either decreased grazing or increased nutrients alone can result in high algal cover.

The results suggest the need for different management strategies for mitigating the effects of fishing and nutrients on reefs with macroalgae (such as many in the Caribbean) and without macroalgae (such as typical offshore Indo-Pacific reefs).

## 20-7

**Managing Uncertainties in The Development Of An Agent-Based Model Of A Complex Coral Reef Ecosystem**

**Felimon GAYANILO*[1]**, John MCMANUS[1]

[1]National Center for Coral Reef Research, RSMAS, University of Miami, Key Biscayne, FL

Agent-based modeling (ABM), an element of the Science of Complexity, is gaining acceptance in main stream ecological science as a viable tool to model complex coral reef ecosystems. Current approaches in agent-based modeling to simulate ecological changes due to anthropogenic and/or natural disturbances in a complex system, such as coral reef ecosystems, rely heavily on our ontological and epistemological understanding of the ecological network. Initialization of the model is inductive and generally, environment and rules are modified and the emergent behavior of the global system is analyzed. Coral reef science is just beginning to understand the linkages and taxonomic attributes of the elements of this diverse and complex ecosystem. These uncertainties and information gaps force researchers to rely heavily on assumed biophysical, temporal, physiological, and sociological rules. This paper addresses the effects of some of these uncertainties by comparing results of simulated scenarios executed by an ABM simulation tool, GAMET (Geographic Agent-based Marine Eco-forecasting Tool). Moreover, options are presented as to how to minimize the effects of these uncertainties, including the strengthening of a global interdisciplinary program, CARRUS (Comparative Analysis of Reef Resilience Under Stress).

## 20-8

**Thresholds And The Resilience Of Caribbean Reefs Under Climate Change**

**Peter MUMBY*[1]**

[1]School of BioSciences, University of Exeter, Exeter, United Kingdom

The deteriorating health of the World's coral reefs threatens global biodiversity, ecosystem function, and the livelihoods of millions of people living in tropical coastal regions. Reefs in the Caribbean are among the most heavily-impacted, having experienced mass disease-induced mortality of the herbivorous urchin Diadema antillarum in 1983 and two framework-building species of coral. Declining reef health is characterised by increases in macroalgae. A critical question is whether the observed macroalgal bloom on Caribbean reefs is easily reversible. To answer this question, we must resolve whether algal-dominated reefs are an alternative stable state of the ecosystem or simply the readily reversible result of a phase change along a gradient of some environmental or ecological parameter. Here, using a fully-parameterised simulation model, we show that Caribbean reefs became susceptible to alternative stable states once the urchin mortality event of 1983 confined the majority of grazing to parrotfishes. We reveal dramatic hysteresis in a natural system and define critical thresholds of grazing and coral cover beyond which resilience is lost. Most grazing thresholds lie near the upper level observed for parrotfishes in nature suggesting that reefs are highly sensitive to parrotfish exploitation. Ecosystem thresholds can be combined with stochastic models of disturbance to identify targets for the restoration of ecosystem processes. We illustrate this principle by estimating the relationship between current reef state (coral cover and grazing) and the probability that the reef will withstand moderate hurricane intensity for two decades without becoming entrained in a shift towards a stable macroalgal-dominated state. Such targets may help reef managers face the challenge of addressing global disturbance at local scales.

## 20-9

**Resilience in A Small Coral World: Disturbance in Networks**

**Stuart KININMONTH*[1]**, Glenn DE'ATH[1], Hugh POSSINGHAM[2]

[1]Australian Institute of Marine Science, Townsville, Australia, [2]University of Queensland, Brisbane, Australia

Coral reefs are declining worldwide due to increasing local and regional stress from fishing, coastal development, run-off and climate change. While disturbance is an essential part of coral reef dynamics, its frequency and intensity has increased. As the health of a reef changes due to stress and disturbance its capacity to recover is partly determined by the connectivity through larval transport. This exchange of larvae between reefs creates a complex system of interactions that can be modelled. Using graph theory models, we discover that ecological connectivity patterns are highly clustered and well connected. This gives rise to the description of the connectivity pattern of coral reefs as 'small world' where individual reefs appear to be improbably well connected. We examine the hydrological and genetic patterns of the central section of the Great Barrier Reef to find a mesoscale small world. We examine the history of disturbance from cyclones, Crown-of-Thorns starfish and bleaching within the coral reef network and discover that the spatial and temporal character of the disturbance differentially affects the network connectivity. Long term monitoring records of reef decline, stasis, or recovery cycles are incorporated into the graphical model. Our model demonstrates the need to understand the functional aspects of coral reefs in order to adequately provide conservation measures.

## 20-10

**Models Of Coral Community Structure, Environmental Variation, And Connectivity**

**Carrie KAPPEL*[1]**, Daniel BRUMBAUGH[2,3], Craig DAHLGREN[4], Alastair HARBORNE[5], Katherine HOLMES[2], Fiorenza MICHELI[6], Peter MUMBY[5], Claire PARIS[7]

[1]National Center for Ecological Analysis and Synthesis, University of California Santa Barbara, Santa Barbara, CA, [2]Center for Biodiversity and Conservation, American Museum of Natural History, New York, NY, [3]4Marine Protected Areas Science Institute, National MPA Center, Santa Cruz, [4]Perry Institute for Marine Science, Jupiter, FL, [5]Marine Spatial Ecology Lab, School of BioSciences, University of Exeter, Exeter, United Kingdom, [6]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [7]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

A suite of physical and biological environmental factors and processes have been shown to structure coral reef communities at local scales. Recently, studies have begun to address the role that other factors, such as temperature, pH, and dispersal potential, play in shaping communities at global and regional scales. Conservation planning and implementation typically take place at the seascape scale (10s – 100s km), creating a need to understand what drives variation in communities at intermediate scales and a demand for easily measured surrogates for biodiversity. We used distance-based redundancy analysis (dbRDA) to assess the role of physical and biological factors in explaining patterns of coral community structure at the seascape level. We examined the relationship between community structure, as measured in detailed field surveys of coral species distributions at nested spatial scales across the Bahamas archipelago, and the measured or modeled environmental variables: depth, vertical relief, wave exposure, grazing intensity by herbivorous parrotfishes, connectivity (based on simulations of larval dispersal for typical spawning and brooding corals), history of hurricane and bleaching disturbances, macroalgal cover and total coral cover, local human population density and tourism intensity. Several of these factors, including incoming coral larval supply (i.e. subsidies) and macroalgal cover were significant predictors of coral community structure. We also examined species-specific patterns of abundance across the archipelago. We used linear mixed-effect models to explain variation in common individual coral species from the genera *Montastraea* and *Agaricia*, relating their abundance to physical and biological variation and connectivity among our sites. For individual species, number of retained larvae (i.e. self-recruitment) was often a significant predictor of abundance. Together these analyses highlight the importance of connectivity, the history of disturbance, and physical and biological processes like grazing and wave exposure in explaining patterns of coral abundance and community structure across the Bahamian seascape.

## 20-11

**Exploring Past And Future Human Impacts On Reef Fish Ranges Via Distribution Models**

**Jana MCPHERSON*[1]**, Julia BAUM[2], Derek TITTENSOR[1]

[1]Biology Department, Dalhousie University, Halifax, NS, Canada, [2]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla, CA

Our study uses species distribution models to identify human-induced changes in the composition of reef fish communities. Species distribution models traditionally combine spatial information on species' occurrence with measures of environmental conditions to delineate individual species' ranges. They are widely used in terrestrial ecology to predict shifts in species' distributions in response to habitat alterations and climate change. We apply these models to coral reefs using data compiled by the Pacific Reef Fish Collaboration (PaReFiCo), an international effort to study humanity's impacts on reef ecosystems. PaReFiCo's data consist of underwater visual sightings of reef fish species from more than 8000 transects conducted at 83 islands across the Pacific Ocean. In order to determine both natural and human-induced constraints on individual species' ranges, potential explanatory variables in the models include not only traditionally used environmental predictors (e.g. temperature, habitat type) but also indicators of anthropogenic stressors (e.g. coastal population density). We are thus able to explore past as well as future human impacts on individual species' occurrence. Layering of individual species' models provides insight into human-caused changes in community composition.

## 20-12

**The New Commons: Why Coral Reef Scientists Should Get Out More**

**robert SEYMOUR*[1]**, Roger BRADBURY[2]

[1]mathematics, UCL, London, United Kingdom, [2]ANU, Canberra, Australia

How do we understand complex ecosystems such as coral reefs? More importantly, what do we understand them for? The current "big idea" in the Life Sciences is Systems Biology, a movement that aims to reverse the paradigm of reductionist research in which more-and-more-detailed properties of smaller-and-smaller components of biological systems are isolated and dissected. Systems Biology aims to pursue a reverse, integrationist agenda, in which whole system properties "emerge" from component processes. It is these emergent properties that promise significant payoffs to humans. Ecology is stuck in a rut with the classical "systems analysis" paradigm: ecosystems are conceived as assemblages that just "do what they do", and we try to understand this "doing" through a description of local interactions between components. Can we develop a Systems Biology paradigm for ecosystems? This talk will argue that we can, and should. Thus, in the absence of obvious naturally evolved ecosystem "functions", we should develop views as to what the "function(s)" of such an ecosystem might mean. Taking such a view forms a high-level conceptual basis for modelling, and can be used to provide a conceptual bridge between high-level functional properties and low-level mechanistic processes. This greatly facilitates modelling and analysis. Such "functions" cannot, and should not, avoid being related to human activity. We must escape from the guilt paradigm in which ecosystems would revert to a harmonious state if only humans would leave them alone. Instead, management should aim to buffer homeostatic properties associated with these functional properties (to maintain "health"). In this endeavour we should think more like medical physiologists and agricultural scientists, using manipulative techniques where necessary. Thus, the future of the Commons must be that of a highly managed landscape, subject to controlled development.

## 20-13

**Foodwebs Of Coral Reef Seascapes Across The Bahamian Archipelago: Network Structure, Biodiversity, Robustness And The Effect Of Rugosity**

**Steven LITVIN*[1]**, Fiorenza MICHELI[1], Jennifer DUNNE[2,3], Peter MUMBY[4]

[1]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [2]Santa Fe Institute, Santa Fe, NM, [3]Pacific Ecoinformatics and Computational Ecology Lab, Berkeley, [4]Marine Spatial Ecology Lab, University of Exeter, Exeter, United Kingdom

Do changes in the diversity of fish assemblages across the Bahamian archipelago lead to significant variability in the structure of coral reef foodwebs and their associated properties? To address these questions we assembled empirical foodwebs for coral reef seascapes surveyed by the Bahamian Biocomplexity Project. This dataset incorporates over 160 species of reef fish censused throughout the archipelago at locations separated by scales of tens to hundreds of kilometers. Differences in foodweb structure associated with factors including the level of fishing pressure, extent of mangroves and the presence of an established marine protected area were determined using ecological network approaches. In addition to the direct comparison of measures of foodweb complexity we estimated the potential effect of species loss among coral reef foodwebs by simulating both the directed and random loss of species and then measuring robustness in terms of secondary extinctions. Further comparisons were carried out utilizing the niche model approach, based on the empirically observed variation in species diversity and connectance across the locations surveyed. To access the role of rugosity on foodweb structure we first calculated the probability individual fish species surveyed in hard bottom habitats were present within a given range of rugosity. Subsequently, foodwebs containing all species likely present within a rugosity range were assembled and the above mentioned network approaches applied. Together, these results provide insight into the drivers of foodweb structure in coral reef seascapes and the degree which perturbations, human induced and otherwise, are transmitted throughout fish communities.

## 20-14

**Predicting Reef Futures Using A Multi-Scale Coral Reef Ecosystem Model**

**Jessica MELBOURNE-THOMAS*[1]**, Craig JOHNSON[1], Tak FUNG[2], Robert SEYMOUR[2]

[1]School of Zoology, University of Tasmania, Hobart, Australia, [2]CoMPLEX, University College London, London, United Kingdom

Models can be effective tools to assess tradeoffs that arise in the exploitation and protection of coral reef systems. The importance of a regional-scale approach to modelling and management is clear, given that reefs are highly connected across regions by ocean currents, social structures, regional economies and global markets. However, there are few regional-scale coral reef models useful to stakeholders for decision support in management and policy development.

We present a spatially explicit regional-scale model of a coral reef system which has been developed as a decision support tool. The model couples a fundamental, local-scale ecosystem-dynamic model to the regional scale by incorporating inter-reef connectivities for larvae, sediments and pollutants. Initial parameterisation is for the Meso-American Barrier Reef system (MBRS). Our approach is generic, so that the model can be transferred between global regions (e.g. Indo-Pacific, East Africa, and other areas in the Caribbean), with flexibility in parameterisation for differing data availabilities.

Despite its conceptual simplicity, the regional model demonstrates complex, non-linear responses to external forcings that have important management implications. We will present examples of several important behaviours for the MBRS, and show how the model can be used to visualise and assess possible reef futures under alternative management scenarios.

## 20-15

**One Fish, Two Fish, Red Fish, Blue Fish: The Use Of Simple Agent-Based Models And Role-Play Games To Communicate Key Messages To Community Groups**

**Deborah CLELAND*[1]**, Rollan GERONIMO[2], Anne DRAY[3], Pascal PEREZ[3], Abigail TRINIDAD[4]

[1]Fenner School of Environment and Society, Australian National University, Canberra, Australia, [2]University of the Philippines, Manila, Philippines, [3]Australian National University, Canberra, Australia, [4]Foundation for the Alternative Management of the Environment, Manila, Philippines

The principal anthropogenic factors driving reef degradation have been known for years, if not decades. Overfishing, sedimentation and nutrient loads are just some of the key impacts of human activities in and around reef communities. Therefore, the future of reefs does not rely on generating new knowledge, but rather on implementing and integrating the knowledge we already have. This will require creating effective links between researchers, managers and communities to promote mutual learning, negotiation and collaborative action for reef management. Combining agent-based models and role-play games, through a technique known as Companion Modelling (ComMod), creates a dynamic and interactive setting that can contribute to research, education and participatory goals across diverse stakeholders. Incorporating the decision-making processes of individuals into each time step, through the role-play game, means that socio-economic rationalities are seamlessly integrated with the bio-physical dynamics embedded in the models. ComMod has been used successfully as a communication and learning tool in participatory workshops in both the Mesoamerican Reef (Mexico) and the Bolinao-Anda reef complex (Philippines). These experiences demonstrate that simple, generic ecological dynamics are very effective in communicating key conservation messages to a lay audience. However, a comprehensive understanding of local cultural, economic and social characteristics is crucial to develop a coupled model/role-play game that can successfully engage stakeholders.

## 20-16

**Noaa Coral Reef Watch Experimental Coral Bleaching Forecast Tool**

**Gang LIU*[1]**, Ludmila E. MATROSOVA[2], M. Cécile PENLAND[3], Dwight K. GLEDHILL[1], C. Mark EAKIN[4], Robert S. WEBB[3], Tyler R. L. CHRISTENSEN[1], Scott F. HERON[4], Jessica A. MORGAN[1], William J. SKIRVING[4], Alan E. STRONG[4]

[1]IMSG at NOAA Coral Reef Watch, Silver Spring, MD, [2]CIRES/NOAA Earth System Research Laboratory Physical Science Division, Boulder, CO, [3]NOAA Earth System Research Laboratory Physical Science Division, Boulder, CO, [4]NOAA Coral Reef Watch, Silver Spring, MD

While NOAA Coral Reef Watch (CRW) near-real-time satellite monitoring of the thermal stress conducive to coral bleaching provides critical and timely information to coral reef managers and scientists, the outlook of potential thermal stress during the future months would be very useful for strategic planning and management. A new prediction tool is being developed by NOAA that seeks to provide a seasonal outlook of thermal stress conducive to coral bleaching. NOAA CRW has teamed up with the Physical Sciences Division of the NOAA Earth System Research Laboratory in developing thermal stress forecast model to provide coral bleaching HotSpot and Degree Heating Weeks forecasts ranging from two-weeks to seasons in advance. HotSpot and Degree Heating Weeks are two parameters that link the anomalously high sea surface temperature (SST) to the onset and intensity of mass coral bleaching and have been used successfully in providing near-real-time satellite bleaching monitoring. The SST forecast model is developed based on NOAA's Linear Inverse Model (LIM) that has successfully produced predictions of tropical Pacific and Atlantic SST anomalies. This presentation will introduce this new tool developed for coral reef managers and scientists.

## 21-3

**Recreational Fishers' Perceptions Of The Costs And Benefits Of The 2004 Rezoning Of Australia's Great Barrier Reef Marine Park**

**Stephen SUTTON*[1]**

[1]Fishing and Fisheries Research Centre, James Cook University, Townsville, Australia

Recreational fishing is a popular use of Australia's Great Barrier Reef Marine Park (GBRMP). In 2004, the Great Barrier Reef Marine Park Authority (GBRMPA) implemented a new zoning plan for the GBRMP that increased no-fishing zones within the Park from 5% to 33% of the total Park area. Anecdotal evidence suggested a high level of opposition towards the rezoning among recreational fishers before and after implementation of the new zoning plan. This study reports on a recent survey of 800 GBRMP recreational fishers that was aimed at understanding fishers' perceptions of the costs and benefits of the 2004 zoning plan and the rezoning process. Results revealed that a majority (70%) of recreational fishers support the new zoning plan and believe it will enhance the sustainability of the Great Barrier Reef and the fisheries it supports. In general, the effects of the new zoning plan on recreational fishing activity appear to be less severe than fishers had expected with most fishers (73%) reporting that the rezoning has had little negative impact on their fishing activity. However, most fishers did not believe that the concerns of recreational fishers were adequately considered in the rezoning process, and trust in the GBRMPA among recreational fishers is low. Results suggest that opposition towards the zoning plan among recreational fishers is due to dissatisfaction with the rezoning and consultation processes rather than dissatisfaction with the outcomes of the new zoning plan. Support for marine protected areas and coral reef conservation among recreational fishers could be enhanced by developing more effective methods of engaging the recreational fishing community in the decision making process.

## 21-4

**New Eco-Development Initiatives Involving Local People in The Conservation Of Coral Reefs in Mahatma Gandhi Marine National Park, Wandoor (India)**

Alok SAXENA[1], **Mani SAXENA*[2]**

[1]Department of Environment & Forests, Government of India, Port Blair, India, [2]Biotechnology, Central Agriculture Research Institute, Port Blair, India

Mahatma Gandhi Marine National Park situated at Wandoor about 29 km from Port Blair is among the first three Marine National Parks in India. It was established in 1983 with the objective of conserving the unique marine diversity particularly the coral reefs found in this area. There are 15 islands within MGMNP but there is no habitation inside the park area. There are 11 villages in the adjoining area having more than 1000 families. The main occupation is fishing. Though no rights are allowed within the Marine National Park but fishing routes are demarcated for providing safe passage to local fishermen. MGMNP is an important eco-tourist site because of its unique marine biodiversity and provides livelihood means to the people living around. In order to involve the local people in the conservation efforts, the Park authorities initiated action at a small level in 2003-04.Tsunami that struck these islands in 2004 affected not only tourism but also the efforts of Park authorities in people's participation. However there has been a significant increase in tourist inflow to these islands in last two years and the park authorities have also recently revived their eco-development initiatives. In a series of meetings by the administration with local people, new initiatives are being taken for providing livelihood means to locals and involving them in the conservation efforts. The present study shows results based on surveys with local people and representatives of administration on the new initiatives, expectations of locals, their increasing awareness and changing attitude towards Park authorities.

## 21-5

**Global Study Of Management Effectiveness Of Marine Protected Areas**

Robert POMEROY[1], **Tammy CAMPSON*[2,3]**

[1]Agricultural and Resource Economics, University of Connecticut, Avery Point, CT, [2]University of Connecticut, Simsbury, CT, [3]University of Connecticut, Storrs

Marine Protected Areas have been established all over the world for the purposes of conservation, fisheries management, or both. While site-specific or regional studies on the management effectiveness of MPAs in meeting one or both of these objectives abound, there are relatively fewer studies that rigorously examine the simultaneous achievement of ecological, socioeconomic and/or governance objectives, and none that attempt to do so on a global scale. Moreover, no prior research has investigated the effects of the timing of management interventions and exogenous or discrete biophysical events on the effectiveness of Marine Protected Areas.

This paper presents research results from a Global Management Effectiveness (GME) evaluation study of Marine Protected Areas. The main objectives of this study are to: 1) determine the socioeconomic, governance and ecological effects (outcomes and outputs) of MPAs; and 2)determine the critical factors (ecological, socioeconomic and governance) affecting MPA outcomes and outputs, as well as the impact of the timing of those factors on the outcomes and outputs of the MPA. The analysis integrates primary data derived from household surveys with extant ecological and control data. This paper will report the findings from the first round of GME study sites, including results from Asia, Africa, and the Caribbean.

## 21-8

**Assessing Economic And Ecological Thresholds in Artisanal Reef Fisheries**

**Louise TEH*[1]**, Lydia TEH[1], Ussif Rashid SUMAILA[1]

[1]Fisheries Centre, University of British Columbia, Vancouver, BC, Canada

Conventional fisheries management approaches are generally considered to be inadequate for managing coral reef fisheries. As an alternative, we apply the resilience concept to examine 'thresholds' of a reef fishery system in order to identify areas where management can enhance socio-economic and ecological sustainability. We use the unmanaged artisanal reef fisheries of Pulau Banggi, Malaysia, as our case study. We find that reef fisheries resources have declined from the past, but have been maintained at a consistent level in the past 3 years. Fish catch composition and fishing effort have also remained stable, and fishing strategies are adapted to seasonal fluctuations. A significant economic perturbation – an increase in fuel price by 20 to 50% - did not cause any noticeable change in fishing behaviour after 11 months, suggesting that the reef fishery is still within economic profitability thresholds. On the other hand, this could also reflect that fishers have a low capacity to adapt due to lack of alternative livelihood options, and limited non-fishing skills and market access. The ecological system might be at a more precarious threshold due to intense fishing for the live reef fish trade, and increasing intrusion of purse seine vessels into artisanal fishing grounds. These pressures are likely to drive down ecological productivity and economic benefits from the fisheries in the future. However, fishers' willingness and capacity to change this downward trajectory is impeded by their economic reliance on the live fish trade, and a general lack of community organization and an attitude of indifference to confront the purse seine fleet. Strategies to strengthen the resilience of Banggi's reef fisheries can include: 1) diversifying economic options for fishers; and 2) developing community capacity and/or community-institutional partnerships to address wider scale pressures such as purse seine intrusions.

## 21-9

**Integrated Economic Valuation in Coral Reef Management: Demonstration, Appropriation And Utilization Of Coral Reef Economic Values For Sustainability And Conservation**

**Rodelio SUBADE*[1]**

[1]Division of Social Sciences, University of the Philippines - Visayas, Miagao, Iloilo, Philippines

A major problem in the utilization of coral reef resources in developing countries like the Philippines is that the full value of these resources is not properly reflected in the market. A big portion of these resources' economic values are not sold in the market and are therefore not accounted for in society's policy and development decision-making

This paper aims to highlight the vital need to integrate economic valuation in coral reef management and in integrated coastal zone management. It uses the total economic value framework, and argues that much of the economic values of coral reef resources have not been properly demonstrated and expressed in the market and policy making, thereby resulting to their over exploitation and damage. Mechanisms on how to demonstrate such economic values (like entrance fees, conservation fees and others) and policies towards capturing them are crucial aspects of integrated economic valuation. A few cases in the Philippines show that this is possible and can provide a good framework in helping attain sustainability and conservation of such national treasures.

## 21-10

**Examining The Persistence Of Coral Reefs Destruction**

**Rijal IDRUS*[1]**, Deirdre HART[1], Eric PAWSON[1]

[1]Geography, University of Canterbury, Christchurch, New Zealand

Despite efforts to eliminate destructive fishing and improve coral reef management such as the multi-donor funded COREMAP Project and other capacity building programs, the state of coral reefs in Indonesia remains under threat and is continuously deteriorating. As in many developing countries, Indonesian coastal communities are often resource rich but income poor. With these paradoxes as a backdrop, this study examines why coastal resources are being continuously degraded, and apparently by the people whose livelihoods depend on them.

We explore the motives and consequences of destructive methods of resource utilisation, and examine the potential for sustainable livelihoods based on coastal resources currently under threat from destructive use patterns via fieldwork in nine coastal communities within the Sulawesi Region of Indonesia.

Field evidence indicates that blast and poison fishing were the most widespread destructive practices. Findings reveal that an array of competing demands and conflicting interests, coupled with inefficient institutional arrangements, have rendered inadequate many resource management institutions and efforts, allowing destructive patterns of resource utilization to persist. Local communities are disempowered when confronted with the intricate network of destructive-fishing actors targeting coral reefs. The existence of this collusive network must be considered in any effort to address problems of effective management.

Our findings also suggest that when a coastal community manages to overcome problems with managing common-pool resources, to establish reciprocal trust and to collectively pursue self-governance, conservation measures can be implemented and a degree of resource sustainability attained. The outcomes provide insight into the dynamic couplings of human and natural aspects of coastal resource systems and, as such, can help improve the decision making process and policies affecting coastal communities in developing nations.

## 21-11

**Ethnographic Studies of Marine-Based Livelihoods in Punta Cana, Dominican Republic**

**Megan STONE*[1]**, Liana TALAUE-MCMANUS[2], Benjamin KUSHNER[3]

[1]Marine Affairs and Policy, University of Miami Rosentiel School of Marine and Atmospheric Sciences, Key Biscayne, FL, [2]Marine Affairs and Policy, University of Miami Rosentiel School of Marine and Atmospheric Sciences, Miami, FL, [3]Punta Cana Ecological Foundation, Punta Cana, Dominican Republic

PESCA (a Partnership for Ecologically Sustainable Coastal Areas) has been initiated by a joint effort between the University of Miami and the Punta Cana Ecological Foundation to evaluate the current state of the coral reef environment in the Punta Cana region and to develop tools to promote sustainable decision-making in the future. We developed an interview questionnaire to guide our ethnographic studies in examining marine-based livelihoods and the social dynamics associated with large-scale coastal development adjacent to coral reef systems.

Preliminary results of studies around fishing and tourism-based employment indicate the critical role of mass domestic migration in both sectors, and where fishing is often an interim occupation in between tourism-based jobs. Migration has widened the networks of livelihood dependence to include workers living with their nuclear family members or extended clan, to others who send remittances to families and dependents residing in different towns. Among fishers, the displacement of coastal villages to locations inland have resulted in a unique structure of owner-crew relations because of the new need for transportation from inland communities to fishing grounds. For tourism workers, separation from nuclear households is common, and "gold-rush" towns forming out of migrant families and individuals with no shared heritage have begun to crowd coastal communities.

Through analyzing life histories, we have examined changes in quality of life over time. Tourism development along the coast has brought higher commodity prices and fragmented communities within the Punta Cana region. It has also brought benefits such as a larger job market, higher wages and better access to basic services. Subsequent analysis will allow us to use the socioeconomic data in identifying management practices to help make coastal tourism evolve as a socially and ecologically viable development sector.

## 21-12

**Towards A Framework For Integrated Conservation Planning in Coastal Catchments And Nearshore Marine Waters**

**Bob PRESSEY*[1]**

[1]Australian Research Council Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

In broad terms, the problem of integrated coastal planning can be stated simply: decision-makers with limited funds for natural resource management must balance the local (within-catchment) benefits arising from their actions with the downstream benefits for freshwater and marine systems. The reality is less simple. The difficulty of resolving choices between local and downstream benefits can be illustrated by listing the main kinds of technical information that managers need. For terrestrial, freshwater and marine environments, they need spatially explicit data on: biodiversity (both depictions of pattern and models of process); ecosystem services (related to soil, water, salinity, acidity and carbon); models of likely expansion or contraction of extractive activities in the absence of management intervention; and the cost, feasibility and relative effectiveness of alternative management actions, including models of downstream effects. They also need to refine qualitative goals into a complex set of quantitative objectives, understand the socio-economic implications of management actions, and develop strategies for involving stakeholders, managing uncertainty and adapting their approaches as new information becomes available. There is presently no framework available for integrating all of this information, although some partial frameworks have been proposed and some organisations have developed specific components. A new research program at James Cook University is coordinating a multidisciplinary project on conservation planning in coastal catchments affecting the Great Barrier Reef. The first stage, reported here, is developing the conceptual and technical framework for integrated planning, identifying missing components of the framework and missing links between components. The framework is intended to be generic and applicable widely to coastal catchments.

## 21-13

**Diet, Health, And Cultural Links With Coral Reef Ecosystems: Dietary Change Over The Last 40 Years in A Hawaiian Community**

**Rebecca PRESCOTT*[1]**, Bruce WILCOX[2]

[1]Zoology, University of Hawaii, Honolulu, HI, [2]Tropical Medicine, Medical Microbiology, and Pharmacology, University of Hawaii, Honolulu, HI

Native Hawaiian culture has depended heavily on the ocean as a primary food source and as a cultural component for generations. However, over the past 40 years, rapid socio-ecological changes in Hawaii, including the introduction of a market economy, dramatic increases in tourism, and alterations to social structures and the environment have changed Hawaiian lifestyles to a more westernized culture. There also has been an increase in obesity, (67%), heart disease, and diabetes. In this study, researchers document dietary shifts in the predominately Hawaiian community of Waimanalo on the island of Oahu (n = 21 individuals interviewed, mean age = 67, 24% female). This pilot study found large shifts in the type of foods consumed and where the foods were collected. Pre- WWII and post WWII, marine fish made up 52.6% and 46.4% of diets respectively, and 100% of fish were caught from sea. During the current post-plantation era (starting late 1960's), ocean-caught fish has declined as a major protein source to 19.4% of diet, accompined by a dramatic increase in foods obtained from markets. In interviews, native Hawaiians identified over-fishing and depletion of ocean resources as a leading cause for shifts in diet. They also discussed restrictions to fishing gear and access to resources, as well as convienience and price of foods at markets as leading to health declines and lower fish consumption. Declines in Hawaiian marine fisheries is the perceived cause of shifts in diet within this community, and other studies have reported declines in coral reef fisheries that were commonly caught in Native Hawaiian communities. We propose that although coral reefs in the Hawaiian Islands are considered to be in fair condition, declines in coral reef ecosystem health may be related to shifts in diet among Hawaiian people and declines in human health.

## 21-14

**Impacts Of Co-Management Of Marine Protected Areas (Mpas) In The Philippines**

**Ronald MALIAO*[1,2]**, Ralph TURINGAN[1]

[1]College of Science, Department of Biological Sciences, Fish Ecophysiology Laboratory, Florida Institute of Technology, Melbourne, FL, [2]Aquaculture Department, Southeast Asian Fisheries Development Center (SEAFDEC) (Previous address), Iloilo, Philippines

While there is a consensus that marine protected areas (MPAs) help rebuild depleted stocks, several studies reported mixed to negative results regarding the efficacy of MPAs as a management strategy. Most MPA impact-assessment studies focused on the status of fisheries, putting the perceptions of local fishing communities on the sideline. We meta-analyzed the impacts of MPAs in the Philippines using social and biological indicators, with an aim to accumulate knowledge of the efficacy of MPAs as a management strategy. Under the social component, we used the co-management impact indicators as prescribed by the Worldwide Collaborative Research Project on Fisheries Co-management (WCRPFC). Under the biological component, we used fish trophic guilds and families as the analytical unit and compared abundance before and after MPA implementation. Our analysis revealed that under the social component, fish abundance, fisher's income, and access to resource were perceived to continually decrease, and the magnitude of decrease was correlated with the duration of MPA management. In contrast, other co-management indicators related to operational level dynamics have significantly improved, indicating that MPAs empower local fishers. The results of the biological component indicated that while total fish abundance has significantly increased, the bulk of the increase was accounted by the non-food species (Pomacentridae, omnivores) while all other groups have either decreased or remained stable relative to the baseline abundance. This result indicated that the relationship between fishing mortality reduction and fish recovery was not straightforward. We interpreted our results in the context of other correlates such as life history traits, effects of habitat alteration, trophic reorganization, genetic responses to exploitation, and Allee effect (depensation). The results of our analysis, integrating social and biological indicators, reveal an alternative view of the effectiveness of MPAs as a management strategy.

## 21-17

**Aspects Of Scaling-Up To Ecosystem Management Of Coral Reefs in The Philippines**

Patrick CHRISTIE[1], **Richard POLLNAC*[2]**

[1]School of Marine Affairs, University of Washington, Seattle, WA, [2]Marine Affairs, University of Rhode Island, Kingston, RI

The objective of the paper is to identify socioeconomic and project process variables impacting aspects of success of coral reef associated management projects in the Philippines. The paper, prepared as part of an ecosystem based management project supported in part by the National Center for Ecological Analysis and Synthesis, re-analyzes three distinct data sets from the Philippines which focus on aspects of coral reef management. The re-analyses focus specifically on variables associated with scaling up management to ecosystem relevant scales and marine protected area (MPA) networks. Size of stakeholder groups, size of management area, population size, density and homogeneity within the context of some 50 environmental, demographic, socioeconomic, cultural, project activity and project output variables are considered. Path analyses are used to test heuristic models constructed on the basis of intercorrelations between the numerous variables. The following variables are significantly correlated with measures of success such as the perception of increased fish near marine protected areas that are part of a network.

Improved coral condition (.727**)

Fishing grounds threatened by illegal commercial fishing (.372*)

Clear leader for MPA (.440**)

Population size (-.427**)

Number of elected community leaders (-.346 *)

Increased compliance (.491**)

Improved enforcement (.349*)

Strict punishment for rule infraction (.407*)

Local community enforcement group involved in MPA enforcement (-.371 *)

Increased intra-community conflict (.390*)

Increased seriousness of conflict (.406*)

n=36; $p<.05$ = *; $p<.01$=**

Multiple stepwise regression establish that the perception of unfair rule enforcement, absence of community groups, and increased tourism increase the likelihood of conflict surrounding MPA management (Adj R2=0.434, $p<0.01$, n=35). Other results will be presented.

## 21-18

**Application Of Participatory Rapid Economic Valuation To Sustainable Community Based Marine And Natural Resource Management in Fiji**

Isoa KOROVULAVULA[1], **Isoa KOROVULAVULA*[1]**

[1]Institute of Applied Sciences, The University of the South Pacific, Suva, Fiji

Economic valuation is used as the main analytical tool to compare the advantages and disadvantages of scenarios on future development. This paper presents a framework that can be applied for valuing the socioeconomic and cultural attributes of biodiversity in marine managed areas in Fiji in monetary terms. This framework has two components. First is a comprehensive and complex quantitative method of valuation. For this, environmental economics is applied, in particular the use of non-market valuation methods. This quantitative types of economic valuation often require extensive understanding of environmental impacts and high-quality data (e.g. on productivity of reef ecosystems and the import of different environmental services inputs) and at times not easy to do. The second component of this economic valuation framework is a partial quantitative economic valuation method. It is referred to as participatory rapid economic valuation (PREV). This method of eliciting economic values incorporates institutional, social, and cultural activities and equity issues at the village or community levels. It is inclusive and participatory in. nature. Hence, PREV method has the ability to provide decision-makers in developing countries like Fiji sufficient information of adequate quality to inform natural and marine resources policy choices.

## 21-19

**Towards Local Fishers Participation in Coral Reef Monitoring: A Case in Tingloy, Batangas, Philippines**

Ana Liza SUBADE[1], **Rodelio SUBADE*[2]**, Zenaida CATALAN[1]

[1]School of Environmental Science and Management, University of the Philippines Los Banos, Los Banos, Philippines, [2]Division of Social Sciences, University of the Philippines - Visayas, Miagao Iloilo, Philippines

Tingloy, composed of five islands is a popular diving site known for its rich coral reefs. However, these reefs are being threatened by man-made stresses and natural disturbances. Thus, a monitoring framework was developed through the integration of scientific and indigenous knowledge in determining and assessing the present status of coral reef environment. One of the benefits of the developed monitoring framework is the empowerment of the fishermen. Fishermen and institutions in the area in cooperation with the academe, provided the major backbone of the framework. The fishermen were interviewed, trained and participated in the whole year monitoring of the coral reef environment. The monitoring framework developed served as an overall guide for monitoring activities and the data gathered served as the baseline information of the coral reef environment in the area.

## 21-20

**"Coastal And Marine Indicators At Your Doorstep" – A Participative Environmental Outreach Program For Schools in Thailand**

**Petchrung SUKPONG*[1]**, Mark WUNSCH[2]

[1]Thailand Programme, IUCN - The World Conservation Union, Bangkok, Thailand, [2]Phuket Aquarium, Phuket Marine Biological Center, Phuket, Thailand

At the Cape Panwa peninsula on Phuket Island, Thailand, intensive resort and housing developments endanger adjacent coral reef flats that have traditionally been used as fishing grounds for octopus, crabs and fish.

This project tries to establish new ways for environmental and science education. It uses creative techniques and the production of audio-visual media in a discourse with children (age 9-12 years) and teachers to create a more intuitive and deeper understanding of local coastal environments and human impact.

To achieve this goal an alliance was formed between environmental educators, the Phuket Aquarium, the local school and a local hotel that provided seed funding as part of their corporate social responsibility (CSR) engagement.

After initial brainstorming and mind mapping the children received lively introductions to marine and coastal habitats, practiced simple investigation and monitoring techniques and produced written and illustrated field diaries. They continue monitoring their reef flat and do their own research on different aspects of marine and coastal ecology.

The children's field diaries and the teacher's feedback have been used to create a media about the marine life. These learning tools visualize the behavior of organisms, monitoring techniques as well as processes and changes in the environment.

The evaluation has shown the effectiveness and weaknesses of these tools that have lead to their refinement.

Through its sincere involvement, the school has become the initiator for an environmental awareness plan that is currently developed with participation of the whole community/with different stakeholders of the community.

Upon completion the learning toolkits will be multiplied and distributed to other schools in the wider region and translated into other languages. The approach has shown that the children have become more aware of their environment and that they are willing and capable to take leadership in environmental issues.

## 21-20

**Strenthening Civil Society To Conserve The Largest Area Of Coral Reef in The South-Eastern Caribbean (The Grenada Bank).**

**Martin BARRITEAU*[1]**, Martin BARRITEAU[1]

[1]Sustainable Grenadines Project, Union Island, Saint Vincent and The Grenadines

Strenthening civil society to conserve the largest area of coral reef in the South-Eastern Caribbean (the Grenada Bank).

The Grenadine islands lie on the Grenada Bank extending some 120 km between the main islands of Grenada and St. Vincent. The majority of the Grenada Bank is less that 50 m deep and supports the most extensive coral reefs and related habitats in the south-eastern Caribbean. The marine and coastal resources of the Grenadines are crucial for sustainable livelihoods and if not properly managed and protected, there will be a gloomy future for many Grenadines people and the marine ecosystems they rely upon.

The Sustainable Grenadines Project (SGP), supported by The Lighthouse Foundation, was developed through a participatory process (Phase 1) involving stakeholder identification and mobilisation, visioning and strategic planning. Phase 2 is a five-year, transboundary initiative based on the strategic plan that seeks to enhance the capacity of civil society to play their role in sustainable development and biodiversity conservation in the Grenadines.

The SGP core activities - planning and training workshops, attachments and exchanges, mini-projects, information dissemination and networking - aim to engage and reorient stakeholders towards sustainable use of the marine resources and the protection of the extensive coral reef-seagrass-mangrove ecosystems of the Grenadines.

The SGP has also been partnering with regional and international organisations including The Nature Conservancy to develop and implement associated projects in support of the above aim. Some of these activities are: water taxi association strengthening, coral conservation training program for schools of the Grenadines, establishment of MPAs, AGGRA and Reef Check monitoring, restoration of wetlands and lagoons, and an alternative livelihood project, on seamoss (*Gracilaria* species) farming.

## 21-21

**Community Buy in Can Make All The Difference in Protecting Valuable Urban Marine Resources: The Hanauma Bay Story**

**Shawn CARRIER*[1,2]**

[1]Sea Grant College Program, University of Hawaii, Honolulu, HI, [2]Hanauma Bay Education Program, Honolulu

The Hanauma Bay Nature Preserve is located on the south-east tip of O`ahu and resides just 10 miles away from world famous Waikiki. Hawai`i's among the most remote archipelagos on earth, and yet receives millions of visitors a year. Hawai`i's official tourism site reads "There's no place on earth like Hawai`i", approximately 20% of marine organisms are endemic to the islands. Visitors contribute greatly to the state economy however environmental impacts are left behind. Hanauma Bay, a flooded volcanic crater is home to a fringing reef, beach, and many species of marine life. Originally part of the Bernice Pauahi Bishop Estate, it was deeded as a public facility to the City and County of Honolulu and then designated as Hawaii's first marine life conservation district in 1967. Its over-popularity in the 1980s led to the establishment of a community organization concerned about the fate of this beautiful resource which helped draft and implement a management plan. An education program was started by the University of Hawai`i Sea Grant College Program at the request of the City and County of Honolulu. Over the years management tools have been refined by the City and State and the Hanauma Bay Education Program (HBEP) has matured. In 2002, a state of the art visitor center opened and a mandatory reef conservation film was introduced. HBEP's mission is to improve understanding and stewardship of coastal and marine resources, through public outreach. Hanauma Bay's recovery is a result of many organizations, a great deal of hard work by many individuals, and sound management practices, demonstrating the positive effect of public education and management. This presentation will address the rich and successful story of Hanauma Bay's development from an overused recreational area to a world-class education center and nature preserve.

## 21-22

**Local Ecological Knowledge And The Management Of Marine Protected Areas in Brazil**

Leopoldo GERHARDINGER[1], **Eduardo GODOY*[2]**

[1]ECOMAR NGO, Americana, Brazil, [2]ICMBio, Brasilia, Brazil

Site visits were done at 9 different Marine Protected Areas (MPAs) along the Brazilian coastline and semi-structured interviews were done with site managers in order to record their perception on the role of local ecological knowledge of fishermen in the management of their sites. The main types of local ecological knowledge useful for MPA management were, in broad terms, the knowledge of resource users regarding spatial distribution and seasonal variation of resources and human use of the seascape within the MPA. This can be summarised as 'where' resources and their users are located in space and time. Other types of knowledge categories were mentioned as valuable, such as knowledge on tidal cycles, species migration, sustainable resource exploitation rates, birds, navigation, wind behaviour, general and specific cycles of nature, amongst others. The utility of LEK systems for MPAs was also acknowledged on their: 1) value to define new MPA sites; 2) utility for patrolling activities (i.e. knowing where and when to focus effort) and; 3) usefulness as baseline data on less researched/assessable areas of the site. Favourable contexts for greater local ecological knowledge influence in marine protected areas management in Brazil were identified: 1) Presence of managers known to the community; 2) Dependence on individual approach adopted by a given officer; 3) MPA category; 4) Presence of a working and representative management council; 5) Identifying the issue of local ecological knowledge as a priority topic for discussion; 6) Presence of local social science research groups and; 7) LEK being readily available or systematised for use in decision making. The study shows a very large perspective for cooperation of fishermen in the management of MPAs in the country, considering the vast coastline (more than 8,000km) and the presence of hundreds of fishing communities in the Brazilian coast.

## 21-23

**Navigating The Transition To Ecosystem-Based Management Of The Great Barrier Reef, Australia**

**Per OLSSON*[1]**, Carl FOLKE[1], Terry HUGHES[2]

[1]Stockholm Resilience Centre, Stockholm University, Stockholm, Sweden, [2]Australian Research Council Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

This article analyses social-ecological conditions that enable transitions towards ecosystem-based management, using the recent governance changes of the Great Barrier Reef Marine Park as a case study. It addresses the interplay between individual actors, organizations, and institutions at multiple levels. We highlight the crucial role of a flexible organization, the Great Barrier Reef Marine Park Authority, which initiated the transition to ecosystem-based management, and the subsequent transformation of the governance regime and provided leadership throughout the process. Strategies involved internal reorganization and management innovation, leading to an ability to coordinate the scientific community, to increase public awareness of environmental issues and problems, to involve a broader set of stakeholders, and to maneuver the political system for support at critical times. The transformation process was triggered by an emergent coral reef crisis, and it shifted the focus of governance from protection of selected individual reefs to stewardship of the larger-scale seascape incorporating 70 bioregions (including many non-reef habitats). The study emphasizes the significance of flexible governance regimes that allow for new forms of management to emerge in response to crisis. It clarifies that top-down decision making, enabling legislation or other forms of social bounds are essential, but not sufficient for shifting governance towards adaptive co-management of complex marine ecosystems.

## 21-24

**Coral Reef Resilience Decision-Making Requires An Integrated Understanding Of Coral Reef Ecosystems**

**Christopher HAWKINS*[1]**, David LOOMIS[2]

[1]Natural Resouces Conservation, University of Massachusetts Amherst, Amherst, MA, [2]Natural Resources Conservation, University of Massachusetts Amherst, Amherst, MA

A social-ecological system-based approach to coral reef management is especially important given that people's social values and activities are at the same time both the major drivers of protection to and degradation of coral reefs. Furthermore, this relationship is dynamic, in that when social values with respect to the natural environment change, as they periodically do, protection activities and negative impacts change in response. Therefore, the implications of using the reef resilience concept to

monitoring programs and management frameworks include institutionalizing holistic management thinking by recognizing the interrelationships between social, political, economic, and natural systems and broadening coral reef ecosystem monitoring parameters. This paper will outline a conceptual management model that discusses the integration of the four systems identified above, provide background about one approach to thinking complexly about coral reef management issues, and present a recent case

study of social-ecological research for the Florida Reef Resilience Program. This study, conducted between May, 2006 and July, 2007 represents a broad examination of attitudes, norms, specialization levels, attributions, and potential conflict among anglers, divers, and snorkelers throughout the Florida Keys. Data were collected in accordance with ecological zones established by the Florida Reef Resilience Program for later integration with other research efforts.

## 21-26

**Social And Ecological Assessments To Plan Improvements In Coral Reef Management Effectiveness In Las Perlas Islands, Panama**

Nohora GALVIS[1], **Nohora GALVIS*[1]**

[1]Coral reefs, Corporacion Propuesta Ambiental, Bogota, Colombia

In order to plan improvements for better coral reef management in Las Perlas Archipelago, two types of assessments of management effectiveness were applied by in situ measurements of the indicators performance and by interviewing different stakeholders to measure how they perceive the performance of the same indicators.

Measurements of perspectives from different stakeholder groups were compared about the importance they assign to key indicators of ecological, social and economic functions which were related to coral reefs ecological integrity, threatens and respective objectives of protection and sustainable use of the related benefits and services.

In Las Perlas, the overall performance was acceptable for most of the survey sites only the perspectives of tourist operators and divers show low effectiveness or acceptance to the management scheme before the new declaration of Special Management Area.

## 21-27

**The Political Aspects Of Resilience**

**Michael FABINYI*[1]**

[1]Resource Management in Asia-Pacific Program, Australian National University, Canberra, Australia

This study aims to investigate the political aspects of resilience in social-ecological systems. Based on long-term anthropological fieldwork in the Calamianes Islands, Philippines, the study focuses on the diverse and contested human interests that make up social-ecological systems. In the Calamianes, what promotes social resilience for one group of people may impact negatively for another group of people, or the ecosystem in which they live. Fishers, for example, have struggled greatly to preserve their patterns of marine resource use, and to oppose any form of regulation. In 2006, regulations to reform the live reef fish trade in the Calamianes were overturned, and the effectiveness of a series of marine protected areas (MPAs) was severely constrained by the actions of fishers in promoting their interests. These interests were based on a strong desire among fishers to maintain their livelihood and economic security, and to avoid shouldering the burdens of conservation that they believed were being unfairly placed on them. Following Armitage and Johnson (2006), this study has found that deciding "for what and for whom are we trying to promote resilience?" becomes a critical question. Answering such a question will require decisions that will favour certain elements or resource users within any social-ecological system, and disadvantage others. The study concludes therefore that such political aspects of resilience thinking require greater attention, and that governance systems that are inclusive, interactive and adaptive (Bavinck et al. 2005) are necessary, if the resilience concept is to be more widely accepted in policy and management arenas.

## 21-28

**Should We Protect The Strong Or Weak? An Analysis Of Risk And Resilience in Marine Protected Areas**

**Eddie GAME*[1]**, Hugh POSSINGHAM[1]

[1]The Ecology Centre, University of Queensland, St.Lucia, Australia

The occurrence of catastrophic disturbances such as cyclones or mass coral bleaching poses a major threat to coral reefs worldwide. Marine reserves have often been touted as way of ensuring recovery from disturbance at a faster rate than unprotected habitats; but should we protect those reefs at greatest risk of unfavourable disturbance we can not control, or instead invest our resources in consolidating the health of those reefs at least risk of such disturbance? We formally define this problem and explore the conditions under which each of these strategies is optimal. If our conservation objective is to maximize the chance at least one reef is in a healthy state then the best strategy is always to protect the reefs at lower risk of catastrophic disturbance. On the other hand, if we wish to maximise the expected number of healthy reefs in our system, then the optimal strategy is more complex; if protected reefs are likely to spend a significant amount of time in a degraded state, either through high disturbance or slow recovery rates, then it is best to protect low risk sites. Alternatively, if our reefs are generally in a healthy state due to fast recovery and low disturbance then we should, counter intuitively, protect the sites at higher risk of uncontrollable disturbance. We illustrate these strategies with an example of cyclone disturbance to coral reefs on Australia's Great Barrier Reef. The optimal conservation strategy with regard to the risk of uncontrollable disturbances can differ dramatically depending on your objective and the level of success expected within reserves. A proper treatment or risk is fundamental to all conservation actions and can indicate surprising routes to conservation success.

## 21-29

**The Implications Of Linked Social-Ecological Systems For American Samoa's Coral Reef Fisheries**

**Arielle LEVINE*[1]**, Stewart ALLEN[1]

[1]Pacific Islands Fisheries Science Center, Honolulu, HI

Even without the presence of a network of no-take marine protected areas (no-take MPAs), current levels of fishing pressure on near-shore coral reefs in American Samoa are low for small, Pacific island territories (Zeller et. al. 2006). This trend has occurred in spite of increasing population levels and improvements in fishing technology. Recent studies comparing current fish catches with archeological records illustrate that catch composition on one American Samoan island is essentially identical to pre-European contact levels (Craig et. al. 2007), indicating surprising stability over time. The reasons for relatively low fishing pressure on American Samoan reefs are complex, but relate largely to improved access to cash and a preference for store bought food, as well as the availability of cheap pelagic fish sold as by-catch or at a discount from the islands' large cannery facility. This has reduced local demand and markets for near-shore fish species; fishing today is predominantly small-scale for recreational and cultural purposes. This unusual combination of social and ecological factors in American Samoa provides a positive example of how certain social factors can result in a reduction in near-shore fishing pressure. However other socially-derived factors, including coastal development, erosion, pollution run-off, and global warming, remain highly relevant to the future and health and resiliency of American Samoa's near-shore coral reefs. These factors prove more difficult to address and require management measures beyond the establishment of no-take MPAs, looking at social and ecological issues on an extended watershed scale.

## 21-30

**Socio-economic and Ecological Monitoring of Coral Reefs at Kood Island, the Gulf of Thailand**

**Makamas SUTTHACHEEP*[1]**, Sittiporn PENGSAKUN[1], Wichin SUEBPALA[1], Dusanee CHOEITONG[1], Thamasak YEEMIN[1]

[1]Department of Biology, Faculty Of Science, Ramkhamhaeng University, Bangkok, Thailand

Fishing remains the most important economic activity associated with coral reefs and provides the main source of protein by local communities. Recently, there has been an expansion in reef based tourism in Thailand. Monitoring of coral communities in terms of ecological changes and coral reef utilization for fisheries and tourism at Kood Island and its vicinity was carried out to assess the socio-economic potential of coral reefs. There was a large area of coral reefs and pinnacles around Kood Island. Several of them have not be surveyed and scientifically reported. Approximately 30 households of Kood Island have small fishing boats. Major fishing gears were crab gill nets and traps for crabs and squids. All fishing products were sold and consumed on the island. However, there were a large number of trawling boats, pushing net boats and light fishing boats for squids from outsiders. Illegal fishing was frequently observed because of weak law enforcement in the area. Currently, tourism development is growing rapidly, especially for building large resorts. Most tourists went to diving at Mu Koh Rang, a nearby island group. Coral reefs of Kood Island largely suffered from the severe coral reef bleaching in 1998 but there was a natural recovery trend. Several coral reef areas have high potential for diving spots, such as Rad Island, Ao Toom and Hin Kong Loi Nam. The local communities has gradually realized the importance of coral reef and seagrass ecosystems for their livelihood through training courses, seminars and public awareness materials for coastal resources conservation. Integration of scientific researches and socio-economic studies is necessary for coral reef management in the Gulf of Thailand.

## 21-33

**Implications Of Coastal Development On Resilience in Linked Socio-Ecological Mexican Caribbean System**

**Jesús ARIAS-GONZÁLEZ*[1]**, Renata RIVERA[2], Yves-Marie BOZEC[1], Fabián RODRIGUEZ-ZARAGOZA[3], Castro-Pérez JOSÉ[4], Carmen VILLEGAS-SÁNCHEZ[1], Gilberto ACOSTA-GONZÁLEZ[1], Hector LARA-ARENAS[1]

[1]Recursos del Mar, Centro de Investigación y Etudios Avanzados del I.P.N., Merida, Yucatan, Mexico, [2]Departamento de Bioquímica y Biología Molecular de Plantas, Centro de Investigación Científica de Yucatán, Merida, Yucatan, Mexico, [3]Departamento de Ecología, Universidad de Guadalajara, Zapopan, Jalisco, Mexico, [4]Biología y Química, Instituto Tecnológico de Chetumal, Chetumal, Quintana Roo, Mexico

Socio-ecological systems (SES) of the Caribbean have evolved in myriad ways, but the majority have under-developed and degradation of coastal resources in common. The worldwide decrease in live coral cover and biological diversity, as well as a phase shifts in coral dominant species due to overfishing, pollution and tourism-associated coastal development, highlight the importance of understanding the source of resilience in linked SES. We have studied Mexican Caribbean reefs from a landscape perspective with three key dimensions: a) structure, i.e. fish and coral biodiversity, geomorphology, reef extension, connectivity; b) ecosystem function, i.e. fish trophic structure, trophic functioning; and c) time, i.e. temporal change of coral reef community structure and function. Our studies have been focused on two socio-ecological system scenarios (artisan fishery and tourism-coral reefs) and different conservation strategies (marine protected and unprotected areas). Until the 1970s, artisanal fisheries were the only human activities in Mexican Caribbean reefs. These included several resources, with heavy selection of conch and lobster, although scale fisheries remained relatively stable. From the 1970s on, the advent of massive tourism development has completely changed coastal resources appropriation regimes and altered ecosystem services, beginning the era of "Gringolandia, a term that reflects the circus-like spectacle of over-sized resorts" like Cancun with a chaotic tourism growth and uneven development. Changes are occurring in biodiversity, which is dependant on reefscape structure and extension, and in ecosystems function, in terms of mass balance and flux. These changes are eroding resilience. Massive tourism development in the Mexican Caribbean puts population connectivity at risk through habitat fragmentation and phase shift from coral to algae dominated ecosystems. Despite investment of millions of dollars in management, the collapse of coral reef system appears imminent. The associated social system will then need to adapt to the emerging algae-dominated ecosystem

## 21-34

**Fishing, Agriculture, Trade And Migration On Small, Overpopulated Islands in Melanesia: Moving Beyond Functionalist Analyses Of Indigenous Coral Reef Resource Use And Management**

**Simon FOALE*[1]**

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

Many studies of traditional management of coral reef fisheries by indigenous communities in Melanesia downplay or ignore the extent to which those communities have been engaged with the global economy since the early colonial era, and exaggerate the extent to which subsistence fisheries actually require management, in support of arguments about the 'adaptive' nature of traditional management institutions. Such functionalist approaches have been critiqued for many years in the anthropological literature but appear to continue to enjoy some currency in the recent efflorescence of cross-disciplinary studies that deal with 'traditional' coral reef resource use. In this paper I present a range of demographic, historical, ecological, anthropological and economic data relating to artisanal and subsistence fisheries on a number of small, over-populated (more than 100 people per square kilometer) islands in Melanesia. A key finding of the study is that on some islands, population densities well in excess of the production capacity of the local swidden agriculture system are supported primarily by cash from beche-de-mer and shark-fin fisheries, neither of which is subject to any form of community-level management. The study also shows the extent to which ties to groups on other, less densely populated islands are actively maintained through marriage, traditional trade, and feasting, and the extent to which this provides an option for emigration in the case of severe drought or cash shortage. The data underline the complexity of marine resource use and its contingency on a wide range of variables in such systems, and highlight the risks inherent in functionalist frames of analysis.

## 21-35

**Management For Resilience On The Great Barrier Reef in The Face Of Climate Change:**

**Laurence MCCOOK*[1,2]**

[1]Research & Monitoring Coordination, GBRMPA, Townsville, Australia, [2]Pew Fellow in Marine Conservation, Townsville, Australia

Globally, coral reefs are under increasing pressure from human stressors, including climate change in particular. Even under optimistic scenarios, significant climate change is now inevitable and large-scale disturbances to reefs will become more frequent and more severe, so that reef managers have a responsibility to maximise the resilience of reefs to those changes.

A number of factors have been identified as contributing to the ecological resilience of coral reefs, including:

- Reducing the extent and rate of climate change;
- Reduction in stressors, such as human derived sediments, nutrients and pollutants;
- Minimising human related disturbances;
- Intact trophic structure, especially larger herbivorous fishes;
- The biodiversity of the system;
- The connectivity and complexity of the ecosystem and the presence of refugia;
- Strong links between communities and different levels of Government, and
- Adaptive and multi-scale management.

The roles of these different factors are illustrated with examples from the management of the Great Barrier Reef. However, in isolation, most of these examples really just amount to good management: what does resilience add to good reef management?

The concept of resilience provides a valuable integrative perspective in both science and management, because:-

i. it provides a basis for recognising, and communicating to the public, that different threats are not independent, but may act synergistically, requiring integrative management; similarly, addressing combinations of threats may provide synergistic benefits;

ii. management for resilience provides the best insurance against future, unforeseen threats (or under-estimated threats);

iii. it allows the integration of ecological, social and economic issues: the "SES" or social-ecological system;

iv. it provides a basis for management which is proactive, as well as responsive to accepted threats.

## 21-36

**Towards A Greater Integration Of Social And Natural Sciences**

**Alexandra COGHLAN*[1]**

[1]Tourism Program, James Cook University, Cairns, Australia

Interdisciplinary teams are now commonplace in large natural resource management research centers. The evolution from pure biologists, to a system approach with ecologists and later the addition of social scientists and geographers reflect our understanding that no natural environment is exempt from human impacts, and that we must examine the system as a whole if we wish to protect it.

There is a recognition that, in order to successfully protect a natural resource such as coral reefs, there must be local support for the projects, and some incentive to preserve and manage the resource. As such many teams with a natural conservation goal, operate within a context of outcome and impact-driven funding. In some cases, the natural scientist who has been working near or alongside the local community for many years whilst studying the resource becomes the most obvious choice, particularly if this person has above-average social skills.

The result of this evolution from biologist/ecologist to social scientist is a new form of outcome driven social science, and a discipline aimed at achieving partnerships to protect natural resources. This paper therefore traces the diverging pathways of social and natural sciences, examining the differing research paradigms and comparing the issues of "isms" (determinism, functionalism and positivism) in the natural sciences and fluffy, fuzzy-wuzziness of the social sciences. We argue that the new social science finds itself somewhere in between.

We examine the outputs of new social scientists and argue for greater integration so that the traditional strands of social science may adopt a more outcome driven approach that allow communities to adapt to rapidly changing natural environments. Finally, we encourage more dialogue, through peer-review publications and conference presentations, between traditional social sciences and the new, emerging discipline, to add new perspectives to each and allow them to learn from each other.

## 21-37

**Exploitation And Trade Of Coral Resources in Bangladesh.**

**Mohammad Zahirul ISLAM*[1]**, Mohammad Sazedul ISLAM[2]

[1]Marine Conservation, Marinelife Alliance, comilla, Bangladesh, [2]Marine Conservation, WCRC, comilla, Bangladesh

In Bangladesh corals are being rapidly and seriously extracted and traded to major tourist town Cox's Bazar. Cox's Bazar coral market possibly the biggest open market of coral and shells in the world. One is called Jhinuk Market containing 22 shops entirely for corals and shells and Laboni beach providing more than 200 shops permanent and 150–200 mobile sellers. The approximate sales are 4-5 hundreds of thousands pcs annually including branching and tabular Acropora sp., and among massive Favites, Goniastrea, Platygyra etc. In Bangladesh the only sources of coral is St. Martin Island and southwestern marine area up to Myanmar and down farther may have connection with Margui Archipelago. But coral trade included the smuggling items from nearby Burma town, Mongdu. During the National Conservation Strategy Implementation Project/MOEF coral protection started by St. Martin Pilot Project and local volunteers of MarineLife Alliance in 2000. Currently much awareness and enforcement conducted by various GO and NGOs, instead hiding coral business ongoing at deferent spots like Cheradia, west beach, and main market. The supply from St. Martin still continuing that is traced in Cox's Bazar market. Collection and selling were done collectively by 24 personnel's at St. Martin Island, recorded during 2001-06 and out of them some were from outside and Myanmar. Several female heads were also engaged in the major smuggling. Many traders initiated the business with financial help from leading NGO, BRAC for curio business. Along with corals, more than 5 metric tons of shells also traded. Thais sp., Monodonta sp., 6000 pieces of cowries Cyprea sp., have been recorded to trade along with and unknown number of sea urchin also to make ash tray. At least total 22 species of shells majority of Gastropods are traded at Cox's Bazar curio center from St. Martin Island.

## 21-38

**Supporting Environmental Stewardship, Conservation, Livelihoods And Environmnetal Education in The Coral Archipelago Of Lakshadweep, India**

**Vineeta HOON*[1]**

[1]Centre for Action Research on Environment Science and Society, Chennai, India

The paper discusses a combination of community-based strategies being carried out in Lakshadweep Islands with micro budgets to address the issues concerned with coral reef conservation and livelihoods. The program is based on our belief that the local community will pay more attention to environmental issues if they have been involved in data gathering, analysis and establishing key learning's. They will then be able to speak with conviction and generate support for local management solutions.

Establishing a community based socioeconomic monitoring team at Agatti. Workshops for environmental wardens and local NGO's and educated youth for conducting socioeconomic assessments, reef related activity monitoring and ecosystem health monitoring. These workshops led to the formation of a local team called the ACRMN.

The coral reef awareness and education project included environmental orientation workshops for schoolteachers and children (classes 6-9) so as to bring in local environment and cultural features in their teachings. The final output was to get a children's perception of their environment and to correlate this with topics in their syllabus.

Discussions with fishers and women using the participatory appreciative enquiry approach and the Sustainable livelihoods framework to establish a livelihood strategy to increase incomes from fisheries. This led to the establishment of the Maliku Hikkimass Producers society at Minicoy.

This paper will discuss the processes adopted; key learning's from each of the projects and provides recommendations for the future.

## 21-39

**Coral Reef Conservation In A Changing Climate**

**Joshua CINNER*[1]**, Tim MCCLANAHAN[2], Joseph MAINA[2], Nick GRAHAM[3], Tim DAW[4], Selina STEAD[3], Katrina BROWN[4], Andrew WAMUKOTA[2], Mebratu ATEWEBERHAN[2], Valentijn VENUS[5], Nick POLUNIN[3]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]Wildlife Conservation Society, Mombasa, Kenya, [3]University of Newcastle, Newcastle, United Kingdom, [4]University of East Anglia, East ANglia, United Kingdom, [5]International Institute for Geo-Information Science and Earth Observation, Enschede, Netherlands

Climate change is likely to pose new challenges to the conservation of the Earth's natural resources by increasing the frequency and intensity of large-scale temperature events, which can profoundly impact sensitive ecosystems such as coral reefs. Addressing these challenges will require a response framework for pragmatic conservation actions informed by site-specific susceptibility to climate change and the capacity of societies to cope with or adapt to change. Depending on a particular location's environmental susceptibility and social adaptive capacity, appropriate conservation actions will require some combination of: (1) large-scale protection of ecosystems; (2) actively transforming and adapting social-ecological systems; (3) building the capacity of communities to cope with change; and (4) donor aid focused on de-coupling communities from dependence on natural resources. We apply our framework to five western Indian Ocean countries, where climate mediated disturbance has greatly impacted coral reefs. We integrate results from an oceanographic environmental model that uses environmental conditions during previous extreme warming events to predict the susceptibility of coral reefs to future bleaching with results from a socioeconomic survey of 29 communities that used eight quantitative indicators to provide a household-level index of social adaptive capacity. We plot communities' mean adaptive capacity against the predicted susceptibility of adjacent reefs to bleaching and examine how differing conservation actions may be appropriate across nations and sites. We find that current conservation strategies are ill-prepared for climate change. In particular, the countries with the highest susceptibility to bleaching and low adaptive capacity are those where marine conservation strategies are highly dependent on reef-related tourism, making the sustainability of this protection strategy under climate change scenarios questionable. Alternatively countries with low susceptibility to bleaching and high social adaptive capacity should be a high regional priority for reef conservation, but in practice these countries are protecting <1% of their reefs.

## 21-40

**Diving Down The Reefs? Intensive Diving Tourism Threatens The Reefs Of The Northern Red Sea**

**Harald HASLER*[1]**

[1]Department of Marine Biology, University of Vienna, Vienna, Austria

Intensive recreational SCUBA diving threatens coral reef ecosystems. The reefs at Dahab, South Sinai, Egypt, are among the world's most dived (>30 000 dives y-1). We compared frequently dived sites to sites with no or little diving. Benthic communities, hard coral cover and condition of hard corals were examined by the point intercept sampling method in the reef crest zone (3 m) and reef slope zone (12 m). Additionally, the abundance of corallivorous and herbivorous fish was estimated based on the visual census method. Sediments traps recorded the sedimentation rates caused by SCUBA divers. Zones subject to intensive SCUBA diving showed a significantly higher number of broken and damaged hard corals and significantly lower hard coral cover. Reef crest coral communities were significantly more affected than those of the reef slope: 95% of the broken colonies were branching ones. No effect of diving on the abundance of corallivorous and herbivorous fish was evident. At heavily used dive sites, diver-related sedimentation rates significantly decreased with increasing distance from the entrance, indicating poor buoyancy regulation at the initial phase of the dive. The results show a high negative impact of current SCUBA diving intensities on hard coral communities and hard coral condition. Corallivorous and herbivorous fishes are apparently not yet affected, but are endangered if hard coral cover decline continues. Reducing the number of dives per year, ecologically sustainable dive plans for individual sites, and reinforcing the environmental education of both dive guides and recreational divers are essential to conserve the ecological and the aesthetic qualities of these dive sites.

## 21-41

**Reef Conservation And Tourism Development An Open Item**

**Barbara REVELES GONZALEZ*[1]**, Arturo ROMERO PAREDES[2]

[1]SER de Quintana Roo, A.C., Chetumal, Mexico, [2]Director, Ecoturismo y Nuevas Tecnologias, Atizapan de Zaragoza, Mexico

In Mexico it´s economic incomes are based on: the sale of the petroleum, the tourism and the entrance of currencies by remittances of Mexicans that work in the United States (US).

In the case of the petroleum is an energy source that has gone exhausting and that currently is considered little viable for the future; for the case of those of remittances originating from Mexican workers in US the current tendency indicates that the next years was stabilized the entrance of currencies for this way and will tend a slope by the adoption of restrictive measures toward the entrance Mexican workers to US

In the case of the tourism is Quintana Roo the state of Mexico that more currencies enters for this activity, its cultural and natural attractions have become place the priority inside the municipal, state, and national development plans; the previous thing has had and will have a very high cost in case of modify not the current strategy of development.

In the present document the development of Quintana Roo is reviewed as focal point of the sun-and-sand-tourism of the last 20 years; taking into account the loss of ecosystems and habitats like: coral reefs, mangrove swamps, seagrass beds, among another; the overuse of the natural resources (fishing resources, vegetation) and the current tendencies of development based on the Land Use Programs the ones that have been adequate the needs of the large hotel chains and/or private economic interests.

The cost-benefits of development as until now has been conducted in relation to natural resources is too high, it is necessary to adopt long-term strategies result in the conservation of natural resources. It is the modification of environmental and development policies which will generate a sustainable future for a very long time.

Key words: coral reef, tourism, Quintana Roo

## 22-1

**Complex Ecological Effects Of Fishing Revealed Using A New Assemblage Assessment Tool That Relies On A Large Unfished Reference Area**

**Alan FRIEDLANDER*[1]**, Joshua SLADEK NOWLIS[2], Edward DEMARTINI[3], Eric BROWN[4]

[1]Biogeography Branch, NOAA, Waimanalo, HI, [2]Economics Department, Stanford University, Stanford, CA, [3]Pacific Fisheries Science Center, NOAA Fisheries, Aiea, HI, [4]Kalaupapa NHP, National Park Service, Kalaupapa, HI

Scientific management guidance is lacking for most tropical marine fisheries because of the exacting data requirements and many assumptions of conventional stock assessment models. The lack of conventional advice often leads to management paralysis even amidst strong claims about fisheries collapses based on analysis of limited or selective data. We produced unconventional preliminary assessments for 55 species within the main Hawaiian Islands (MHI) by comparing abundances there versus within the Northwestern Hawaiian Islands (NWHI) Marine National Monument—a large, virtually unfished reference area. Nearly three-quarters of the species appeared to be depleted in the MHI with abundance levels less than 25% of the NWHI. Large mobile predators were especially affected, but many other target and non-target species appeared to be in poor condition as well. When small no-fishing areas within the MHI were used as reference points, our impression of stock status would have been overly optimistic, particularly for stocks in the worst condition. By comparing size frequency distributions for certain species in the two areas, natural and fishing mortality rates were developed. Since NWHI populations experience little fishing pressure, mortality rates there represent natural mortality whereas the MHI populations experience both natural and fishing mortality. Analysis of the highly prized blue trevally (Caranx melampygus) suggested that recent fishing rates are almost double a reasonable proxy for maximum sustainable yield and that the spawning potential ratio was 11% of reproductive potential. With the help of a larger and therefore more appropriate unfished reference area, we were able to provide strong evidence of depleted fish stocks likely caused by fishing on Hawaiian shallow water reefs.

## 22-2

**Current and Future Sustainability of Island Coral Reef Fisheries**

**Katie NEWTON*[1]**

[1]School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom

Overexploitation is one of the principal threats to coral reef diversity, structure, function, and resilience. Although it is generally held that coral reef fisheries are unsustainable, little is known of the overall scale of exploitation or which reefs are overfished. Here, on the basis of ecological footprints and a review of exploitation status, we report widespread unsustainability of island coral reef fisheries. Over half (55%) of the 49 island countries considered are exploiting their coral reef fisheries in an unsustainable way. We estimate that total landings of coral reef fisheries are currently 64% higher than can be sustained. Consequently, the area of coral reef appropriated by fisheries exceeds the available effective area by ~75,000 km2, or 3.7 times the area of Australia's Great Barrier Reef, and an extra 196,000 km2 of coral reef may be required by 2050 to support the anticipated growth in human populations. The large overall imbalance between current and sustainable catches implies that management methods to reduce social and economic dependence on reef fisheries are essential to prevent the collapse of coral reef ecosystems while sustaining the well-being of burgeoning coastal populations.

## 22-3

**The Need For Adaptive Management And The Challenges Of Climate Change**

**Brigid KERRIGAN*[1]**

[1]Fisheries, Queensland Department of Primary Industries & Fisheries, Brisbane, Australia

The Great Barrier Reef World Heritage Area on the east coast of Australia supports an ecologically sustainable coral and marine aquarium fin fish fishery. The collection of coral is focused in two regions adjacent to large population centres which also support significant tourism industries centred on the Great Barrier Reef. The collection of aquarium fin fish is also concentrated in areas that typically have access to required land-based infrastructure. Due to the operations of both fisheries they are highly visible and come under significant scrutiny from stakeholders. To ensure the continuation of these fisheries within a World Heriatage Area both management and industry are rethinking there approach. The added challenge is adapting management and the operation of the fisheries to the potential changes in the coral reef system that are/will occur in response to climate change. This paper outlines the adaptive co-management fisheries model being developed jointly by government and industry to deal with the uncertain challenges of climate change and oppositional public opinion of a coral fishery within the Great Barrier Reef World Heritage Area.

## 22-4

**Coupled Changes in Structure And Function in Reef Fish Assemblages: How Predators Increase Fisheries Production**

**Stuart SANDIN*[1]**

[1]Marine Biology Research Division, Scripps Institution of Oceanography, La Jolla, CA

A growing number of surveys are revealing that coral reef ecosystem structure can vary greatly, especially in response to anthropogenic stressors. Reef fish assemblages suffer a first line of impact, with large-bodied, predatory species being disproportionately removed by fishing. Despite consensus regarding such qualitative shifts in fish assemblage structure, we currently lack detailed information about ecological consequences of these shifts. From the perspective of reef fisheries, the basic question remains unanswered – how does alteration of fish assemblage structure affect productivity, i.e., production of new fish biomass per unit time. Production is the fundamental currency of fisheries management.

I have developed new analytical approaches to explore patterns of reef fish production, using both theory and statistical estimators. I will demonstrate how trophic redundancy within reef fish assemblages leads to very high energetic efficiency on reefs, and how such trophodynamics can support fish assemblages dominated by predators (e.g., inverted trophic pyramids). Systematic removal of top trophic levels (as by heavy fishing pressure) can dramatically shift biomass and production patterns of lower trophic levels, resulting in reduced productivity from the fish assemblage as a whole. Using visual count data collected across a dramatic gradient of fishing pressure, I have estimated the realized changes in fishery production (in units of instantaneous biomass production) that follow from reductions of predator biomass. Predators systematically reduce the size of prey fish relative to species-specific size maxima, resulting in a prey fish assemblage that is building more biomass through time. In the absence of predators, prey fish are more consistently near their species-specific maximum size, and thereby shunt more energy toward reproduction and respiration and less toward somatic production. Thus, the interests of conservation and fisheries management appear aligned – by maintaining (or rebuilding) predator populations, there is capacity to simultaneously maintain (or rebuild) productivity of the fishery.

## 22-5

**Fishing Pressure, Productivity, And Competition For Resources: Malthusian Overexploitaton And Efforts To Overcome It On Kenyan Coral Reefs**

Tim MCCLANAHAN[1], **Christina HICKS*[2,3]**, Emily DARLING[4]

[1]Marine Program, WCS, New York, NY, [2]Coral Reef Conservation Project, Mombasa, Kenya, [3]Marine Sciences and Technology, University of Newcastle, Newcastle, United Kingdom, [4]Simon Fraser University, Burnaby, BC, Canada

Trends in an artisanal coral reef fishery were examined using a ten year time series along a gradient of fishing intensity spanning 75 km of Kenya's most populated coastline. As predicted by Malthusian scenarios; catch per unit effort (CPUE), mean trophic level, functional diversity of fished taxa, and diversity of gear declined, while total annual catch and catch variability increased with increasing fishing pressure. The fishery was able to sustain high (~16 tons km-2 year-1) but variable yields at high fishing pressure due to the dominance of a few productive herbivorous fish in the catch. The effect of two separate management strategies to overcome this Malthusian pattern was investigated: fisheries area closure and elimination of the dominant and most "competitive" gear (pulled seine nets). We found that sites within 5 km of the enforced closure showed significantly lower total catch and catch per unit effort (CPUE), but increased yield stability and trophic level of catch than predicted by regression models normalized for fishing effort. Sites that had excluded illegal beach seine use through active gear management exhibited increased total catch and CPUE. Time for space substitutions confirmed positive correlations between time since closure and trophic level and between time since pull seine removal and CPUE. There was a strong interaction between closure and gear management, which indicates that for closures to be effective at increasing catch, there must be simultaneous efforts at gear management around the periphery of the closures. We propose that Malthusian effects are responsible for the variation in gear and catch and that active management through reduced effort and reductions in the most competitive gear have the greatest potential to increase the functional and trophic diversity and per-person productivity.

## 22-6

**Demographic Shifts in Coral Reef Fish Communities Across A Gradient Of Human Disturbance**

**Benjamin RUTTENBERG*[1,2]**, Stuart SANDIN[1], Sheila WALSH[1], Scott HAMILTON[3], Mary DONOVAN[3]

[1]Scripps Institution of Oceanography, La Jolla, CA, [2]Marine Science Institute, University of California Santa Barbara, Santa Barbara, [3]Marine Science Institute, University of California Santa Barbara, Santa Barbara, CA

Over the past few decades, direct human impacts have been increasing on coral reefs worldwide. Researchers have documented changes in individual size and community structure, and declines in the yield of reef-based fisheries resulting from these impacts. Still, there have been fewer studies of demographic shifts driven by anthropogenic effects, and nearly all of these have examined only fishery species. We examine demographic patterns from five species from a variety of trophic levels on two nearby atolls in the Line Islands, Kiritimati Island and Palmyra Atoll. These islands are similar biogeographically and oceanographically, and yet differ greatly in the level of human impacts. We present age-based demographic data, obtained using standard techniques in otolith ageing from collections of the study species from both islands. We found striking differences in demography among islands, and these patterns differed across trophic groups. On unfished Palmyra, top predators (piscivores) were larger and longer-lived than on more heavily-fished Kiritimati, though individual growth rates were comparable. In contrast, species in lower trophic groups, including mid-level predators, were smaller, experienced higher rates of mortality, and grew faster on Palmyra than on Kiritimati. Our data suggest that anthropogenic impacts lead to indirect demographic changes; on relatively impacted Kiritimati Island, the removal of piscivores leads to lower rates of predation on lower trophic groups and increased sizes and longevity, whereas on relatively pristine Palmyra, the presence of large populations of top predators results in greater predation pressure, higher rates of mortality, and faster growth for lower trophic groups. Similar data from other atolls in the Line Islands chain corroborate these findings. Improving our understanding of species specific changes that result from human disturbance can help us develop more functional approaches to managing reef fisheries.

## 22-7

**Distribution Pattern, Habitat Overlap And Trophic Interaction Of Trawl Catches Within The Ragay Gulf, Philippines Coastal Fisheries Ecosystem**

**Lualhati LACHICA-ALIÑO*[1]**, Laura DAVID[1], Matthias WOLFF[2], Porfirio ALIÑO[1], Catalina RAÑOLA[1]

[1]University of the Philippines, Marine Science Institute, Quezon City, Philippines, [2]University of Bremen, 2 Center for Tropical Marine Ecology (ZMT), Bremen, Germany

A comprehensive resource and ecological assessment was done in Ragay Gulf, Philippines. Exploratory trawl-fishing surveys characterized the distribution patterns of trawl fish catch and assessed the external factors influencing the variability of the catch within the gulf. Species composition of commercial and municipal fish catches was compared to those found within coral reef, seagrass, mangrove and soft bottom communities, to determine the degree of overlap of their associated species within the gulf's fisheries catches. Mass-balanced trophic models using species-specific ecological groups were developed to quantify the trawl fisheries' impact on the temporal biomass budget of the ecosystem. Cluster analysis based on the 38 commonly occurring and abundant species in the trawl catches revealed northern (less exposed) and southern (exposed) species clusters associated with the prevailing circulation pattern and phytoplankton density in the gulf. Further analysis of the trawl catches composition revealed two other distinct clusters indicative of the spatial distribution and intensity of the trawl fishery in the gulf. We differentiated these areas as "highly fished" and "less fished" areas. Fifty percent of the multigear fisheries catch overlapped with the four coastal habitats. Species associated with soft bottom habitats had the highest overlap with the trawl fishing areas while overlap of municipal fisheries catch was highest with species associated with coral reefs and seagrass habitats. Forty-five years historical reconstruction of the trawl fisheries using ECOSIM showed a significant decrease in the biomass of the large high value fisheries groups together with an increase of cephalopod biomass. Subsequent 10-year simulation scenarios of a trawl fishery ban revealed that important resources such as large and medium sized carnivores would not have been significantly reduced had there been a timely application of fisheries gear regulations.

## 22-8

**Impacts of Non-Professional Fisheries on Reef Fish Communities. A Case Study in New Caledonia (Western Pacific)**

**Nicolas GUILLEMOT*[1]**, Pascale CHABANET[2], Marc LEOPOLD[1], Olivier LE PAPE[3], Marion CUIF[1]

[1]Institut de Recherche pour le Développement, CRISP Program, Noumea, New Caledonia, [2]Institut de Recherche pour le Développement, Ste Clothilde, Reunion, [3]Pôle Halieutique, Agrocampus Rennes, Rennes, France

The imminent creation of a massive nickel mining complex will soon increase demographic pressure on the rural Northwest coast of New Caledonia (Western Pacific Ocean). As a consequence, fishing pressure is expected to significantly rise. Our objectives were 1) to assess to what extent six years (2002-2007) of underwater visual censuses (UVC), conducted over 60 permanent transects, reflected the fishing pressure characterised by 165 surveys of non-professional fishermen conducted in 2007 ; 2) to plan for an optimized long-term monitoring program (adequate methodologies and sampling design) to monitor the predicted fishing impact. In the study area, including three villages and five Melanesian tribes, surveys showed that non-professional fishing uptakes (~171 tons) are far more important than professional uptakes (~35 t). Non-professional fishermen target a large diversity of biotopes (barrier, intermediate and fringing reefs, mangroves, soft bottoms) and fish families. The main families targeted are Lethrinidae, Acanthuridae, Scaridae, Mugilidae, Siganidae, Serranidae, Haemulidae, Ludjanidae, Carangidae, Sparidae, Gerreidae and Kyphosidae. Furthermore, fishing practices (gear, targeted species, yearly landings) differed strongly between tribes and villages, which underlines the necessity to monitor every aspects of these non-professional activities. UVC reflected partially the effects of this complex fishery landscape. After that survey information was translated into spatially-explicit information and integrated into a GIS, UVC results compiled by biotopes and species reflected 36% of the survey information. Specifically, several key landing indicators (yield, species mid-size) were successfully related to UVC indicators (biomass, species mid-size), and both proved to be consistent for a long-term monitoring. However, UVC's sensitivity remains not completely appropriate to fully measure non-professional fishery impacts. Adequate quantification could be partially based on UVC but methods such as video observations (avoiding diver biases) could provide complementary data on targeted species. Furthermore, validation should still be based on surveys, especially targeting non-professional fishermen.

## 22-9

**Comparative Evaluation Of Reef Fish Resources Adjacent To Densely-Populated South Florida, Usa: Anthropogenic Impacts And Implications For Management**

**Todd KELLISON*[1]**, Vanessa MCDONOUGH[2], Doug HARPER[1], James TILMANT[3]

[1]Southeast Fisheries Science Center, NOAA Fisheries, Miami, FL, [2]Biscayne National Park, National Park Service, Homestead, FL, [3]Water Resources Division, National Park Service, Ft. Collins, CO

Assessing temporal and spatial trends in reef resources is important for ecosystem and fisheries management in coral reef ecosystems. Biscayne National Park (BNP), FL, USA, encompasses the northern portion of the FL Keys coral reef tract and is adjacent to a local human population of ~2.5 million (regionally ~ 6 million) in a county that has experienced considerable increases in human population (47%) and recreational fishing vessels (48%) over the past 25 years. Despite being a national park, commercial and recreational fishing is allowed in BNP. We compared the status of reef fish resources in BNP with (1) historical data and (2) data from reefs adjacent to less-populated areas along the FL Keys to assess the relative condition of reef fish resources in BNP. For the historical comparison, we repeated a study to compare current (2006-2007) reef fish community structure in BNP with that observed during 1977-1981. Reef fish communities changed considerably over time with significant declines in species richness and frequency-of-occurrence of fishery targeted and non-targeted species. For the spatial comparison, we used three data sources to compare trends in abundance and length-frequency distributions of multiple fishery-targeted species along the FL Keys. Regardless of data source, species-specific proxies for abundance and length-frequency distributions were predominantly lowest and smallest, respectively, in and around BNP. The historical trends and spatial patterns observed are consistent with those expected in heavily utilized reef systems and may continue given predicted increases in human population and fishing pressure in southern FL. Results are discussed in terms of prospects for adaptive ecosystem and fisheries management in BNP.

## 22-10

**Revealing Patterns Of Impact Of Fishing On Fish Resources From A Large Scale Regional Program**

**silvia PINCA*[1]**, ribanatake AWIRA[1], pierre BOBLIN[1], melba WHITE[2]

[1]spc, noumea, New Caledonia, [2]MIMRA, majuro, Marshall Islands

A large scale program was conducted in the Pacific region to assess the status of commercial resources and support countries in managing fisheries. Underwater visual censuses and socio-economic interviews were carried out for 5 years to collect resource status information from 17 countries. One of the main difficulties in evaluating the condition of a fishery is the lack of knowledge of the conditions that existed before fishing began. Moreover, records of changes over time are often missing, especially on a large scale. The alternative choice to understanding variation in resource availability is to compare resource status at different sites of similar environmental conditions (location, geomorphology, habitat) but under different fishing pressures. Taking into account one specific but localized historical data set along with acquired knowledge from frequent underwater observations, we decided to focus on comparing records of size and size ratio (ratio between average size and maximum size of a species) together with biomass of target commercial species to identify responses in fish populations. By analyzing groups of sites of similar geomorphogical and environmental conditions, but different levels of fishing pressure, we could find significant negative relations between in situ total commercial fish stock, carnivore mean size, specific commercial families and species size ratio and selected indicators of fishing pressure: values of extrapolated catch per village, density of fishers per area and percentage of population practicing fishing as source of income rather than simply sustenance. Such results give a noteworthy contribution to the search for indicators of fishing status which can be used when assessing fish stocks for the purpose of management.

## 22-11

**Where Have All The Big Fish Gone? Distribution Of Remaining Large Reef Fishes in The Hawaiian Archipelago**

**Benjamin RICHARDS*[1]**, Emily LUNDBLAD[1], Brian ZGLICZYNSKI[2], Marc NADON[1], Robert SCHROEDER[1], Russell BRAINARD[2]

[1]NOAA Coral Reef Ecosystems Division, Joint Institute for Marine and Atmospheric Research, University of Hawaii, Honolulu, HI, [2]Coral Reef Ecosystems Division, NOAA National Marine Fisheries Service, Honolulu, HI

This study represents one of the first and most comprehensive efforts to investigate habitat preference of large reef fishes in the Hawaiian Archipelago. Physical characteristics of the coral reef including depth, slope, rugosity, and habitat type have been shown to play a critical role in the distribution of many reef fishes. However, research has generally focused on small spatial scales and on species living in tight association with the reef (e.g., Chaetodontidea, Pomacanthidea, Pomacentridea). While it stands to reason that similar relationships should exist, little work has focused on quantifying the effects of these habitat parameters on larger reef fishes (e.g., Carcharhinidea, Carangidea, Lutjanidea, Scaridea), many of which contribute to the highest trophic levels, are wide ranging, have extended ontogenies, and are most vulnerable to exploitation, habitat degradation and ecosystem change. This study synthesizes data collected biennially (2000-2006) along 700 surveys covering approximately 1500 hectares. Biomass and numeric density distributions of large reef fish (>50 cm TL) were analyzed with respect to depth, slope, rugosity and habitat type in a GIS framework. Bathymetric data were derived from multibeam sonar, IKONOS and LIDAR surveys. Habitat type was determined using published benthic habitat maps. Initial analyses support earlier research showing a less dense large fish population in the main Hawaiian Islands compared to the Northwestern Hawaiian Islands. Significant correlation was found between overall biomass of large reef fishes and average depth, slope, and rugosity along each transect. These results provide the scientific basis for efficient and targeted habitat-based management strategies for large reef fish, begin to define essential fish habitat for these species, and lay the foundation for similar investigations across the wider Pacific Region.

## 22-12

**Historical Photos Document Changing Reef Fish Communities**

**Loren MCCLENACHAN*[1]**

[1]Scripps Institution of Oceanography, La Jolla, CA

The importance of historical data in marine management has been demonstrated, particularly for species whose populations were reduced significantly prior to the onset of ecological data collection. Coral reef fisheries are frequently small-scale and affected by overfishing over long time periods, so that data on long-term trends are lacking. Photographs from historical archives contain information on the species composition and size structure of landings before fisheries or ecological data are available. Using photographic data from the recreational fishing industry in the Florida Keys, I quantified changes in size structure of large reef fish over the past half century (1956-2007). This extensive data set provides temporal trends in the community composition of exploited reef fish and offers baseline information on natural abundance and body size. The average size of individual trophy fish declined from 91.7 cm (SE 2.4) to 42 cm (SE 1.2) and from 19.9 kg (SE 1.5) to 3.8 kg (SE 0.3) between 1956 and 2007. The size of sharks, the largest fish targeted, dropped from 204 cm in 1956 to 87 cm in 2007. Shifts in the species and size of individuals caught demonstrate a loss of the largest predators from the reef environment. The goliath grouper (Epinephelus itajara), with an average size of 135.3 cm (SE 3.2), was the most commonly caught trophy fish in the 1950s, but was rare by 1965. The largest fish frequently caught by recreational fisheries in 2007 were snappers (Lutjanus spp. and Ocyurus chrysurus), with an average size of just 34.4 cm (SE 2.4). This remnant fishery based on increasingly small individuals underscores the depletion of reef fish communities, and the overall degradation of Florida's coral reef ecosystem. The results of this study illustrate the need to consider long term data in assessing the conservation status of exploited animals.

## 22-13

**An Appraisal of Marine Resource Use in the Far North of Madagascar: Challenges and Opportunities for Marine Conservation in Antsiranana**

**Rachel LENANE*[1]**

[1]Centre for the Environment, The University of Oxford, Epsom, United Kingdom

Design of marine conservation plans can be informed using contextual socio-economic information to develop conservation strategies that integrate sustainable livelihoods (Wilkinson *et al*., 2004; Malleret-King *et al*., 2006; Richardson *et al*., 2006).

In Northern Antsiranana, Madagascar, knowledge and beliefs were collected during interviews with 207 informants over an eight week period. Within this region marine resources represent a primary source of livelihood for the population and Protected Areas (PAs) are expanding rapidly under national legislation. By creating a narrative of local people's perceptions and use of the marine environment using qualitative methods possible conservation management strategies are identified.

In Antsiranana the marine resource trade involves numerous stakeholders operating at various spatial scales; subsistence fishermen to international holothurian exporters.

High levels of artisanal fishing provides subsistence for rural communities. Holothurian collecting is also an important activity in this region often providing households with their only source of cash income. Informants identify damaging methods of resource extraction and declining fish and holothurian populations. Knowledge of government regulations is limited and the problem is further exacerbated by low levels of formal education.

Varying types of exploitation need to be identified prior to implementing management plans as each will have specific environmental and economic impacts. Thus a stratified management plan is required to protect both livelihoods of coastal inhabitants and marine ecosystems.

Management strategies explored rely upon a combination of limits on area, time, gear and size, rather than strict PAs. It is thought that the dispersal of larval fish and holothurians, and increased pressure on surrounding marine ecosystems by displaced fishers, will have negligible effects on the benefits of PAs.

Using data from this study, in conjunction with previous ecological surveys, it might be possible to initiate an integrated, context specific approach to managing these marine ecosystems of exceptional but declining biodiversity.

## 22-14

**Observations Of Antillean Fish Trap Contents in Southwest Puerto Rico: Ways To Reduce Coral Reef Habitat Damage And Improve Catch Quality**

**Anthony MARSHAK*[1]**, Ronald HILL[2], Peter SHERIDAN[3], Richard APPELDOORN[4]

[1]Deparment of Marine Sciences, University of Puerto Rico, Mayaguez, Puerto Rico, [2]NOAA Fisheries, Southeast Fisheries Science Center, Galveston Laboratory, Galveston, TX, [3]NOAA Fisheries, Southeast Fisheries Science Center, Panama City Laboratory, Panama City, FL, [4]Department of Marine Sciences, University of Puerto Rico, Mayaguez, Puerto Rico

Abstract: The shelf-wide distribution of Antillean fish traps has been monitored in southwest Puerto Rico since 2002 to evaluate the benthic impacts of trap fishing within coralline habitats. Of 1438 traps documented in surface surveys to date, 161, stratified by habitat, were assessed by divers to quantify damage and record trap contents. Observed traps were predominantly arrowhead-style traps with 5-cm hexagonal vinyl-coated mesh composed either of wood or rebar frames. Most traps inspected were found within colonized hardbottom habitats dominated by soft corals at intermediate depths (12-18 m), although traps were also surveyed in high relief reef, algal flat, seagrass beds, and sediment (sand or mud) habitats. Fishes composed 78% of the total individuals caught, of which butterflyfishes, grunts, surgeonfishes, trunkfishes, and parrotfishes were most abundant. The Caribbean spiny lobster, *Panulirus argus*, was the most frequently trapped species across all habitats. Traps set in colonized hardbottom areas of moderate to high relief contained the highest numbers of observed organisms. Traps set in high relief reef habitat caught higher numbers of less valuable herbivorous fishes, with *Chaetodon capistratus* and *C. striatus* being the most numerically dominant species. Trap contents observed within less structured habitat types, such as algal flats and mud, consisted mostly of trunkfishes and grunts. Within these habitats, *P. argus* was the most frequently observed species. Due to coincident presence of spiny lobster, and a higher percentage of commercially valuable fish species, the results suggest that fishers could improve economic efficiency by fishing traps only in areas of lower structural complexity, while lessening potential for gear damage to more complex coralline habitat types.

## 22-15

**Parrotfish Densities Across A Fishing Intensity Gradient in The Caribbean**

**Denise DEBROT*[1]**, J. Howard CHOAT[2], Juan M. POSADA[3], D. Ross ROBERTSON[4]

[1]Dpto. Biología de Organismos, Universidad Simón Bolívar, Caracas, Venezuela, [2]James Cook University, Townsville, Australia, [3]Dpto, Biología de Organismos, Universidad Simón Bolívar, Caracas, Venezuela, [4]Smithsonian Tropical Research Institute, Panamá, Panama

Parrotfishes (Scaridae) are important components of subsistence and commercial reef fisheries throughout the Caribbean, most notably at locations were predators (e.g. groupers, snapper) have been intensively fished. Here, we compare the abundance of scarids at seven localities across a latitudinal gradient in the Caribbean (from west to east, Belize, San Blas, Curacao, Bonaire, Las Aves, Los Roques and Barbados) with differing fishing intensities for parrotfishes. At each locality we surveyed at least five sites separated by kilometers, and across different reef habitats. To estimate densities, counts were made for all species of scarids along 30 x 10 m belt transects, and along 400 x 15 m transects for the large bodied scarids. Los Roques, a National Park offshore Venezuela were fishing is restricted, supports the highest densities of the large-bodied scarids *Scarus guacamaia*, *S. coelestinus* and *S. coreuleus*. At the neighboring Las Aves, an area heavily fished for predators, but with little fishing directed to scarids, densities were also high for *S. coelestinus* and *S. coreuleus*. Bonaire, a well protected reserve, supported the highest densities of the excavating scarid *Sparisoma viride* and the large grazing scarid *Scarus vetula*. In contrast, the densities of the large bodied parrotfishes at moderate to intensively fished sites (San Blas, Belize, Barbados and Curacao) were up to 10-fold lower than at Los Roques, and were absent from all sites at Barbados. Our results suggest that parrotfish may be vulnerable to intensive fishing, and thus highlight the importance of fisheries management for the protection of reef fishes.

## 22-16

**The Effects Of Fishing And Harmful Algal Blooms On Sponge Ecology in The Florida Keys Usa**

**Donald BEHRINGER*[1]**, Mark BUTLER IV[2]

[1]Department of Fisheries and Aquatic Sciences, University of Florida, Gainesville, FL, [2]Department of Biological Sciences, Old Dominion University, Norfolk, VA

Sponges are a prominent component of coral reefs and, along with octocorals, they dominate the biota of shallow hard-bottom habitat in the Florida Keys (Florida, USA) marine ecosystem. Yet, remarkably little is known about the ecology of the large sponge species that dwell in hard-bottom or the structure, ecological function, or resilience of hard-bottom communities. Our poor understanding of these communities has been highlighted in recent years by questions about the possible impacts of ecosystem perturbations and resource exploitation on hard-bottom habitat. For example, hard-bottom communities in Florida have been subject to recurring algae blooms which can cause massive sponge die-offs; the most recent occurring in 2007. Furthermore, there are concerns about the possible ecological impacts of commercial sponge fishing on hard-bottom community structure and function. In the case of sponges, resolution of these issues has been hampered because there is no stock assessment, the most basic population dynamics for the pertinent sponge species are largely unknown, and the effect of the fishery on commercial sponges and allied species have never been studied. We conducted a series of studies to better understand: (a) the basic population dynamics of commercial sponges, (b) the impact of the sponge fishery on sponge communities, and (c) the effect of a cyanobacteria bloom in 2007 on sponge and octocorals abundance and diversity. This presentation will highlight the key findings of each of these studies, which suggest that sponge communities are robust to current rates of commercial sponge exploitation but are rapidly decimated by the cyanobacteria blooms that continue to plague Florida Bay.

## 22-17

**Managing Fishing Gear To Encourage Ecosystem-Based Management Of Coral Reefs Fisheries**

**Tim MCCLANAHAN*[1]**, Josh CINNER[2], Joseph MAINA[3], Carlos RUIZ SEBASTIAN[4], Shaun WILSON[5], Nick GRAHAM[5]

[1]Marine Programs, Wildlife Conservation Society, Mombasa, Kenya, [2]Marine Biology, James Cook University, Townsville, Australia, [3]CRCP, Mombasa, Kenya, [4]CRCP, Durban, Australia, [5]Marine Science, University of Newcastle, Newcastle, United Kingdom

We present data from two poor tropical countries, Papua New Guinea and Kenya, and show that there is a unique and consistent partitioning of the capture of species and functional groups by gear that can be used to potentially influence ecological processes and biodiversity on coral reefs that can also respond to disturbances such as coral bleaching. Hook and line capture a higher proportion of top carnivores/piscivores and target species with low susceptibility to coral bleaching. Traps and spear guns capture mostly herbivores/ominvores and target the highest proportion and number of fish species that are moderately susceptible to the impacts of coral bleaching. Nets mainly target carnivores/invertivores. The use of specific gear can be actively managed to encourage the recovery of select functional groups and adaptively managed under conditions such as high erect algae cover, sea urchin dominance, low coral cover, and coral bleaching. We present a simulation and conceptual model that examines projected effects of the gear and effort on the yields and ecological processes in the coral reef ecosystem and suggest mechanism for how this model might be practically implemented.

## 22-18

**Evaluation Of Alternative Management Strategies For The Eastern Torres Strait Reef Line Fishery**

**Ashley WILLIAMS*[1]**, Rich LITTLE[2], Gavin BEGG[3]

[1]Fishing and Fisheries Research Centre, School of Earth & Environmental Sciences, James Cook University, Townsville, Australia, [2]Marine and Atmospheric Research, CSIRO, Hobart, Australia, [3]Australian Fisheries Management Authority, Canberra, Australia

Commercial harvest of coral reef fish in the eastern Torres Strait (ETS), Australia is shared between Torres Strait Islanders and non-indigenous fishers, but to date no formal assessment of the fishery has been done, and no resource allocation or management strategies directed at the special circumstances in the Torres Strait currently exist. Here, we evaluate the strengths and weaknesses of a range of alternative management strategies related to the harvest and conservation of coral trout (*Plectropomus leopardus*), the primary target species in the ETS Reef Line Fishery (RLF). We worked with Islander and non-indigenous commercial fishers and fisheries managers to identify specific stakeholder objectives and feasible alternative management strategies to pursue them. We used a meta-population and harvest simulation model (ELFSim) to assess the combined effects of four regimes of effort control, three minimum legal size regimes and two area and two seasonal closure regimes on the status of coral trout, and compared their likelihoods of meeting conservation and fishery objectives. Results of simulations indicated that a two-month seasonal closure was a good measure for addressing conservation objectives, but tended to reduce the ability to satisfy fishery objectives. Similarly, closing areas to fishing and increasing the minimum legal size were generally good strategies for conservation objectives, but performed poorly for fishery objectives. Lowering effort was the more robust strategy for achieving both conservation and fishery objectives. This research provides a framework for the impartial evaluation of the performance of alternative management options to meet diverse and often competing objectives of stakeholders in the ETS RLF.

## 22-19

**The Status Of The Artisanal Seine Net Fishery in Rodrigues Over A 5-Year Period**

**Emily HARDMAN*[1]**, Alasdair EDWARDS[2], Jovani RAFFIN[1]

[1]Shoals Rodrigues, Rodrigues, Mauritius, [2]Division of Biology, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom

The seine net fishery is of great socio-economic importance to Rodrigues, with landings making a significant contribution to the total catch (42% of lagoon fish catches). Fishing activities however, appear to be impacting on fish stocks and catches have declined significantly between 1994 and 1997. An assessment of the status of the fishery commenced in 2002 and 5 years of data have now been obtained. Working in collaboration with 4 fishing teams during the seine net open season, the total length of each individual caught was determined. Over the 5-year period a total of 68,013 fish were measured. The data show that the Catch per Unit Effort and mean monthly earnings per fisher have declined significantly during this 5 year period. Although the fishery is highly multi-species with 122 species recorded, 80% of the fish landed were from 10 species, most of which are herbivores or small invertebrate feeders. The most important species during all years was the Rabbitfish, *Siganus sutor*. There has however been a change in species composition of the catch over the 5 year period with species such as *Naso unicornis* decreasing in abundance, whereas small species such as *Acanthurus triostegus* and *Gerres longirostris* increased in importance. The modal length of *S. sutor, Lethrinus nebulosus* and *Caranx melampygus* has decreased between 2002 and 2006 and over 60% of fish were caught before they reached maturity. The data indicate that the fishery has become dominated by small, herbivorous fish and that serious recruitment overfishing is occurring for some species. As a result, 4 marine reserves have now been proclaimed in Rodrigues in order to allow fish stocks to recover and to promote sustainability of fisheries in the Rodrigues lagoon.

## 22-20

**Coral Reef Fisheries For The Future? Know The Historic Baseline**

**Dirk ZELLER*[1]**, Shawn BOOTH[1], Roxanne DICKINSON[2], Lou FROTTÉ[3]

[1]Fisheries Centre, University of British Columbia, Vancouver, BC, Canada, [2]Stanford University, Stanford, CA, [3]Insitut National Polytechnique de Toulouse, Castanet, France

Small-scale fisheries in the tropical Pacific are important culturally and for food security, yet remain extensively under-reported in national statistics which inform global data presented by the Food and Agriculture Organization of the United Nations (FAO). This contributes substantially to the undervaluation of their importance to communities, both socio-politically as well as economically. We present historic baseline catch reconstructions for the 1950-2004 period for 20 small island countries in the tropical Pacific. The reconstruction approach develops estimates of likely total catch using all available information sources, including grey literature and localised case-studies, combined with conservative assumptions, expansions and interpolations. The reconstruction suggests that unreported catches over this time period were at least equal to reported catches, but range as high as a 17-fold discrepancy. Important also is that for several countries the time series reverses from an increasing to a declining trend over time. This is likely due to localised overfishing, as well as changing consumption patterns in an era of generally high population growth rates and increasing population centralization. The discrepancy in national and hence FAO statistics is primarily driven by consistent under-representation of non-commercial (subsistence) catches in most of the island countries. While reliable yearly estimates are expensive and difficult to obtain, and are the prime reason for incomplete catch accounting by many counties, the fundamental importance of these catches to food security, especially under increasing climate change stresses cannot be underestimated. Regular, albeit non-annual, country-wide estimates of total catches should be undertaken as a priority activity by all countries, interpolated for intervening years, and included in national data reported to FAO. Due to financial and human resource limitations, such work should be facilitated or undertaken by regional agencies, e.g., the Secretariat of the Pacific Community (SPC).

## 22-21

**Applying An Optimal Resource Space Concept To Small Scale Reef Fisheries Management**

**Lydia TEH*[1]**, Louise TEH[1]

[1]Fisheries Centre, University of British Columbia, Vancouver, BC, Canada

Fishers operate according to an optimal resource space whose boundaries are defined by economic profitability, technological sophistication, and socio-cultural preferences. These 'invisible' boundaries can affect fishers' willingness to comply with, and ability to adapt to spatial restrictions. Better understanding of the factors that shape optimal resource spaces can thus lead to management decisions that are more aligned with fishers' perspectives and have a higher likelihood of being complied with and adopted. We investigate the coral reef fisheries of Pulau Banggi, Sabah, Malaysia, where a marine protected area is proposed. Our objectives are i) map fishers' optimal resource space; ii) explain ecological, socio-cultural, and economic factors that influence fishers' optimal resource space; and iii) apply optimal resource space concept to spatial management of small scale reef fisheries. We use data from fish catch logbooks to track the fishing activities of 21 fishers. We conducted semi-structured interviews with fishers to explore factors that dictate their resource use space, including market forces, fishers' motivations and perceived constraints. We find that fishers function within an optimal resource space that is delineated by socio-cultural factors such as family ties, and distance from resident village. Even though fishers are aware of locations where they perceive more fish can be caught, they rarely fish those places. While Banggi fishers face invisible boundaries that restrict them to habituated fishing grounds, outsider fishers do not face such restrictions and are not prevented from exploiting Banggi's open access fisheries. The optimal resource space concept can be applied towards analyzing user conflict, compliance, and equity issues. In the context of marine protected areas, it can help in designing spatial management strategies that are socially acceptable and ecologically sustainable to fisheries and fishing communities.

## 22-22

**Improving Management Of Coral Reef Fisheries in Data Limited Situations: Experiences From The Parfish Methodology**

**Robert WAKEFORD*[1]**, Suzannah WALMSLEY[2], Robert TRUMBLE[1], Paul MEDLEY[3]

[1]MRAG Americas, Inc., Saint Petersburg, FL, [2]MRAG Ltd., London, United Kingdom, [3]Independent Consultant, Alne, United Kingdom

Coral reef fisheries are complex systems. This is due primarily to the multi-species, multi-gear and high labour mobility that often occurs within the fisheries sector. Since many small-scale fisheries operate in remote areas and/ or in developing coastal states, the quality and quantity of data necessary to undertake basic fisheries management, including robust stock assessments, are often lacking. However, it is becoming more widely acknowledged that local stakeholder participation is an essential pre-requisite to improve overall management of the resource, but this has rarely engaged them directly within a stock assessment framework to provide information on the status of the resource. This study presents a summary and comparison of three pilot studies undertaken in Turks and Caicos, Tanzania and Puerto Rico that have been used to demonstrate a new fisheries management tool that enables stakeholders to participate directly in the stock assessment process. Through the development of a participatory fish stock assessment (ParFish) methodology, fishers are engaged at the beginning of the management process to contribute their valuable knowledge about the fishery. Using a Bayesian statistical model, information obtained from fishers help inform prior statistical distributions that are used to estimate parameters in the stock assessment model. The results have shown that this approach can be used successfully to establish preliminary estimates of stock status in data limited situations.

## 22-23

**Effectiveness Of Minimum Legal Size As A Fisheries Management Tool in A Multi-Sectoral Reef Fishery**

**Sara BUSILACCHI*[1,2]**, Gavin BEGG[3], Ashley WILLIAMS[2]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [2]Fishing and Fisheries Centre, School of Earth and Environmental Science, James Cook University, Townsville, Australia, [3]Australian Fisheries Management Authority, Canberra, Australia

Minimum legal size (MLS) is one of the oldest and most widely accepted management tools in fisheries and is usually based on the mean length at which 50% of a population become mature. The effectiveness of a MLS depends on a range of factors including the biology of the species, fishing behaviour, fishing gear, post-release survival, other management arrangements and compliance. In this presentation we assess the effectiveness of MLS's when applied to manage two of three sectors in a multi-sectoral fishery. The reef finfish fishery in Torres Strait, Australia, is shared among three sectors: an indigenous subsistence sector and two commercial sectors (an indigenous and a non-indigenous). In an effort to retain its cultural value, the subsistence sector is currently not regulated. However, the two commercial sectors are managed by numerous regulations including a MLS for the commercially important species. It is normal practice within indigenous communities for subsistence fishing to occur during commercial fishing trips, even though this is inconsistent with legislation. Subsistence catch taken during commercial fishing trips was monitored between May 2005 and May 2006 using an access point survey in three Torres Strait communities. We estimated that, on average, 22% of the total catch taken during commercial trips is used for subsistence. Coral trouts (*Plectropomus* spp.), carangids and snappers (*Lutjanus* spp.) were the most retained species for subsistence and were also the most commercially important. Results showed that, for some of these species, undersize fish (less than the MLS) represented 80% of the subsistence catch taken during commercial fishing trips. We conclude that the effectiveness of this management tool relies on the understanding of its rationale and its acceptance by indigenous communities.

## 22-24

**Bias Of Cpue Revealed By Considering Fisheries As Predator Prey Systems**

**Meaghan C. DARCY*[1]**, Steven JD MARTELL[2]

[1]Zoology / Fisheries Center, University of British Columbia, Vancouver, BC, Canada, [2]Fisheries Center, University of British Columbia, Vancouver, BC, Canada

The Hawaiian bottomfish fishery is a multi-species fishery, where the target species (mainly eteline snappers and one grouper species) are associated with deep reef structures and are caught using handlines. This fishery exemplifies many reef associated, multi-species fisheries, where the fishing gear simultaneously captures multiple species. Assessment of status for each species is based on effort-aggregated commercial catch statistics and single-species assessment models. Aggregation of these data assumes that the capture probabilities and targeting of each species are constant over time and those species-specific catches per unit effort (CPUE) indices are proportional to abundance. Using single-species assessment models with effort-aggregated data may be problematic because the assumption of proportionality is likely to be violated due to changes in targeting and or changes in species composition and changes in fishing technologies.

To account for species composition effects in the multi-species fisheries, we develop an effort dynamics sub-model that partitions the total effort into components of handling time and time spent searching (i.e., Holling's Disc equation). It explicitly allows for handling time influences and the differences in catchability among target and non-target species. We tested this approach using stochastic simulation-estimation experiments, where the dynamics of individual fish populations that make up a multi-species fishery and typical fisheries dependent data (i.e., species specific catch data and aggregate effort data). Simulation results demonstrate that increased handling time leads to a hyperstable index of abundance (i.e., catchability declines less rapidly than biomass) which would lead to overestimates of abundance in the classic single-species assessments. Ignoring handling time effects for fisheries such as, handline fisheries, where a large component of effort includes gear set-up and retrieval and removal of catch from the gear, results in biased abundance estimates.

## 22-25

**Estimating Harvest Pressure On Bahamian Coral Reefs Through Seafood Consumption**

**Liana TALAUE-MCMANUS*[1]**, Joy HAZELL[2]

[1]Marine Affairs and Policy, University of Miami Rosenstiel School of Marine & Atmospheric Science, Miami, FL, [2]Florida Sea Grant Lee County Extension, University of Florida, Fort Myers, FL

We designed a seafood consumption survey to compare harvest pressure estimates derived from coral reef fisheries monitoring in the Bahamas. Specifically, we estimated the fishing pressure on four major marine food resources via consumption estimates and a review of trade statistics. In addition, we disaggregated domestic consumption into urban and rural resident and tourist populations. Our sample included 221 urban respondents, 351 rural residents, and 351 tourists.

For the period of study from 2003 to 2004, we estimated annual consumption for four species: conch (Strombus gigas) consumption reached 4200 mt; grouper complex, 7910 mt; spiny lobster (Panulirus argus), 4580 mt; and snapper complex at 3200 mt. Tourists consumed 17% of conch available in the Bahamas; 14% of grouper; 12% of lobster, and only 4% of snapper. Mean weekly consumption by tourists was almost twice that of resident populations for conch and grouper, although the standard deviations were sufficiently wide to make the differences statistically insignificant. Of the four major seafood items, the spiny lobster posted the greatest trade pressure with about 69% of total catch exported to foreign markets and 31%, domestically consumed. The fisheries monitoring system in the Bahamas did not document 86% of estimated total conch catch based on consumption and trade statistics. The same holds true for 94% of grouper catch, 39% for lobster and 77% for snapper. In the absence of a proper fisheries monitoring program, a food consumption survey for residents may be implemented annually. For tourists, exit surveys can include queries on food consumption.

For species-specific seafood, consumption estimates provide a realistic complement to traditional fisheries monitoring. For multi-species seafood like groupers and snappers, a population-level monitoring using fisheries-based methods remains critical for management.

## 22-26

**Flawed Data, Reef Fisheries, And Food Security: A Close Inspection Of Marine Fisheries Catches in Mozambique, Tanzania, Fiji, And The Solomon Islands**

**Jennifer JACQUET*[1]**, Dirk ZELLER[1]

[1]Fisheries Centre, University of British Columbia, Vancouver, BC, Canada

Good management decisions often require good data. We present a simple taxonomy for fisheries catch data that can be used as a "smell-test" when considering data quality and level of reporting. When it comes to reporting, underreporting of fisheries catches is the likeliest outcome, which inevitably leads to misallocations of fisheries resources. We demonstrate underreporting of fisheries catches has occurred in four countries where local people rely heavily on coral reef fisheries for food security: Mozambique, Tanzania, Fiji, and the Solomon Islands. We present the results of catch reconstructions for these countries for the time span of FAO reporting (1950 to the present) and, in some cases, new estimates of per capita fish consumption. Reconstructed marine fisheries catches for Mozambique, for instance, are 6.2 times greater than those reported by FAO based on country reports and countrywide per capita fish consumption is estimated to be 9 kg per capita, three times what had been previously calculated based on reported data. In Tanzania, reconstructed catches now include the reef fisheries of Zanzibar and the result is that catches are 1.7 times greater than FAO reports. Finally, we discuss the policy implications of newly reconstructed reef fisheries catches, make recommendations on how to improve reporting for each country, and suggest alternatives to FAO datasets.

## 22-27

**No-Take Areas, Uncertainty And Coral Reef Fisheries Management**

**Richard APPELDOORN*[1]**, Susan SINGH-RENTON[2], Mauro GONGORA[3]

[1]Department of Marine Sciences, University of Puerto Rico, Mayaguez, Puerto Rico, [2]Caribbean Regional Fisheries Mechanism, Kingstown, Saint Vincent and The Grenadines, [3]Capture Fisheries Unit, Belize Fisheries Department, Belize City, Belize

No-take reserves are advocated as a core strategy for resource management. Within coral reef fisheries, much debate has centered on the roll of enhancing catch through individual movement from protected to unprotected areas (spillover). This debate largely ignors other critical roles reserves may play within a management context, such as maintaining spawning stock and providing control areas to assess fishing impacts. These roles directly relate to countering the degree of uncertainty traditionally characterizing data poor coral reef fisheries. This is illustrated with a recent assessment in Belize of queen conch, a commercially important gastropod inhabiting sea grass, sand and hardbottom habitats of Caribbean reef ecosystems. Visual census and landings data show the back reef conch population and fishery consist overwhelmingly of juveniles. With intense fishing having been maintained for many years, the alternative hypotheses were either that the fishery was severely recruitment overfished and near collapse, or that recruitment was sustained by an unknown spawning stock. In Belize, use of scuba for fishing is banned, effectively creating a no-take area in the deep waters in front of the Belizean barrier reef. Deep water surveys of density and size-structure found adult conch to be abundant at all stations, that these lived longer than those found in shallow areas, and that much of these conch resulted from direct settlement and not migration from shallow areas. Monitoring in small shallow reserves extending into backreef areas was sufficient to demonstrate sustained recruitment over years, much higher densities of juveniles and adults, and suggested significant spillover into fished areas. No-take areas were thus critical for maintaining the Belizean fishery in the face of intense fishing by maintaining a deep-water spawning population, and demonstrating the validity of this interpretation to management agencies.

## 22-28

**Determining The Appropriate Size Of Closed Areas For Protecting Spawning Aggregations Of Large Groupers Using Hydro-Acoustics**

**Richard S. NEMETH*[1]**, Elizabeth KADISON[1], Jeremiah BLONDEAU[1]

[1]Center for Marine and Environmental Studies, University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.)

Many species of tropical groupers (Serranidae) form annual spawning aggregations at predictable times and locations. This makes them extremely vulnerable to over-fishing which has lead to the extirpation of many spawning aggregations world-wide. Because a single spawning aggregation may represent the entire breeding potential of a local population, each one must be carefully protected. Seasonal or permanent fishery area closures can provide effective protection, but unfortunately the placement of closure boundaries is often disputed by fishermen because boundaries are not based on biologically relevant data. In most cases relatively little is known about the area occupied or the movement and migration patterns associated with spawning. The aim of this study was to determine the spatial and temporal pattern of movement and migration associated with spawning aggregations of Nassau (*Epinephelus striatus*) and yellowfin (*Mycteroperca venenosa*) grouper within the Grammanik Bank (GB), a small (1.5 $km^2$) seasonal closure on the southern shelf edge of the US Virgin Islands. Five male and 5 female groupers of each species were acoustically tagged and released on the aggregation site. An array of 17 acoustic receivers were placed in an overlapping curtain around the GB closure and east and west along the shelf edge, and could detect fish transmitters within a 400m radius. Both species commonly moved 1 to 3 km in a few hours and could cover 20 km in a 24 hr period. Movements of tagged groupers at the spawning site carried them across the GB closure boundaries and exposed them to fishing mortality on a daily basis. Moreover a consistently used migratory pathway was also detected between the GB and another large marine protected area (MCD) 3 km west. These results indicate that the GB boundaries should be increased to at least 10 $km^2$ and include the area between the GB and MCD.

## 22-29

**Alternance Of Opening And Closing Times To Fishing Of A No-Take Zone in Martinique (Lesser Antilles)**

**Géraldine CRIQUET*[1]**

[1]EPHE, Perpignan, France

Due to littoral ecosystems degradation and overfishing, a decrease of stocks of coastal species occurred in Martinique in the last decades. In order to block this process, several No-Take Zones (NTZs), managed by the Regional Council of Fishery, have been implemented. The particularity of these NTZs is the possibility of opening for a period goes from four to six months. The objective of the study is to assess the impact of this alternance of opening and closing periods on the reef fish community of a Caribbean cost area, Ilet à Ramier. Experimental fishing with Antillean traps were done simultaneously in the NTZ and in the adjacent non protected area (NPA) during a closing then an opening period. Total catches in the NTZ decrease of an half while those of surrounding area stay equal. But both in opening and closing period, total catches in NTZ are higher than in NPA. During the closing period, biomass of Acanthuridae, Scaridae and Lutjanidae are higher in the NTZ, biomass of Serranidae are equal both in NTZ and in NTA; and Haemulidae are more present in NTA. During the opening period, patterns are the same except for Serranidae witch biomass is higher outside the NTZ. But, while the families' biomass in the NPA stays equal we observe a decrease of Acanthuridae and overall Scaridae biomass in the NTZ. So what will be the long-term impacts of several opening periods on the reef fish community and the artisanal fishery operating on the area?

## 22-30

**Are No-Take Marine Reserves Helping To Sustain Fish Stocks? Tracking Larval Dispersal And Connectivity Of Fish Populations Within The Great Barrier Reef Marine Park.**

**David WILLIAMSON*[1,2]**, Richard EVANS[1,2], Geoff JONES[1,2], Garry RUSS[1,2], Simon THORROLD[3]

[1]School of Marine & Tropical Biology, James Cook University, Townsville, Australia, [2]Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [3]Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA

No-take marine reserves have generally been established with the primary goal of protecting or restoring natural states of biodiversity and ecosystem productivity. It has been widely demonstrated that given time and adequate protection, no-take reserves can produce clear benefits for exploited species within reserve boundaries. Higher abundances of target fish species, with larger average sizes, ages and higher potential reproductive output are commonly demonstrated effects of reserve protection. In recent years there has been increasing interest in the potential contribution of no-take reserve networks to the sustainability of fisheries resources. Increased egg production per unit area of reef, means that reserves may potentially operate as sources of fish larvae. Larvae which are dispersed to surrounding open reefs may provide a recruitment subsidy to exploited fish stocks. Limited empirical data on larval dispersal distances, scales of population connectivity and export effects of no-take marine reserves remains an impediment to expansion of marine reserve networks. Furthermore, the optimal location, size and spacing of no-take reserves within networks cannot be accurately defined in the absence of such data.

Here we outline experimental trials of a new technique which utilises enriched stable isotopes to provide maternally transmitted markers from female fish to their offspring. These trials have demonstrated that the technique is effective and safe for use on large commercially important reef fishes and that treated fish present no consumption risk for humans. We also provide an overview of a research project utilising these trans-generational markers to track the dispersal of larvae of two recreationally and commercially important fish species from no-take marine reserves in the Great Barrier Reef Marine Park.

## 22-31

**Temporal Effects Of Marine Reserves On Target Fishery Species On Near-Shore Reefs Of The Great Barrier Reef, Australia**

**Richard EVANS*[1]**, David WILLIAMSON[1], Garry RUSS[1]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia

The Great Barrier Reef Marine Park was established in 1975 to enable the management of the world's largest network of coral reefs. Access to the reef is limited by boat size and weather conditions. The Great Barrier Reef (GBR) is routinely referred to as one of the best managed coral reef systems. However, the GBR still faces similar issues to the rest of the world, i.e. nutrient run-off, coral bleaching, tourism, and exploitation. To manage these impacts in a large area, a multiple-use zoning plan was fully implemented in 1988. In 2004, the new Representative Areas Program was implemented to protect biodiversity, which increased the protected areas from 4.5% to 33.4% of the entire Great Barrier Reef Marine Park. Since 1998, underwater visual surveys were conducted around three near-shore continental island groups over 600km apart. These easily accessible reefs are heavily used by recreational fishers and not commercial fishers. This study demonstrates greater density and biomass in no-take marine reserves consistently over at least 5 years for two target species, *Plectropomus* spp. (coral trout) and *Lutjanus carpnotatus* (Snapper). Thus showing that recreational fisheries can impact on fish stocks as much as commercial and/or subsistence fisheries. Furthermore, with the implementation of the Representative Area Program, our research group designed a BACI sampling experiment to test the effect of the new zoning plan on the target fishery species. Recent results from this study demonstrate rapid increases in density and biomass for both species (*Plectropomus* spp. and *L. carponotatus*) by at least 50% within two years. This presentation also investigates temporal trends of the broader fish community and the benthos in relation to no-take marine reserve protection.

## 22-32

**Science to Support Coral Reef Fisheries Management: Lessons from the U.S. Coral Reef Conservation Program**

**Thomas HOURIGAN*[1]**, James BOHNSACK[2], Robert SCHROEDER[3]

[1]Office of Habitat Conservation, NOAA National Marine Fisheries Service, Silver Spring, MD, [2]Southeast Fisheries Science Center, NOAA/National Marine Fisheries Service, Miami, FL, [3]Pacific Islands Fisheries Science Center, NOAA/National Marine Fisheries Service, Honolulu, HI

The United States National Oceanic and Atmospheric Administration's Coral Reef Conservation Program supports effective management and sound science to preserve, sustain, and restore valuable coral reef ecosystems. Fisheries on U.S. reefs face many of the same challenges as those elsewhere, and addressing the adverse impacts of fishing on reef ecosystems has been a major area of focus over the program's first seven years. Integrated habitat mapping, monitoring, and targeted ecological research in both the Atlantic and Pacific are providing new insights and improved fishery management tools.

1) Habitat-stratified monitoring of reef fishes has enhanced survey precision, provided insights in how fishes use different habitats, and allowed fishery independent stock assessments of both targeted and non-targeted species.

2) New techniques allow researchers to identify nursery grounds of fish and track ontogenetic movements to the reef.

3) Broad-scale geographic surveys across gradients of fishing effort indicate that even low levels of exploitation can fundamentally alter biomass of exploited species and trophic relationships in ecosystems.

4) Hydroacoustic surveys are revealing spawning aggregation sites that can be linked with protection.

5) Monitoring of marine reserves has confirmed their efficacy in increasing the size and number of previously exploited species within reserve boundaries.

Examples of where these research results are being applied to U.S. reef fisheries management and challenges for future research will be presented.

## 22-33

**Are The Coral Reef Finfish Fisheries Of South Florida Sustainable?**

**Jerald S. AULT*[1]**, Steven G. SMITH[1], James T. TILMANT[2]

[1]Marine Biology and Fisheries, University of Miami, Rosenstiel School of Marine and Atmospheric Sciences, Miami, FL, [2]Water Resources Division, National Park Service, Fort Collins, CO

If healthy reefs are Florida's future, exploitation of reef fish stocks must be reduced. Numerous sustainability indicators revealed that most of Florida's reef fish species are seriously overfished, assuming they are functioning as a unit stock. Annual growth in recreational fishing effort compounds this problem. We used fish population abundance and size structure data from fishery-independent (reef fish visual census) and fishery-dependent (creel surveys) monitoring programs from the Florida Keys and Biscayne National Park to estimate stock mortality rates and current reproductive potentials of the seven most commonly harvested reef fish species. We found that the majority of species in the snapper-grouper complex for which exploitation parameter estimates could be made are below the 30% Spawning Potential Ratio (SPR) federal standard for stock sustainability. Once stock exploitation status was determined, alternative fishery management actions that could possibly reduce fishing mortality and increase reproduction potential sufficiently to achieve sustainable stock conditions were evaluated. Results indicated that, when using only traditional management approaches, such as increased minimum harvest sizes or decreased bag limits, rather radical changes will be needed to achieve sustainable stock conditions for most species, and any improvements may be negated by a continued increase in fishing effort in a relatively short period of time. We conclude that non-traditional fishery management actions, such as limited entry or permanent removal of a portion of the stock from exploitation will likely be needed to achieve long-term sustainability of Florida's coral reef finfish fisheries into the future.

## 22-34

**The Relevance of Traditional Ecological Knowledge for Modern Management of Coral Reef Fisheries in the South Pacific**

**Marc LÉOPOLD*[1]**, Jean-Brice HERRENSCHMIDT[1], Randy THAMAN[2]

[1]IRD (Insitut de recherche pour le developpement), Noumea, New Caledonia, [2]USP (University of the South Pacific), Suva, Fiji

Traditional ecological knowledge (TEK) has received great attention in coral reef associated fisheries as a way to adapt modern management strategies to local environmental conditions. This specialized knowledge refers to group identity, techniques and skills which have been accumulated through generations, and improved by individual experiences. We analysed the socio-cultural role of TEK for resource management in traditional Melanesian communities in New Caledonia. A multidisciplinary survey of Ouvea customary marine tenure and fishing regulations was realized in 2006. Main chiefdoms and clans were questioned about past and present fishing activities, maritime territory rights, taboo areas and toponyms, customary authorities, socio-cultural practises and belief related to marine resources, and vernacular knowledge on marine organisms. Aerial photographs helped to collect spatial information (fishing grounds, chiefdoms boundaries…). Fishing customary rules (marine reserves, collective fishing of schooling species and access rights to well localized reef and mangrove areas) were primarily related to cultural events and social organization. Subsistence and commercial fishing co-occurs in this socio-cultural context. The relationships between TEK, population needs and uses of the environment were still tight but have changed since 1850s. Unquantifiable loss of indigenous knowledge has occurred. Nowadays, to fill the needs, modern users shunt this TEK and behave in relation to their own perceptions. Our results suggest that Ouvea customary management system is now socially rather than ecologically driven. Better consideration of socio-cultural aspects in resource conservation issues may therefore indirectly help to increase awareness on resource depletion and biodiversity loss. This emphasizes the need to enhance the socio-cultural role of TEK in South Pacific islands to achieve ecosystem sustainability.

## 22-35

**A Method For Assessing The Catch Sustainability Of Ornamental Fish Bycatch, With An Emphasis On Families Pomacanthidae And Chaetodontidae**

**Caroline FEITOSA*[1]**, Maria Elizabeth ARAÚJO[1], Beatrice FERREIRA[1]

[1]Federal University of Pernambuco, Recife, Brazil

The global effects of reef fish captured as bycatch – including ornamental species – are poorly known. Most fishes captured for the aquarium trade in Brazil belong to the Pomacanthidae and Chaetodontidae families. This study aimed to record the occurrence of bycatch ornamental fishes in trap fisheries and to assess the susceptibility and recovery of some fishes from the aquarium trade's major families. Each species was assessed according to two groups of criteria: (1) their relative vulnerability to capture by traps and (2) their population's relative recovery capacity related to sustaining mortality due to fishing. Within each group, each species was ranked (1-3) based on individual criteria representing distribution, catchability, diet, reproductive biology, removal rate for the aquarium trade, and mortality. These criteria were then weighted according to their importance and each species' mean weighted ranks for the two groups of criteria were plotted. Nineteen ornamental fish species from 14 genera and 10 families were recorded. The order of the species least likely to be sustainable was *Holacanthus tricolor*, *H. ciliaris*, *Chaetodon striatus*, and *Pomacanthus paru.* These benthic species that inhabit coral reefs are highly susceptible to capture by traps. *C. striatus* and *P. paru* were the most likely to be sustainable, although highly susceptible to capture. Although somewhat subjective, this approach is very promising for data-poor situations and may be the only one available for researchers and managers of diverse fisheries like the Brazilian trap fisheries, which occur in areas of high species richness such as coral reefs.

## 22-36

**Ornamental Fisheries As An Option To Commercial Fisheries: Would Fishermen Make The Switch?**

**Antares RAMOS-ALVAREZ*[1]**

[1]Zoology, University of Oxford, Oxford, United Kingdom

The aquarium trade in Puerto Rico is an area where many factors remain unstudied. Public policy has been implemented without taking into consideration the carrying capacity of the ecosystem or the species and with even less understanding of the users needs. Changes in fishing quotas and fishing permits were made without proper consultation or warning, making it hard for fishermen to assimilate. Past studies have found that fish are being extracted safely below the quota, when the opposite was thought. With increasing *vedas* (closed seasons) on key commercial species and SCUBA diving becoming a popular fishing method among young fishermen, ornamental fisheries might be an obvious option for these fishermen. In this study we interviewed a total of 51 fishermen, including ornamental and commercial, to further understand their needs and perceptions on fisheries, using semi-structured interviewing methods. Commercial fishermen were asked about their knowledge in the aquarium trade and they were asked if they saw it as a possible income option in the time of the *vedas.* The results present mixed views regarding the switch to ornamental fisheries (even a seasonal switch) due to the high price of the fishing permit for this type of commerce. Commercial fishermen that fish using SCUBA perceive ornamental fishing as a possible income option. This research brings light into the management of these resources as well as a possible need to change policy. Further research is suggested to look into the life histories of the key ornamental species so that more complete and specific management plans and changes in policy are made.

## 22-37

**Pacific-Wide Reduction Of Reef Fish Biomass Near Human Population Centers**

**Robert SCHROEDER*[1]**, Benjamin RICHARDS[1], Marc NADON[1], Brian ZGLICZYNSKI[2], Russell BRAINARD[2]

[1]Coral Reef Ecosystem Division, JIMAR-University of Hawaii and NOAA-Pacific Islands Fisheries Science Center, Honolulu, HI, [2]Coral Reef Ecosystem Division, NOAA-National Marine Fisheries Service, Pacific Islands Fisheries Science Center, Honolulu, HI

Reef fishes comprise the most important renewable resource sought on Pacific coral reefs. Healthy reef fish assemblages are essential for maintaining ecosystem integrity that supports sustainable reef fisheries. Many of these resource species are particularly vulnerable to overfishing, especially targeted large/predatory species, with negative ecosystem consequences. Biennial assessments of coral reef fish assemblages were conducted around 50 U.S. Pacific Islands (from Guam to Hawaii to Samoa) from 2002 to 2007 using two complementary visual-census methods: (belt-transect [all fish] and towed-diver survey [large fish]). At the island level, regression analysis showed a strong trend of decreasing total fish biomass density with increasing human population (~proxy for fishing pressure). Highest total fish biomass density (>6.4 t/ha) was found at uninhabited Jarvis Island in the U.S. Line Islands and lowest (<0.2 t/ha) at Oahu, Hawaii (population ~900,000). The two survey methods showed generally similar trends. Apex predators were most abundant at uninhabited and/or remote islands, and lowest near human population centers. Overall, the remote, nearly pristine equatorial U.S. Line Islands (Jarvis, Kingman, Palmyra), U.S. Phoenix Islands (Howland, Baker), and Wake Atoll supported the highest fish biomass density, followed by the Northwestern Hawaiian Islands, and then by the remote northern islands of the Marianas Archipelago and atolls of American Samoa (Rose and Swains). Islands near major population centers had the lowest fish biomass density (e.g., the heavily exploited main Hawaiian Islands, the southern Mariana Islands, and the populated American Samoa Islands [Tutuila and Manua group]). This study is the first comprehensive, long-term, Pacific-wide assessment of coral reef fish assemblages using the same methodologies by the same group of researchers. Such ocean-wide comparisons of near-pristine islands to populated islands are valuable for providing the scientific basis for management options and affording managers an incentive to act.

## 22-38

**Spatio-Temporal Patterns Of Abundance, Size Frequency Distribution And Biomass Of Groupers in The Philippines**

**Samuel MAMAUAG*[1]**, Cleto NAÑOLA, JR. [2], Porfirio ALIÑO[1], Melchor DEOCADEZ[1]

[1]Marine Science Institute, University of the Philippines, Quezon City, Philippines, [2]University of the Philippines-Mindanao, Davao City, Philippines

Groupers are apex predators on coral reefs that have slow growth, long life span and with low rates of natural mortality and recruitment. High exploitation levels on reefs in the Philippines may result in over-fished grouper stocks. Using fish visual census, spatio-temporal patterns of abundance, size frequency distribution and biomass of groupers were determined for six local biogeographic areas in the Philippines including sites with Marine Protected Area (MPA). Species assessed included *Plectropomus leopardus*, *Cephalopolis cynostigma*, *C. boenak*, *C. argus*, *C. urodeta*, *Epinephelus fasciatus* and *E. coioides*, among others. Composition of groupers varied among biogeographic regions with South China Sea and Sulu Sea showing greater number of species. Sulu Sea which includes Tubbataha reefs, the largest MPA in the Philippines, had the highest total biomass and also showed more larger groupers compared to others. *P. leopardus* showed the lowest abundance while *C. urodeta* and *C. argus* were the highest. These suggest that the larger *P. leopardus* have already been extirpated in many areas with some sites (e.g. Bolinao in Lingayen Gulf) having no records of size reaching sexual maturity (>30 cm TL). The level of regulation of fishing pressure suggests that *C. urodeta* and *C. argus* can attain larger sizes in the MPAs such as those in Tubbataha. Aside from fishing pressure, other patterns of distribution were confounded by the habitat preferences of the species (e.g. *C. boenak*, *E. fasciatus* and *E. coioides*) that showed some association with distinct habitat types, depth, and their biogeographic location range. These findings suggest that bigger MPAs need to be established for critical life history stages such as spawning aggregation sites since there are still records of moderate to high abundance despite the high fishing pressure.

## 22-39

**Red Hind (*epinephelus Guttatus*) Spawning Aggregations in The U.s. Virgin Islands: Movement And Migratory Patterns**

**Elizabeth KADISON*[1]**, Richard NEMETH[1], Jeremiah BLONDEAU[1]

[1]Center for Marine and Environmental Studies, University of the Virgin Islands, St. Thomas, Virgin Islands (U.S.)

Spawning aggregations of commercial reef fish are extremely vulnerable to over fishing and have been decimated in tropical systems throughout the world. Seasonal and permanent fishery area closures are effective for protecting spawning aggregations however adequate size and placement of closures is dependent on accurate knowledge of the location of the aggregation site as well as movement patterns of fishes immediately before, after and during spawning. The Marine Conservation District (MCD) is a 41 km2 reserve on the Puerto Rican shelf edge that has been closed for ten years to all bottom fishing. Red hind (*Epinephelus guttatus*) spawn annually in the eastern quarter of the reserve in numbers estimated to be greater than 80,000 over a 0.35 km2 area. Tag returns of fish tagged on the spawning site indicate that red hind move west and northwest to home ranges outside of the protected area when spawning ends. The aim of this study was to determine migration routes to the aggregation site as well as movement patterns of fish while on the site between spawning events. Hydro-acoustic transmitters were inserted into red hind of both sexes caught in the aggregation area over two spawning seasons. Receivers were deployed in curtain arrays around the site and along the shelf-edge of the insular platform to detect tagged fish up to 300m away. Little significant daily movement was detected while fish were on the aggregation site over the two month spawning period indicating that the MCD was adequate in size and location to protect fish during this time. Overall spatial and temporal movement patterns were differential between sexes, however specific migratory routes were identified. These followed particular habitat types and could serve as predictors for migratory patterns of red hind in similar aggregations, influencing decisions for other marine reserve boundaries.

## 22-40

**Effects Of MPA Status On The Population Structure And Age-Based Demography Of A Heavily Exploited Reef Fish, *Lethrinus Harak***

**Brett TAYLOR*[1]**

[1]Marine Laboratory, University of Guam, Hagatna, Guam

Marine protected areas (MPAs) have been considered the most practical fishery management option for small island nations where imposing size/effort restrictions on fisherman is problematic. The success of this management option in facilitating recovery of heavily fished stocks has been well documented with numerous examples of increased abundance and biomass of target species within well protected areas. However, the success of MPA implementation in preserving exploited fish stocks for the longer-term can only be evaluated through the collection of more detailed information such as demographic parameters and accurate abundance estimates. In this study I compared total abundance, growth, age, length frequency, mortality and biomass of *Lethrinus harak* between two marine preserves and two fished sites on the pacific island territory of Guam. This fish is among the most important food fishes on Guam and is heavily exploited in both the commercial and recreational inshore fisheries. Given that landed biomass of *L.harak* has decreased significantly in the past decades despite increases in fishing intensity, I set out to test whether (1) there were significant differences in the population parameters I measured and (2) whether these results were correlated with the degree of protection from fishing. Abundance data collected by visual census, using an optimized sampling design stratified by habitat, has revealed a clear ontogenetic shift in habitat preference at all sites. Juveniles are restricted to seagrass areas while adults occupy numerous backreef habitats. For one MPA-nonMPA pair, density was greater in the fished site due to a greater abundance of juveniles, while overall biomass and spawner biomass were 4 and 142 times greater in the MPA, respectively. As habitat preferences differ among the life stages of *L.harak*, those MPAs on Guam which contain little or no juvenile habitat play a greater role in protecting older individuals with a higher reproductive potential.

## 22-41

**Using Length-Frequency Data To Identify Management Options: A Case-Study Based On Five Years Monitoring Of The Large Seine Net Fishery Of Rodrigues Island, Indian Ocean**

**Alasdair EDWARDS*[1]**, Emily HARDMAN[2], Jovani RAFFIN[2]

[1]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]Shoals Rodrigues, Pointe Monier, Mauritius

The large seine-net fishery in the 240 km² shallow lagoon of Rodrigues Island is of great socio-economic importance in terms of both protein and employment. Seine net fishing is undertaken by teams of 15 and 30 fishers, using four to eight boats. Annual landings from the fishery of 190 to 300 tonnes have been recorded since 2000. Working with local fishing cooperatives, the NGO Shoals Rodrigues has monitored the seine catch since 2002, recording the species and total length of each fish caught during 125 sampled fishing days. A total of over 68,000 fish in 110 species have been sampled with data on each individual entered on a specially designed database to facilitate analysis. The fishery is diverse and the most commonly caught species include *Siganus sutor, Valamugil seheli, Naso unicornis, Acanthurus triostegus, Lethrinus nebulosus, Mulloidichthys flavolineatus, Caranx melampygus* and *Gerres longirostris*.

Analysis of the length-frequency distributions for the primary species in the catch suggests that several of the main species caught are being severely overexploited but that others are being exploited sustainably at close to optimal levels of effort. The overexploited species tend to be those that are deeper bodied (e.g. *Siganus sutor*) and thus caught at a younger age, whereas the sustainably exploited species tend to be those that are shallow-bodied (e.g. goatfish and mullet) and thus caught much later in life.

A surplus yield model based on government fisheries statistics suggests that the fishery may be at a sustainable level overall. However, the length-frequency data shows that several species are heavily overexploited. Data on length at first capture shows that an increase in mesh size is unlikely to be practical. A network of marine reserves and an MPA are being implemented in an effort to ensure sustainability in the face of excess fishing pressure.

## 22-43

**Patterns in A Catch-And-Release Sport Fishery Targeting A Pristine Stock Of Caranx Ignobilis At Midway Atoll**

**Raymond BOLAND*[1]**, Frank PARRISH[1]

[1]NMFS/NOAA, Pacific Islands Fisheries Science Center, Honolulu, HI

From 1996 to 2001, a catch-and-release charter fishery was conducted in waters of the U.S. Fish and Wildlife Service Wildlife Refuge at Midway Atoll in the Northwestern Hawaiian Islands. In the history of the coral atoll, this was the first and only organized fishing directed at giant trevally (*Caranx ignobilis*) and it caught a total of 751 fish. Fishing logs indicated an overall trend of increased fishing effort throughout the 6-year period. Catch per unit of effort (CPUE) derived as catch per day, per trip, per boat hour, and per hook-hour declined between one-half and one-third of initial levels, then increased from 1999 to 2001. The increase of CPUE during the later part of the study corresponded to wider spatial distribution of the fishing effort throughout the atoll. In 1998 the U.S. Fish and Wildlife Service implemented a tagging study at Midway Atoll, tagging 356 *C. ignobilis* of which 24 were recaptured, 4 more than once. Time periods at liberty for the fish ranged from 0 to 389 days and movement was seen across the atoll. Recapture data for fish tagged at Midway and at neighboring atolls showed no movement of jacks between atolls. Treating the adult jacks at Midway Atoll as a closed population and assuming a constant capture probability, the number of resident jacks was estimated at 2590 (± 793 SE). The data from Midway indicates catch and release fishing has a measurable effect on the atoll's jack assemblages. It is not known whether the decline is a result of post release mortality from capture events; or the result of experienced jacks avoiding fishers.

## 22-44

**Behavioral Effects Of Fishing On Coral Reefs**

**Elizabeth MADIN*[1,2]**, Steven GAINES[3,4], Robert WARNER[1,2]

[1]Dept. of Ecology, Evolution, and Marine Biology, University of California - Santa Barbara, Santa Barbara, CA, [2]Marine Science Institute, University of California - Santa Barbara, Santa Barbara, [3]Marine Science Institute, University of California - Santa Barbara, Santa Barbara, CA, [4]Dept. of Ecology, Evolution, and Marine Biology, University of California - Santa Barbara, Santa Barbara

The community-level consequences of predator removal, and indeed the mechanisms behind them, are poorly understood in coral reef systems. However, the majority of coral reefs globally experience some degree of fishing pressure, much of which is focused on predatory fishes. To date, most research on this topic has been focused on changes in the density of prey species as the principal mechanism causing the effects of fishing to cascade through coral reef communities. However, an entirely different pathway exists by which fishing, and therefore predator removal, could fundamentally alter marine ecosystems: changes in the behavior of prey species. The Line Islands represent a gradient in human influence that ranges from nearly pristine coral reefs to ones with key upper trophic levels functionally removed. We used this system to ask whether prey fishes behave differently over a gradient of fishing intensity and thus predator biomass. We quantified behaviors of a suite of prey fishes spanning different functional groups, focusing on behaviors that are subject to a risk-reward trade-off and play a potentially important role in mediating benthic community structure. We found that these prey fishes exhibit demonstrable shifts in behavior over the gradient of predator biomass. In particular, time spent foraging versus sheltering and patterns of movement over feeding areas appear to be constrained by the level of predation risk imposed by predators. Our findings demonstrate that fishing on coral reefs may strongly affect prey species' behavior, and further suggest that these behavioral responses may have important implications for benthic community structure in ways not predicted from traditional density-mediated trophic cascade models.

## 22-45

**Reproduction, Habitat Utilization, And Movements Of Hogfish (*lachnolaimus Maximus*) in The Florida Keys: A Comparison From Fished Versus Unfished Habitats**

**Roldan MUNOZ*[1]**, Michael BURTON[1], Kenneth BRENNAN[1], R. O. PARKER, JR. [1]

[1]National Marine Fisheries Service, National Oceanic and Atmospheric Administration, Beaufort, NC

Few studies conducted within reserves have examined the reproductive behavior of exploited reef fishes. We tested the hypothesis that reproductive output should be greater in a marine reserve (i.e., greater density and sizes of inhabitants) relative to a fished area. Our study took place in the Florida Keys National Marine Sanctuary in the Western Sambos Ecological Reserve (closed to fishing) and the Middle Sambos (fishing permitted). At these sites we gathered detailed information on microhabitat utilization of hogfish (*Lachnolaimus maximus*), their movements, encounter rates, and their reproductive behavior. Most of the data were collected with focal animal observations and the behavioral data geographically logged with a hand-held GPS. Multivariate analyses of microhabitats present on home ranges and utilized by hogfish indicate no overall differences between study sites, yet hogfish movements were greater at the fished site. Furthermore, despite a greater survey effort at the fished study site, no reproductive activity was seen there. In marked contrast, spawning was readily observed at the reserve site where 55 spawns were recorded from 6 different harems. Encounters with the potential to be inherently disruptive (i.e., male-male) tended to occur at a higher rate at the fished site. Conversely, encounters capable of stabilizing social groups (i.e., male-female) tended to occur at a higher rate in the reserve. These data suggest a breakdown of social structure at the fished site and highlight the role that marine reserves may play in the maintenance of reproductive output by site-attached fishes, particularly those with complex social and mating systems that experience intense fishing pressure; the easily-speared *L. maximus*, characterized by harem territories and female-to-male sex change, is a good example of such a species.

## 22-46

**Population Genetic Structure Of A Coral Reef Ecosystem Apex Predator, The Gray Reef Shark (Carcharhinus Amblyrhynchos)**

**Rebekah HORN*[1]**, William ROBBINS[2], Douglas MCCAULEY[3], Philip LOBEL[4], Mahmood SHIVJI[1]

[1]National Coral Reef Institute, Nova Southeastern University, Dania Beach, FL, [2]Cronulla Fisheries Research Centre, NSW Department of Primary Industries, Cronulla, Bangladesh, [3]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [4]Biology Department, Boston University, Boston, United States Minor Outlying Islands

Sharks play a major functional role as apex predators in coral reef ecosystems, raising concerns that their ongoing overexploitation will compromise the integrity and sustainability of reefs. The gray reef shark (*Carcharhinus amblyrhynchos*) is a strongly coral reef associated species whose populations are known to have declined substantially in some regions. There is no information on population structure in this species to aid in their management and conservation. We are assessing genetic structure in this species by using entire mitochondrial control region sequences and 15 nuclear microsatellite loci as markers. 93 gray reef shark samples were obtained from across the species' Indo-Pacific distribution (eastern Indian Ocean [Madagascar/Seychelles], Central Pacific [Hawaii], Southwestern Pacific (eastern Australia, Palmyra, Palau, Cocos (Keeling) Islands]). Mitochondrial (AMOVA) and microsatellite (STRUCTURE) data concordantly identify the Hawaii population as a distinct genetic group relative to other sampling locations. The microsatellite data further identify 3 distinct overall gray reef shark groups (eastern Indian Ocean, Central Pacific, and Southwestern Pacific). Our current analyses do not show any evidence of population structure among islands of the Southwestern Pacific, although this question is being further addressed with additional samples from more locations. These results show strong genetic differentiation exists in gray reef shark populations separated by expanses of open ocean, and suggest proper management of this declining species will have to occur at the very least on a regional geographic scale.

## 22-47

**Population Genetic Structure Of The Parrotfish Scarus Ghobban in The Western Indian Ocean And Its Implication For Fish Stock Management**

**Oskar HENRIKSSON*[1]**, Shakil VISRAM[2], Ruby MOOTHIEN PILLAY[3], Sadri SAID[4], Mats GRAHN[1]

[1]School of life science, Sodertorns university college, Huddinge, Sweden, [2]CORDIO East Africa, Mombasa, Kenya, [3]Mauritius Oceanography Institute, Quatre Bornes, Mauritius, [4]Institute of Marine Sciences, University of Dar es Salaam, Zanzibar, Tanzania

Much is unknown about the population structure of fish in the Western Indian Ocean (WIO). The knowledge of the genetic structure of a population is essential for the optimal designation of fish stocks this knowledge is important for sustainable management. Most fish stocks are today defined and managed by countries and not geographical regions. However, fish populations do not adhere to political boundaries, hence neither should the management of fish stocks. This study aims to investigate the genetic structure and connectivity of Scarus ghobban which is important for subsistence fishing in the WIO. Little research has so far been conducted on S. ghobban, and for this reason not much is known of its potential for migration and the genetic connectivity between different regions. The spatial genetic variation at 16 locations has been examined: 3 sites on Mauritius, 5 sites in Tanzania and 8 sites in Kenya. Levels of population differentiation were investigated using the DNA fingerprinting method Amplified Fragment Length Polymorphisms (AFLP). Results indicate the presence of several genetically differentiated subpopulations of S. ghobban, which might need to be managed separately. The implication of this data is that the current scale of management in the region is too local. Today the foremost management regime is mainly through beach management units which operate on a scale far smaller than the size of the potential fish stocks.

## 22-48

**Central Pacific Survey Reveals Lower Reef Shark Density Near Human Population Centers**

**Marc NADON*[1]**, Benjamin RICHARD[1], Brian ZGLICZYNSKI[2], Robert SCHROEDER[1], Russell BRAINARD[2]

[1]CRED, JIMAR-NOAA-PIFSC, Honolulu, HI, [2]CRED, NOAA-PIFSC, Honolulu, HI

Biennial surveys (2000-2007) of coral-reef shark populations were conducted around 50 U.S. Pacific Islands in several regions: the Hawaiian Archipelago, the Marianas Archipelago, the Line Islands, the Phoenix Islands, and the American Samoa Archipelago. Two fisheries-independent census methods were implemented by divers: stationary point counts and towed-diver surveys. Five species of sharks were recorded in sufficient frequency to allow meaningful statistical analyses: grey reef shark (*Carcharhinus amblyrhynchos*), galapagos shark (*Carcharhinus galapagensis*), whitetip reef shark (*Triaenodon obesus*), blacktip reef shark (*Carcharhinus melanopterus*), and tawny nurse shark (*Nebrius ferrugineus*). Preliminary analyses showed a highly significant negative relationship between grey reef and galapagos shark densities and proximity to human population centers (e.g., proxy for potential fishing pressure and other human impacts). Average combined numerical density for these two species near population centers was less than 1% of densities recorded at the most isolated islands (e.g., no human population, very low present or historical fishing pressure or other human activity). Even around islands with no human habitation but within reach of populated areas, gray reef and galapagos shark densities were only between 15 and 40% of the population densities around the most isolated near-pristine reefs. Trends in whitetip and blacktip reef shark numbers were similar, but less dramatic. Tawny nurse shark densities were low around most islands. This study is the first fisheries-independent large-scale survey of shark populations in the central Pacific. From our preliminary results we infer that some shark populations near human population centers are severely depleted.

## 22-49

**From Depensation To Compensation: Processes That Drive The Recovery Of A Depleted Population**

**Robert GLAZER*[1]**, Gabriel DELGADO[1], Lonny ANDERSON[2], David HAWTOF[3], Paul KUBILIS[4]

[1]Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission, Marathon, FL, [2]Keys Marine Laboratory, Florida Fish and Wildlife Conservation Commission, Layton, FL, [3]Florida Fish and Wildlife Conservation Commission, Marathon, FL, [4]Program for Environmental Statistics, University of Florida, Gainseville, FL

The recovery of a depleted population depends to a great extent on the interactions between life history strategies and ecological processes. Using data from a 10-year study, we show the processes that affected how a population of queen conch (Strombus gigas) recovered in the Florida Keys archipelago. We describe the progression of the recovery from its initial stages where it was at critically low densities and was dominated by depensatory processes resulting in limited reproductive encounters. As the population density increased, the proportion of the population engaged in reproductive encounters also increased; however, the area occupied by the population remained relatively constant. In 1999, when the maximum density was achieved (approximately 1,100 conch per ha), compensatory processes predominated and the area occupied by the population expanded rapidly with a concurrent and significant shift of the population into less-favorable habitat. These processes help to explain recovery of depleted or endangered species and may provide guidance to managers on how best to design protected areas.

## 22-50

**Changes in Ecosystem Structure Induce Trade-Offs in Storage And Reproduction Across Fishes From Multiple Trophic Levels**

**Sheila WALSH*[1]**, Benjamin RUTTENBURG[1,2], Scott HAMILTON[3], Mary DONOVAN[3], Stuart SANDIN[1]

[1]Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, [2]Marine Science Institute, University of California, Santa Barbara, Santa Barbara, [3]Marine Science Institute, University of California, Santa Barbara, Santa Barbara, CA

Ecosystem structures characterized by different predation, competition, and resource regimes may select for specific energy allocation strategies at the organismal level. Shifts in energy allocation between somatic storage and reproduction may ultimately have consequences that scale back up to the ecosystem level. We tested the effect of changes in ecosystem structure on total weight, liver weight, and gonad weight for five species of fish, each representing a different trophic level. We collected fishes from a cross-island and a within-island gradient of predator biomass to control for biogeographic and regional-scale oceanographic effects. The gradients also represent gradients in resource availability. Fish weight at length decreased with increasing predator biomass for all species except the top predator. The effect was increasing with decreasing trophic level, suggesting that lower trophic level species were also affected by decreasing resource availability. Liver weight at weight of unreproductive fishes showed a similar pattern to total weight. Gonad weight at weight, however, showed differences in the direction of the effect across trophic levels. Gonad weight decreased for higher trophic level fishes but increased for lower trophic level fishes. The difference in the effect on reproductive allocations may be due to the compounded effects of increased mortality and decreased resource availability. The trend of decreasing weight at length with decreasing fishing pressure, a proxy for predator biomass, was found to be general when our data were compared to published data from other regions. Our results indicate a community-wide response in energy allocation to changes in ecosystem structure. Ecosystems dominated by predators and coral may actually increase fish community productivity by inducing shifts in energy allocation away from storage and toward reproduction. However, the net effect will depend on the relative contribution of and interactions between somatic and population growth.

## 23-1

**Conservation Of Coral Reefs By The Global Network Of Marine Protected Areas**

**Camilo MORA*[1]**

[1]Dalhousie University, Halifax, Canada

Marine Protected Areas (MPAs) are being used as a primary solution to the worldwide decline of coral reefs, but there is no global summary of their performance. In this project, I carried out a global survey to assess the regulations of MPAs and their enforcement and compliance and used existing databases to assess their levels of risk from human threats. I found that whilst 18% of the world's coral reefs are covered by MPAs, only ~2% is in areas of adequate conservation status, and less than 0.01% in areas of excellent status. Troublingly, a threefold increase in the number of existing MPAs is estimated to be necessary for the protection of ecological processes that maintain the high diversity of coral reefs. The inefficiency and insufficiency of existing MPAs in protecting coral reefs globally highlights the current vulnerability of this ecosystem and the need for an urgent reassessment of global-scale conservation strategies, if the worldwide decline of coral reefs is to be reduced.

## 23-2

**Mohéli Marine Park, Comoros – Successes And Challenges Of The Co-Management Approach**

Melissa HAUZER[1], **Chris POONIAN*[2]**, Cheikh MOUSSA IBOURA[3]

[1]C3-Comores, Iconi, Comoros, [2]Community Centred Conservation (C3), London, United Kingdom, [3]Mohéi Marine Park, Moheli, Comoros

Mohéli Marine Park (Parc Marin de Mohéli, PMM) was the first Marine Protected Area (MPA) to be established in the Comoros in 2001. Initially regarded as a model for co-management of marine resources, PMM is now operating at a vastly reduced capacity following an end to external funding sources. An assessment of current perceptions of local stakeholders of PMM was recognized as an essential first step in rebuilding its capacity and effectiveness as an MPA. This study aimed to ascertain stakeholders' current perceptions of PMM, using focus group interviews to evaluate six key parameters: (1) basic awareness, (2) value, (3) effectiveness, (4) environmental threats and solutions, (5) stakeholder roles and responsibilities and (6) future aspirations and expectations. It was apparent that most local communities were aware of the importance of PMM, but felt that it had failed to include their needs or consider their input in its management. Concern was expressed for the lack of sustainability or alternative livelihoods; inequitable distribution of benefits; exclusion of women; continuing environmental threats and a concurrent lack of enforcement of regulations. The key recommendations to arise from this work were: (1) ensure sustainability through effective financial planning and promotion of low-cost, appropriate management techniques; (2) mobilize local communities to create a truly co-managed PMM; (3) ensure tangible benefits to local communities through realistic alternative livelihood options, particularly for fishers; (4) ensure equitable sharing of benefits and awareness of PMM, (5) involve women in the management of PMM, they are the primary local educators and motivators for future generations; (6) inform law enforcement officials and members of the justice system to ensure understanding, respect and enforcement of PMM regulations.

## 23-3

**Systematic Marine Conservation Planning Towards A Representative Areas Network in Aceh, Indonesia**

**Yudi HERDIANA*[1]**, Stuart CAMPBELL[1], Andrew BAIRD[2]

[1]Wildlife Conservation Society - Indonesia Marine Program, Bogor, Indonesia, [2]Australian Research Council Centre of Excellence for Coral Reef Studies (ARCCoERS), Townsville, Australia

A turbulent history and geographic isolation have prevented systematic surveys of coral reef resources in Aceh. Following the Indian Ocean tsunami, ecological studies revealed that while most marine habitats where unaffected by the tsunami, many reefs were seriously degraded as a result of decades of destructive fishing and poor coastal development. The recovery of these degraded reefs following dramatics reductions in human activity as a result of the tsunami is remarkable. Ironically, socio-economic recovery in Aceh is re-introducing anthropogenic threats as fishing pressure and coastal development increase. Some conservation initiatives are in progress, however, these also pose a threat because they lack coordination and integration. A systematic marine conservation plan is required to allow natural recovery processes to continue and to protect marine resources from emerging threats. Here we outline an Initiative planning process following the 'Systematic conservation planning' guidelines (Margules and Pressey, 2000) in which the conservation goal was to protect at least 30% of existing coastal ecosystems. Data for the analysis included ecological (e.g. coral substrate, reef fish condition, invertebrate), socio-economic (e.g. fishing pressure) and reef resilience data collected from 64 sites within the province. Spatial information for this analysis (e.g. mangrove habitat, distance to inhabitant) was derived from satellite imagery due to an extended coast line, habitat complexity, variation in accessibility and the number of existing stakeholders throughout the region the optimal approach suggested was the establishment of many small protected areas in a network as opposed to a few large areas. Furthermore, our analysis also suggests that existing MPAs in Aceh do not achieve the target of habitat representation. This work provides a solid basis for the establishment of a network of MPAs to achieve the conservation goals for the region and protect and enhance livelihoods.

## 23-4

**Changes in The Reef Fish Biomass in Karimunjawa National Park: A Test Of The Effectiveness Of Government Gazetted Marine Parks in Indonesia**

**Rizya ARDIWIJAYA*[1]**, Andrew BAIRD[2], Tasrif KARTAWIJAYA[3], Stuart CAMPBELL[3]

[1]Marine Program Indonesia, Wildlife Conservation Society, Bogor, Indonesia, [2]ARC Centre of Excellence Studies - Coral Reef Studies, James Cook University, Townsville, Australia, [3]Wildlife Conservation Society, Bogor, Indonesia

In August 2005 following extensive community consultation, national legislation was enacted that changed the boundaries of zones that regulate fishing and other marine resource use activities in Karimunjawa Marine National Park in the Java Sea, Indonesia. The park included 5 management zones ranging from a no-take area to open access. Here, we report the results of three years of monitoring reef fish assemblages conducted to evaluate the effectiveness of the zoning regime. Fish biomass within the park has decreased by 40% since 2005. This decrease was mostly caused by a reduction in the numbers of large fish and decreases in the abundance of some of the more common family eg. Scaridae. Further analysis by trophic groups indicated that the biomass of carnivores, herbivores and planktivores had all decreased compared to 2005. Missing carnivores included large individuals from targeted families eg. Lutjanidae, Haemulidae, Serranidae and Lethrinidae whose biomass has decreased by 41 % from 2006. Scaridae fishes where the dominant herbivores and their biomass decreased by 35% from 2005. Caesionidae were the most abundant planktivore and their biomass decreased by 57% from 2006. This decrease in the biomass of Scaridae was linked to an increase in fish catch recorded within 2006. While this initial three years of monitoring is not sufficient to be confident of these trends in fish fluctuations, the decrease of several target species is a cause for concern and they should continue to be monitored. Furthermore, many of the declines were evident in all management zones, including the no-take zone, which suggests stronger enforcement and greater engagement with the fishing communities is required to prevent a continued decline in fish stocks within the park.

## 23-5

**Measuring Success in Managing Two Marine Protected Areas: Process, Indicators And Lessons in Palawan Province, Philippines**

Giselle PB SAMONTE-TAN[1], **Michael D PIDO*[2]**, Nadia P ABESAMIS[3], Ma Celeste A PONTILLAS[2], Shellane NAGUIT[3], Romeo B TRONO[3]

[1]Conservation International, Crystal Drive, VA, [2]Palawan State University, Puerto Princesa City, Philippines, [3]Conservation International-Philippines, Quezon City, Philippines

In the tropics, few efforts have been directed at evaluating the effectiveness of marine protected areas (MPAs). Concrete correlations between management actions and desired conservation outcomes are not adequately demonstrated. This paper describes the process, indicators and lessons learned in developing monitoring and evaluation (M&E) programs to assess the effectiveness of management regimes for Tubbataha Reef National Marine Park (TRNMP) and Coron Island Ancestral Domain (CIAD), both situated in Palawan Province, Philippines. The TRNMP (designated as a World Heritage Site in 1993), covers 33,200 hectares of offshore reefs of exceptionally high biodiversity. The CIAD covers 22,284 hectares of ancestral land and waters, whereby the indigenous peoples (Tagbanwa) was awarded a Certificate of Ancestral Domain Title in 1998. The process undertaken to develop the M&E programs included: stakeholder consultations and consensus on biophysical, socioeconomic and governance indicators; creation of an M&E team; data collection; information sharing; capacity building of M&E team; and institutionalization of management structure for implementation. Biophysical indicators measure how much of the marine resources, biological diversity, individual species and habitat is protected; socio-economic indicators largely measure the economic status in terms of household occupational structure; and governance indicators are mostly process indicators. The lessons learned are: active involvement of the local government units is crucial for effective MPA management; capacity building for the management staff and participating agencies is a major bridge for overcoming technical difficulties in undertaking M&E functions; developing partnerships between the local government and the local stakeholders helps in accessing relevant information; and a multi-disciplinary approach, utilizing relevant mix of indicators, provides a more complete assessment for measuring the success of MPAs. This study is an output of Conservation International-Philippines' project on "Development of Management M&E Programs for Two Protected Areas in Palawan" with funding from the United States National Fish and Wildlife Foundation.

## 23-6

**Using Ichthyoplankton Distribution in Selecting Sites For An Mpa Network in The Sulu Sea, Philippines**

Pacifico II BELDIA[1], **Wilfredo CAMPOS*[1]**, Cesar VILLANOY[2], Maritess CANTO[2], Porfirio ALINO[2]

[1]Oceanbio Laboratory - Division of Biological Sciences, University of the Philippines in the Visayas, Miag-ao, Iloilo, Philippines, [2]Marine Science Institute, University of the Philippines Diliman, Quezon City, Philippines

This investigation was conducted to provide data and information needed to establish an ecologically functional network of MPAs in the Sulu Sea Basin, by making use of data on fish larval (ontogenetic) distribution and composition, as well as dispersal modeling in identifying areas with potentially high recruitment (sink) and or areas with high potential as egg and larval sources. Highest egg and larval concentrations were observed in the immediate vicinity of the atolls and reefs along Cagayan Ridge and in embayments along the western border of Sulu Sea (east coast of Palawan) during Summer, suggesting that these areas are major sources of eggs and larvae within the Basin at this time of the year. During the transition to the NE Monsoon (October), highest egg concentrations were observed in the same areas, but larvae were most abundant along a north-south mid-basin transect from Cuyo Is. to Cagayan Ridge. Large-scale circulation patterns show that the atolls and reefs of Cagayan Ridge may be a major source of recruits to coastal habitats along the east coast of Palawan during the Summer. This link may be disrupted during the transition to the NE Monsoon as the prevailing strong northeasterly current isolates Cagayan Ridge from Western Sulu Sea. During this season, the Cuyo Group of Islands appears to be a major source of propagules to the western half of Sulu Sea, while potential exchange within atolls and reefs within Cagayan Ridge is also at its maximum. The ontogenetic distributions of several larval groups, together with dispersal modeling, are further examined to verify the above scenarios.

## 23-7

**Multiple Direct And Indirect Effects Of A Marine Reserve On Caribbean Fish And Benthic Communities**

**Alastair HARBORNE*[1]**, Peter MUMBY[1], Carrie KAPPEL[2,3], Craig DAHLGREN[4], Fiorenza MICHELI[5], Katherine HOLMES[6], James SANCHIRICO[7], Kenneth BROAD[8], Ian ELLIOTT[9], Daniel BRUMBAUGH[6]

[1]School of Biosciences, University of Exeter, Exeter, United Kingdom, [2]National Center for Ecological Analysis and Synthesis, University of California Santa Barbara, Santa Barbara, CA, [3]Hopkins Marine Station, Stanford University, Pacific Grove, [4]Perry Institute for Marine Science, Jupiter, FL, [5]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [6]Center for Biodiversity and Conservation, American Museum of Natural History, New York, NY, [7]Department of Environmental Science and Policy, University of California, Davis, Davis, CA, [8]Rosenstiel School of Marine and Atmospheric Science, Division of Marine Affairs and Policy, University of Miami, Miami, FL, [9]School of Biosciences, University of Exeter, Exeter

Data documenting many of the effects of no-take reserves are surprisingly scarce, and trophic cascades are particularly poorly understood. Here we examine both the direct and indirect effects of the Exuma Cays Land and Sea Park (The Bahamas) by sampling benthic and fish communities inside and outside the reserve, with surveys stratified by habitat ('*Montastraea* reef' and 'gorgonian plain'). To distinguish reserve effects from natural variation, we compared changes inside and outside the reserve with those seen at equivalent spatial scales in other reef systems in the Bahamian archipelago that lack reserves. Reserve-level differences in benthic or fish communities not documented in other reef systems were categorised as 'robust' effects, and were limited to *Montastraea* reefs. The reserve supported an average of ≈15% more fish species per site compared to outside the reserve. Increases in fish biomass and differences in community structure inside the reserve were limited to large-bodied groupers. This increased population of piscivorous large grouper has the potential to reduce the key process of macroalgal grazing by parrotfish prey. However, because large-bodied parrotfishes escape the risk of predation from large piscivores, the negative predation effect was overwhelmed by the positive effects of reduced fishing pressure, resulting in a net doubling of grazing. Increased grazing by parrotfishes in the reserve has lowered macroalgal cover, and caused previously undocumented changes in benthic community structure compared to sites outside the reserve. Furthermore, reduced macroalgal cover has doubled the density of coral recruits. Finally, a higher biomass of urchin predators within the park has reduced populations of the ecologically-important *Diadema antillarum* compared to outside the park. Caribbean marine reserves are a key conservation tool with a range of beneficial effects, but the trophic cascade between urchins and their predators demonstrates the complexities of restoring key processes in disturbed ecosystems.

## 23-8

**Reef Fish Spawning Aggregations Are Vulnerable: The Role Of SCRFA In Promoting Their Conservation And Management**

Patrick COLIN[1], Michael DOMEIER[2], Janet GIBSON[3], Brian LUCKHURST[4], Martin RUSSELL[5], Yvonne SADOVY[6], **Terry DONALDSON*[7]**

[1]Coral Reef Research Foundation, Koror, Palau, [2]Marine Conservation Science Institute, Falbrook, CA, [3]Wildlife Conservation Society, Belize City, Belize, [4]GCFI, Umbria, Italy, [5]Great Barrier Reef Marine Park Authority, Townsville, Australia, [6]University of Hong Kong, Hong Kong, China, People's Republic of, [7]Marine Laboratory, University of Guam, Mangilao, Guam

The Society for the Conservation of Reef Fish Aggregations (SCRFA) was formed to raise awareness of the vulnerability of reef fish spawning aggregations (FSAs) to exploitation and other negative impacts. SCRFA works towards the protection and management of FSAs while promoting a greater understanding of their form and function. SCRFA maintains a data base of known FSAs and reef fish spawning aggregation sites (FSAS); most are not managed yet, while others are afforded some form of protection from the creation and maintenance of marine protected areas, time and season closures, sales bans during spawning seasons, are reductions in effort. These management tools are usually employed singly or, to a lesser extent, in combination. SCRFA has initiated international calls for action at ITMEMS 2 and 3, at the 4th IUCN World Fisheries Congress, and elsewhere to promote conservation awareness and to stimulate the design and implementation of management efforts to achieve conservation goals. SCRFA utilizes two principal methods of surveying FSAs and FSAS towards meeting these goals. Fisher interview surveys gather local knowledge of spawning aggregation location, use, and history. Field surveys, following methods described in the SCRFA Methods Manual, are conducted to verify fisher survey data, characterize FSAS, and describe the current status of FSAs. SCRFA has conducted surveys in Fiji, Indonesia, Micronesia, Palau, Papua New Guinea, Sabah (east Malaysia), and the Solomon Islands. The outcomes of these surveys, coupled with analyses of data in the SCRFA data base, may be used to assist fisheries and conservation agencies and entities in protecting and managing FSAs and FSAS, as well as promote future research into FSA dynamics. These outcomes will be described in greater detail.

## 23-9

**Movement Patterns Of The Highfin Grouper (Epinephelus Maculatus, Serranidae) in A Fragmented Coral Reef Habitat: Implications For The Design Of Marine Reserves**

**Olivier CHATEAU*[1]**, Laurent WANTIEZ[1]

[1]LIVE, University of New Caledonia, Noumea, New Caledonia

Acoustic telemetry was used to examine the movement patterns of 7 Highfin Groupers (*Epinephelus maculatus*, Serranidae) in a fragmented habitat in New Caledonia, over a period of 375 days. The studied area included a marine reserve and two unprotected reefs separated by large areas of lagoon soft bottoms (900 m and 2000 m). The fish were detected between 7 days and 341 days. Only one fish show strong site fidelity within the hydrophone network during the study. The other fish were not detected by the same hydrophone more than 8 consecutives days. Four fish (57%) were exclusively detected on the reef where they were released. Three of them realized large within-reef movements (> 3 km) in spite of their short monitored period (up to 78 days). Three other fish (43%) were detected on a different reef than the reef where they were released. The minimum distance covered during their monitored period (9 days to 341 days) ranged from 11 km to 24 km. Three patterns of between-reef movements were identified for these fish including installation outside the reserve, multiple between-reef movements within the area, and punctual excursions outside the daily home range. The identified patterns of movements suggest the capacity for the studied fish to disperse with time. The within-reef movements confirm that partial reefs closures may not be effective to protect *E. maculatus*. The detected between-reef movements show the ability for *E. maculatus* to carry out medium-scale movements in a fragmented habitat and suggest that the studied reserve do not protect the entire population of this species.

## 23-10

**No-Take Reserves And The Benthic Assemblages Of Florida's Coral Reefs**

**Lauren T. TOTH*[1]**, Richard B. ARONSON[2], S. Robertson SMITH[3], Thaddeus J. T. MURDOCH[4], Staci A. LEWIS[5]

[1]University of South Alabama, Mobile, AL, [2]Dauphin Island Sea Lab, Dauphin Island, AL, [3]Department of Biology, Georgia State University, Atlanta, GA, [4]Bermuda Zoological Society, Flatts FL BX, Bermuda, [5]Environmental Science and Policy Department, George Mason University, Fairfax, VA

Marine protected areas have become common tools for coral reef management. Despite their widespread use, it is unclear whether the affects of protection can be translated to beneficial impacts on the benthic assemblages. The aim of this study was to characterize changes in community structure within the Florida Keys National Marine Sanctuary following the establishment of no-take reserves from 1998 to 2007. Reefs both inside and outside 3 no-take zones were surveyed using underwater video transects. A comparison between No-take and reference sites was used to determine if protection had an effect on benthic composition. A significant overall decrease in coral cover found at all sites and was consistent with trends throughout the Caribbean. The declines were in part due to the losses of the once-abundant population of *Monastrea* spp. There have been other significant changes in species dominance of scleractinian corals, and several species present at the onset of this study are no longer detectable. Despite such marked changes in benthic assemblages, there was no conclusive relationship between these shifts and levels of protection of the reefs. Although there was high cover of macroalgae during several sampling periods, substrate suitable for larval settlement accounted for 27-90% of total cover during the sampling periods. This indicates that despite the effect that no-take reserves may be having on fish populations, the causes of the continuing decline in the health of reefs in the Florida Keys operate at spatial and temporal scales beyond the scope of such protection.

## 23-11

**Scaling Up To Networks Of Marine Protected Areas in The Philippines: Biophysical, Legal, Institutional And Social Considerations**

**Alan WHITE*[1]**, Kem LOWRY[2], Patrick CHRISTIE[3]

[1]Gobal Marine Initiative, The Nature Conservancy, Honolulu, HI, [2]University of Hawaii, Honolulu, HI, [3]School of Marine Affaires, University of Washington, Seattle, WA

Marine protected areas (MPAs) are an accepted means of protecting coral reef and associated habitats and enhancing near-shore fisheries. The growing number of MPAs is stimulating the formation of planned and managed MPA networks. This study documented and learned from the development of MPA networks in the Philippines and identified critical success factors and issues. Methods were field observation by participation in MPA and fisheries management projects and a focused interview protocol that gathered opinions and observations of primary MPA network stakeholders. Findings showed that an MPA network is defined through social and ecological criteria. From a social perspective, a network is comprised of people and organizations that manage component MPAs, benefit from the network, and promote the networks' viability through shared administrative responsibility and information. To qualify ecologically, individual MPAs must interact in an ecologically meaningful manner (e.g., source or sink of larvae and propagating organisms, protection for quality habitat and threatened or endangered species, etc.) that enhance fisheries and biodiversity conservation. Thus, a MPA network is composed of individual MPAs founded on an institutional framework that supports interaction, not just a group of individual MPAs. The study found that while social and ecological criteria are shaping MPA networks through science based planning, integrated management and coordination, there exist numerous issues related to scaling up to networks from single MPAs. Issues pertain to: limiting access to resources, boundary delineation, monitoring compliance, finding common goals and identity, and conflict resolution. Success factors included common institutional processes and legal support, improved understanding of benefits from a network and improved habitat conditions and fishery yields associated with MPAs.

## 23-12

**Finding The Right Fit For Ecosystem-Based Management in The Philippines**

**Rose-Liza OSORIO*[1]**

[1]Coastal Conservation and Education Foundation, Inc., Cebu, Philippines

Spatial scales for ecological marine protected area networks do not necessarily fit into existing governance frameworks in the Philippines. The Philippines adopts a highly decentralized approach to coastal management including marine protected area (MPA) management. Each local government authority exercises management powers and responsibilities over their coastal zone which is measured from the shoreline to 15-km seaward of municipal waters. The local government initiatives have resulted to the establishment of over 300 MPAs in Central Philippines to improve marine habitats and enhance fishery resources, with only 20-30% of MPAs effectively managed with sustainable fishery benefits. With the increasing number of MPAs, the need for joint MPA management efforts in order to increase management effectiveness as well as protect areas beyond MPA boundaries has arisen. Thus, a definitive governance structure has been sought within the fisheries ecosystem scale following the ecosystem-based management approach. This paper will present the management strategies, outcomes and lessons of the Local Governance for Coastal Management Project for the Management of Coral Reefs and Fisheries in the Philippines since January 2002. The project has been working towards scaling-up the geographic scope to achieve the desired results in fisheries ecosystem management by expanding from a municipal up to a much broader collaboration at the inter-local government unit, provincial and regional scale. It focuses on activities that address the needs in institutional building and strengthening, fisheries management, habitat management, foreshore management, and coastal law enforcement.

## 23-13

**Some Hints About The Impacts Of Watershed Management On Mpas in The South Pacific Islands**

Gilbert DAVID[1], **Pascal DUMAS*[2,3]**, Marc DESPINOY[3], Morgan MANGEAS[3], Jean-Brice HERRENSCHMIDT[3]

[1]IRD, St Denis, Reunion, [2]University of New Caledonia, Noumea, New Caledonia, [3]IRD, Noumea, New Caledonia

The high islands of the Pacific are characterised by short and steeply-sloping watersheds, where erosive events can generate large sediment material run-off loads that threaten the adjacent reefs, even when these are protected by a Marine Protected Area (MPA). Because of the increasing population pressure, industry, land clearance and associated new agricultural land and other human activities are growing, thus increasing their negative impacts. To this background, the establishment of MPAs should be accompanied by an integrated management policy.

Besides, in small islands, the reef and most of the watershed are integral parts of the same village or chiefdom territory. In a region where place is the very foundation of identity, a physical bond links people to their territory, i.e. to the space that they have taken ownership of to perpetuate the social group and to satisfy their vital needs. The right spatial unit, in which any integrated watershed /coastal zone management initiative must be implemented, should be first defined.

Our global objective is to foster the emergence of an integrated cross-cutting approach based on public policy tools, monitoring methodology and local-scale stakeholder dynamics. The monitoring statement is based on a scientific foundation and indicators suited to Pacific Island settings coming from remote sensing analysis, environmental risk mapping, territoriality and socio-economic values assessment, watershed dynamics and hydrological modelling, gathered in a unique *Environmental Information System*, a Web interoperable GIS system. All the relationships between those data are then studied in order to achieve modelling and adapted integrated management policy.

## 23-14

**The Need To Use A Large-Scale Ecosystem Based Approach To Improve Future Coral Reef Management**

**Billy CAUSEY*[1]**

[1]National Marine Sanctuary Program, NOAA, Key West, FL

Scientists and managers have recognized the plummeting health of coral reefs in the Wider Caribbean for two decades. Decline in living coral cover and coral recruitment continues to occur both inside intensely managed marine parks and sanctuaries, as well as remote coral reefs. These changes are affecting the diversity and complexity of coral reef biota throughout the region. The primary cause of coral decline remains a topic of scientific debate. While traditional coral reef management practices have had some local successes, local and regional decline of corals continues. Strategies that reduce direct impacts to coral and seagrass beds, such as mooring buoys and boating restrictions, have had positive results. Marine zoning has demonstrated benefits to heavily fished species in some protected areas. Research, monitoring, and education programs have helped managers and stakeholders better understand the complexities of coral reefs and their biological and socioeconomic importance. Yet, coral reefs have continued to decline at all scales due to the impacts of climate change, land-based sources of pollution, habitat destruction and overfishing. Traditionally, coral reef managers have focused management activities within the boundaries of their specific protected areas. However, recent experience has demonstrated that managers need to be effective at broader spatial scales. The future success of coral reef management relies on the utilization of remote sensing technologies applied across broad spatial extents in an ecosystem-based approach. The global impacts of climate change on coral reefs, coupled with regional and local stressors, require managers to consider less traditional strategies to protect and conserve coral reefs. We must work cooperatively and in partnerships across both domestic and international jurisdictional boundaries, using a large-scale ecosystem-based approach to management. Such an approach must consider broad-scale watershed influences, physical and biological connectivity, reef resilience and collaborative interagency and stakeholder relationships to improve ocean governance.

## 23-15

**Defining The Biogeography Of An Endangered Reef Fish Spawning Aggregation To Inform Marine Reserve Planning And Evaluation**

**Brice SEMMENS*[1]**, Phillippe BUSH[2], Scott HEPPELL[3], Christy PATTENGILL-SEMMENS[4], Bradley JOHNSON[5], Croy MCCOY[5], Leslie WHAYLEN[6]

[1]Northwest Fisheries Science Center, NOAA Fisheries, Seattle, WA, [2]Cayman Islands Government, Cayman Islands Department of the Environment, Grand Cayman, Cayman Islands, [3]Oregon State University, Corvallis, OR, [4]Reef Environmental Education Foundation (REEF), Key Largo, FL, [5]Cayman Islands Department of the Environment, Grand Cayman, Cayman Islands, [6]Islamorada, Village of Isands, Islamorada, FL

Protections on spawning aggregations are critical to the long-term sustainability of many marine fishes, particularly groupers and snappers. The two biggest stumbling blocks for effective management of marine fish aggregations are: 1) limited information regarding the spatial and demographic influence of aggregation sites (i.e.- how many fish, where are they from, what is their demographic status?), and 2) limited experiences regarding socio-political methods for implementing conservation strategies. We will present results from an acoustic tagging project in the Cayman Islands explicitly designed to evaluate the recent decision to establish known Nassau grouper (Epinephelus striatus) spawning sites as marine reserves. Our study defines the biogeography of a large spawning aggregation in a group of islands separated by abyssal water, and demonstrates that aggregations can be exclusively and exhaustively representative of local (island-specific) stocks of reproductive-aged fish. Our findings will allow the Cayman Islands government to assess the current and future impacts of protections afforded local spawning aggregations.

## 23-16

**Inferring The Appropriate Spatial Scale Of Design And Management For Mpa Networks: An Interdisciplinary Case Study From The Bahamian Archipelago**

**Daniel BRUMBAUGH*[1,2]**, Kenny BROAD[3], Craig DAHLGREN[4], Alastair HARBORNE[5], Katherine HOLMES[1], Carrie KAPPEL[6], Fiorenza MICHELI[7], Jessica MINNIS[8], Peter MUMBY[5], Claire PARIS[3], James SANCHIRICO[9], Richard STOFFLE[10]

[1]Center for Biodiversity & Conservation, American Museum of Natural History, New York, NY, [2]National MPA Center, NOAA, Santa Cruz, [3]Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [4]Perry Institute for Marine Science, Jupiter, FL, [5]School of Biosciences, University of Exeter, Exeter, United Kingdom, [6]National Center for Ecological Analysis and Synthesis, Santa Barbara, CA, [7]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [8]School of Social Science, College of The Bahamas, Nassau, Bahamas, [9]Department of Environmental Science and Policy, University of California - Davis, Davis, CA, [10]Bureau of Applied Research in Anthropology, University of Arizona, Tucson, CA

Designers of MPA networks, both in theory and in practice, typically use biodiversity representation or population connectivity as criteria for the placement or spacing of individual MPAs. Rarely, however, do researchers or planners integrate inferences from both of these criteria with those derived from the study of various human dimensions. The Bahamas Biocomplexity Project (BBP), a large collaborative project, was initiated to (1) address how networks of ecologically-connected marine protected areas (MPAs) may function across realistic seascapes; and (2) respond to recent management directions in The Bahamas. Drawing on approaches from oceanography, population genetics, ecology, anthropology, and economics, the BBP is integrating theory and data in statistical and computational models about Bahamian coastal dynamics. Major areas of interest include the critical seascape dimensions for conservation planning and the crucial interactions and feedbacks among physical, biological, and social systems that can influence how MPAs and MPA networks function. Across the Bahamian archipelago, several lines of evidence, including variation in species-habitat relationships, simulations of population connectivity, population genetics, and sociopolitical considerations, suggest that primary conservation planning for coral-reef ecosystems should occur at the scale of major islands.

## 23-17

**The U.s. Coral Reef Task Force: A Model For Fostering Coral Reef Management At National To Local Scales**

**Beth DIEVENEY*[1]**, Roger GRIFFIS[2]

[1]National Ocean Service, NOAA, Silver Spring, MD, [2]National Marine Fisheries Service, NOAA, Silver Spring, MD

The purpose of this study was to assess the strengths and challenges of U.S. Coral Reef Task Force (USCRTF) efforts to mobilize U.S. coral reef conservation at local to international levels. The unique success of the USCRTF has been its ability to bring together government entities with diverse mandates to identify national goals and foster work at the local level that addresses both local and national priorities for coral reef conservation. The USCRTF includes 12 U.S. Government agencies, seven states and territories, and three Freely Associated States. This broad membership makes the USCRTF uniquely situated to promote coral reef conservation in a holistic, ecosystem-based approach. The USCRTF developed the first U.S. National Action Plan to Conserve Coral Reefs and the National Coral Reef Action Strategy which both serve to define and direct its overarching goals, objectives, and activities. These national goals were further refined into place-based Local Action Strategies (LAS) to address six priority threats: over-fishing, land-based sources of pollution, recreational overuse and misuse, lack of public awareness, climate change, and coral bleaching/disease. The LAS provide a framework for USCRTF member agencies to identify and address these threats and additional local needs, connect local priorities to national goals, coordinate Federal agency actions with local management of reef resources, and increase collaboration and resources to implement conservation actions. In addition, LAS provide a means to specifically focus on the needs of one region or jurisdiction while also providing a mechanism to apply adaptive management among and between the various regions. The USCRTF has also utilized its diverse membership to promote a broad suite of other management, research, and technical tools to more effectively and collaboratively manage coral reef ecosystems.

## 23-18

**Mesoamerican Marine Protected Area Effects on Resource User Livelihoods**

**Mark ZEGLER*[1]**

[1]Interdepartmental Graduate Program in Marine Science, University of California Santa Barbara, Santa Barbara, CA

This paper analyzes the changes in the livelihoods of local coastal resource users that occurred due to the designation of marine protected areas in Belize and Mexico within the Mesoamerican Barrier Reef Systems (MBRS). These marine protected areas are situated in coastal waters of the Bacalar Chico Marine Reserve and the Parque Nacional Arrecifes de Xcalak in Belize and Mexico respectively and were both established to promote biodiversity conservation and economic development. Fieldwork in 2004-2005 documented the changes that occurred to local livelihoods in the conservation, fishery, and tourism sectors. The modifications to coastal governance regimes changed local livelihoods in each case study area. Implementation of marine protected areas reduced fishery pressure on many commercial fish species, and increased pressure on some species targeted by tourist sport fishing boats. In both cases, some locals benefited as conservation and tourist use expanded, while others lost jobs in the fishery sector. The results of this research indicate that marine protected areas affect livelihoods and shift use from commercial fishing to conservation and tourist use of the reef. Geographic information system analyses of informant map biographies indicate that the spatial patterns of livelihood activities changed within the boundaries of each respective marine protected area. Evidence suggests protected area networks can be effective in promoting societal goals for conservation and development if geographic, institutional, and social factors are included in the design process.

## 23-19

**Coral Cover, Reef Fish Abundance And Revenues Of Gilutongan Marine Sanctuary, Central Philippines From 1998 -2007**

**Pamela Alma AMOLO*[1]**, Rizaller AMOLO[1]

[1]Coastal Conservation and Education Foundation Inc., Cebu City, Philippines

Gilutongan Marine Sanctuary (GMS) is a 15ha marine protected area (MPA) in Central, Philippines. It was established as a means to rehabilitate degraded reef and address dwindling fish catch. Its management has proven to be an effective strategy that has made it an important tourism destination and has generated economic revenues. This study examines the trends of the benthic community and reef fish population from the 10-year biophysical monitoring conducted in GMS from 1998 – 2007. It also compared the tourist arrival and revenue generated by the MPA . Benthic data showed a significant change in live hard coral cover and coral mortality index, both inside and outside the marine sanctuary, after 10 years of protection. A significant difference in fish abundance was observed inside and outside portions of the MPA. Tourist arrival and revenue rapidly increased over the first 3-years of protection and has gradually level-off in recent years. This paper also presents lesson learned in managing MPAs involving community and tourism activities. Some of which includes: management and monitoring of tourism and other potential impacts is a crucial element for MPA sustainability. Also, revenues from MPA should benefit the community primarily involved in its management.

## 23-20

**Seaweed Farming: An Alternative Livelihood, A Last Resort, Or Subsidising Overfishing Of Coral Reefs?**

**Nicholas HILL*[1,2]**, EJ MILNER-GULLAND[3], Marcus ROWCLIFFE[1], Guy COWLISHAW[1], Amado BLANCO[4], Heather KOLDEWEY[5]

[1]Institute of Zoology, Zoological Society of London, London, United Kingdom, [2]Division of Biology, Imperial College London, London, United Kingdom, [3]Division of Biology, Imperial College London, Ascot, United Kingdom, [4]Project Seahorse Foundation for Marine Conservation, Cebu City, Philippines, [5]Zoological Society of London, London, United Kingdom

A lack of options is frequently seen as the cause of overfishing and destructive fishing on coral reefs. Alternative livelihoods have therefore been embraced to address this problem. Seaweed farming is one such alternative. Some authors have recognised that seaweed farming may just become one component of a diversified livelihood in poor communities, limiting its ability to reduce fishing pressure. However, cases do exist where seaweed farming achieves this goal. But few studies have examined the conditions under which it does so, and, more importantly, the conditions under which it can result in the opposite effect. We compare the situation in island communities on Danajon Bank in the central Philippines where seaweed farming is being actively promoted and has lead to different outcomes. Using interviews and group research, we examine the conditions under which seaweed farming reduces fishing pressure at a household and community level. In one community, unique environmental conditions and community-level attributes appear to have reduced fishing pressure following the uptake of seaweed farming at both the community and household level, resulting in a perceived increase in fish abundance. Elsewhere, we find that for some households it only acts as an activity of last resort when fishing is no longer viable. Of greatest concern, seaweed farming appears to be subsidising some households' intensive fishing activity in heavily degraded areas where they are operating at a loss and would otherwise not be able to continue fishing. Understanding the conditions that lead to these different outcomes will help us to develop more effective management interventions when confronted with issues of poverty. We address the conditions that have led to these different outcomes.

## 23-21

**Fishery Management For Artisanal Reef Fisheries in Developing Countries: A Holistic Economic Approach**

**Christopher LIESE*[1]**

[1]Social Science Research Group, SE Fisheries Science Center, National Marine Fishery Service, NOAA, Miami, FL

This paper argues that traditionally exploited renewable resources in developing countries, in particular artisanal coral reef fisheries, are difficult or impossible to manage with classical fishery management tools. Further, given many special characteristics of these fisheries, even the usual policy objectives need to be questioned. By taking a closer look at the setting and the decisions that underlie the behavior of the fishing households, a different approach to management reveals itself. A set of policy options, based on a broader economic scale and new to the fisheries context, is more likely to be feasible and effective at conservation.

The explicit treatment of household-level behaviors and market settings, in addition to selected social and demographic elements, adds important dimensions to the management problem. The combination of these economic, social and demographic forces largely determines fishing pressure and hence the biological health of the resource. In turn, the status of the resource profoundly affects human well-being. A collapse will create unemployment, worsen poverty and possibly lead to large population movements. As a result, governments must find ways to conserve these resources in an effective, practical and equitable manner.

This paper tries to identify these second best solutions, i.e. feasible policies that might conserve the current health and potential of the resource in spite of it being exploited under an open access property rights regime. For instance, income diversification and alternative employment programs, usually an afterthought to conservation projects, should be reevaluated as primary tools for conservation. Further, long-term family planning policies and policies leading to poverty reduction are likely to have the greatest impact. The coral reef fishery of Minahasa, Indonesia serves as illustration throughout this paper.

The views expressed herein are my own.

## 23-22

**Coral Reef Resource Values, Trade and Sustainability**

**Benjamin STARKHOUSE*[1]**, Louise TEH[1], Lydia TEH[1], Yvonne SADOVY[2], Rashid SUMAILA[1]

[1]Fisheries Center, University of British Columbia, Vancouver, BC, Canada, [2]University of Hong Kong, Hong Kong, Hong Kong

Coral reef ecosystems are high in marine biodiversity, and are also significant socio-economically as a source of food and income in many developing countries. Trade in coral reef resources brings up biological as well as social and economic issues. The removal of target species causes disturbances to the structure of the coral reef ecosystem. Increasing demand for trade products can lead to the depletion of many fish and invertebrate stocks, resulting in economic hardship for fishers who target these species for artisanal and subsistence purposes.

First, we give an overview of our project on coral reef values, trade and sustainability. Second, we give details on the coral reef valuation component of our project. The objective being to examine the net benefit of coral reef resource export trade relative to the benefits from other uses of reef resources to the source country, here, Fiji. Although Fiji is selected for a case study, the outcomes are expected to have much broader application, especially to the island countries of the Pacific. Fiji relies on its coral reef ecosystems for food, tradable commodities and tourist dollars. Even though a substantial contributor to Fiji's economy, a comprehensive, national-level valuation of the coral reef sector is nonexistent. We will present an in depth analysis of the socio-economics of Fiji's coral reef resources. Our focus is on all reef-associated species harvested for food (finfish, invertebrates and plants), the marine aquarium industry, industrial and commercial uses of coral, reef products that are processed and/or exported, such as trochus shells, and coral reef related tourism such as diving, snorkeling and fishing. The results from this study will reveal the true direct use value of Fiji's coral reefs and can assist resource managers in developing socio-economically sustainable coral reef resource use strategies.

## 23-23

**Coral Reef Reserves In Vanuatu; Ecological Vs. Socio-Cultural Impacts**

**Christopher BARTLETT*[1]**, Charley MANUA[2]

[1]SEES, James Cook University, Townsville, Australia, [2]Nguna-Pele Marine Protected Area, Port Vila, Vanuatu

This paper examines people's perceptions of local social-ecological systems as influenced by the presence of community-based coral reef management initiatives in the Republic of Vanuatu. National and regional Melanesian characteristics, such as strong customary marine tenure and decentralized governance, are highlighted as integral to understand the existence of local marine reserves as well as to give context to historical marine resource use patterns. We assess human-nature interactions and perceptions of marine resource levels and management of all individuals from six (6) small insular communities; three (3) with strong local management regimes, three (3) without. The research employs a comparative analytic methodology based on socio-cultural and ecological participatory research. We demonstrate that communities with the most robust local management regimes and long-term coral reef reserves, have significantly different average perceptions of the SES including stronger local governance, social cohesion, management responsibility and human agency. Results indicate that small-scale marine reserves and associated activities in insular Melanesia may have influence into village social and cultural realms that transcend intended ecological benefits. It will be intimated by the authors that these social and cultural impacts may be of the most valuable benefits of marine reserves to be gained by the SES in small Melanesian communities with extremely limited sea tenure areas. This thesis is discussed in light of the temporal and spatial scales necessary for effective management of coral reef ecological systems. We conclude that some small Melanesian marine reserves, combined with the village social and cultural attributes they enhance, significantly contribute to regional management capacity, thus enriching the marine reserve 'effectiveness' debate

## 23-24

**A Business Approach To Coral Reef Management: The Main Hawaiian Islands Seascape Strategy Model**

**Melissa BOS*[1]**

[1]Conservation International, Honolulu, HI

The frontier of coral reef management involves the application of business principles and tools to conservation planning and implementation. Many current management strategies are limited by reductionism and lack of financial planning. The Main Hawaiian Islands Seascape Strategy is an example of a holistic, business-like approach to marine resource conservation. In the business analogy, a conservation planner becomes an executive of a conservation business. The business plan begins with the description of the company's product, in this case, management of ecosystem goods and services. Long-term direct and opportunity costs of management are compared with market and non-market values of ecosystem goods and services. Potential customers, revenue streams, and investment portfolios are analyzed. Commercial marketing techniques are used to target consumer behavior. Liabilities and risks of management scenarios are taken into consideration. Economic incentives and market-based approaches are included in implementation. The business approach, coupled with strategic stakeholder consultations, scientific assessments, and governance reviews, will allow management planning to progress beyond the target of sustainability to ecological, economic, social, and cultural prosperity.

## 23-25

**Economic Valuation Of The Shoreline Protection Services Provided By Coral Reefs And Mangroves – Implications For Management**

**Lauretta BURKE*[1]**, Sean PADDY[2], Charmaine O'BRIEN-DELPESH[2], Emily COOPER[1]

[1]People and Ecosystems Program, World Resources Institute, Washington, DC, [2]Institute of Marine Affairs, Carenage, Trinidad and Tobago

Coral reefs and mangroves play a critical role in protecting shorelines across the Caribbean. By reducing wave energy, coral reefs mitigate both routine erosion and damage from waves associated with small and moderate storm events. Mangroves play an increasingly important role in mitigating waves and storm surge associated with Category 3 hurricanes and larger storm events. Shoreline protection is an important and economically valuable ecosystem service. Maintaining the integrity of coral reefs and mangroves is essential to retaining their shoreline protection benefits.

Shoreline protection will become increasingly important as sea surface temperatures rise, storm intensity increases, and sea levels rise. Coastal planning to avoid development in areas that are most vulnerable to waves and storm surge, and to protect key mangrove and reef areas will become increasingly important under a changing climate.

Under a project on economic valuation of coral reefs and mangroves in the Caribbean, The World Resources Institute (WRI) and the Institute of Marine Affairs (IMA) have developed a framework for evaluating the relative vulnerability of the shoreline to waves and storm damage, and the relative share of shoreline protection contributed by these habitats. The framework integrates ten physical characteristics (including coastal elevation, slope, geomorphology, exposure, wave energy, storm regime, vegetation, and coral reef characteristics) to arrive at an index of relative stability of the shoreline. Policy makers can also use the framework to evaluate the potential economic "damages avoided" in coastal areas due to the protection provided by coral reefs and mangroves.

The methodology has been applied in Tobago, St. Lucia and Belize, and provides a valuable tool for identifying vulnerable areas and planning coastal development under changing climate, as well as valuing these shoreline protection services. The results point to the economic sense of retaining mangroves and supporting healthy coral reefs in vulnerable coastal areas.

## 23-26

**The Involvement Of The Private Sector in Marine Protected Area Planning, Management, And Conservation: Case Studies From The Indo-Pacific**

**Rick MACPHERSON*[1]**, Sherry FLUMERFELT[2], Florence DEPONDT[2]

[1]Conservation Programs, Coral Reef Alliance, San Francisco, CA, [2]Coral Reef Alliance, San Francisco, CA

Science is effective in informing the design of successful marine protected areas (MPAs), only if balanced with socioeconomic, cultural, and political realities. The importance of involving community stakeholders in MPA planning, design, and management is now widely acknowledged and accepted. One key coral reef stakeholder group that has received increasing attention in recent years are private sector marine recreation providers (MRPs)–dive, snorkel, kayak, and boating operators. MRPs in coral reef tourism destinations have a vested economic interest in supporting coral reef conservation, as their business depends upon a healthy reef. They can play a key role in successful conservation if educated, aware, and involved in the process. MRPs can also pose frustrating obstacles for marine park/resource managers if their needs are not addressed and they are not part of conservation planning. The Coral Reef Alliance (CORAL) works in the Indo-Pacific to build the support and collaboration of MRPs in marine protected areas. Through case studies we illustrate the importance and process of involving MRPs in coral reef conservation strategies. Participation of this key stakeholder group not only builds local support for conservation, but also helps fulfill critical conservation objectives such as financial support of resource management costs, assistance with biophysical monitoring of reefs, patrolling and reporting violations, educating visitors on best environmental practice, and providing local communities with non-extractive, non-destructive employment alternatives.

## 23-27

**Incorporating Traditional Management Practices Of Indigenous Peoples Of Tawi-Tawi, Philippines in Coral Reef Management**

**Filemon ROMERO*[1]**

[1]Center for Oceanographic Studies, Mindanao Sate University, Cainta, Rizal, Philippines

Tawi-Tawi province, part of the Sulu Archipelago reef complex, divides two large marine ecosystems: The Sulu Sea and the Celebes Sea. This reef complex, constituting about 25% of the total reef cover of the Philippines, performs a very critical ecological function as the spawning and nursery ground of varied marine species but also serves as corridors for migratory marine mammals, fish stocks and turtles. To address the threats to this reef complex like dynamite and cyanide fishing, the WWF Coastal Resources and Fisheries Conservation Project (CRFC) Tawi-Tawi was implemented. Management strategies that worked included laymanizing the baseline assessment results on coral reefs, reef fishes, mangroves and seagrasses as well as fisheries studies into IEC materials produced in local dialects either in broadcast or print. Engaging local government early on and providing counterparts for the initiatives developed their sense of ownership. Indigenous beliefs and traditional management systems like habitats of "revered" species, fear of retribution from the ancestors, traditional seaweed farming system, traditional "ownership" were incorporated in the management framework. The Fatwah (Islamic Guidelines) on Environmental Management were likewise developed. Coastal law enforcement remains the weakest link and needs to be improved because of some institutional and organizational problems. The declared Marine Protected Areas, all of which are coral reef ecosystems, were the spatial scale on reef conservation ranging from 84 to 3,500 hectares. The MPA Management Boards were organized and the Management Plans formulated and implemented with community participation. Now, mechanism for local environmental governance has been set up, destructive fishing practices reduced and coastal habitats protected by the communities resulting to improved fish catch and livelihood opportunities for the coastal villages. Biological indicators are used to measure coral reef management success. Likewise socio-economic indicators have also been used.

## 23-28

**An analysis of community-based marine management in Fiji Islands: Case study of Korolevu-i-wai districtt**

**Patrick FONG*[1]**, Joeli VEITAYAKI[2], Bill AALBERSBERG[3]

[1]Institute of Applied Science, The University of the South Pacific, Nasinu, Fiji, [2]School of Marine Studies, The University of the South Pacific, Suva, Fiji, [3]Institute of Applied Science, The University of the South Pacific, Suva, Fiji

The participation of local people in resource management planning, designing and implementation in Fiji has proven to contribute to the effective and sustainable management of reef systems and resources. This paper presents the results of an anlysis of a community-based management (CBM) arrangement in Korolevu-i-wai district. The result of the CBM initiative in this region has been successful with notable positive outcomes. The resource management through the CBM approach has created better overall outcomes at present (2004 onwards) than those of the former system and period. The anlysis revealed that the social cohesion amongst the community members, the perceived condition of the fishery and reef system, the condition of the terrestrial and village environment and the community's understanding of the values of the marine environment and the resources associated with it have greatly improved in the district after the initialization of the CBM project. The average CPUE and income level of fishers in the district have also increased as results of the initiative

The assesment confirmed that the key conditions for the achievement of the positive impacts of the CBM project in Korolevu-i-wai District are: political support through the recognition of the rights of the community to make development and management decisions regarding the marine environment, economic status of the community, decision making group homogeneity, people's dependence on the marine resource as a source of income, availability of alternative sources of income, active participation of the community in project implementation and coordination and support and advice from outside agencies. This analysis has established that there are vital links between the roles of the marine environment in the livelihood of the people, the impact of the people's management roles in the sustainability of the marine environment, and the social and economic elements associated with it.

## 23-29

**"To Live With The Sea"; Development Of The Velondriake Community-Managed Protected Area Network, South West Madagascar**

Alasdair HARRIS[1], **Raj ROY*[1]**

[1]Blue Ventures Conservation, London, United Kingdom

Madagascar's south-west coast supports some of the largest coral reef systems in the western Indian Ocean. These reefs are essential to the survival of the indigenous Vezo people who rely on healthy marine resources for food, transport, cultural identity and income. However coastal populations are growing rapidly and international fisheries companies have begun exploiting the region's waters through a sophisticated collection network to supply an expanding export market. In recent years local fishers have begun reporting declines in the size and number of their catches.

Following a pilot marine no take zone launched three years ago in the remote fishing village of Andavadoaka, project partners are now working with 23 neighbouring villages, and fisheries collection companies to develop a network of community-run marine and coastal protected areas that will span more than 800-square kilometres and protect coral reefs, mangroves and seagrass beds along Madagascar's south-west coast. The villages, grouped into three constituent geographic regions, have established a management committee which serves as a liaison between conservation scientists and community members, providing input and insight into all phases of conservation planning, from research activities to implementation of management plans.

Along with protecting biodiversity and livelihoods, the network aims to increase environmental awareness among communities, expand local and national capacity for biodiversity conservation and serve as a model for other community conservation and governance initiatives across Madagascar and elsewhere. Velondriake aims to benefit villages within the network by empowering members of the local communities as managers of their own natural resources, enabling communities to contribute directly to the development of sustainable resource management systems to support local culture and livelihoods. Additional benefits are being brought to partner organisations through the capacity building resulting from involvement of personnel in the project and the improved availability of data, lessons learned and best practice guidelines.

## 23-30

**Assessment Of *Trochus Niloticus* From Shallow Reef Habitats Off The Hienghène And Pweevo Communes Of New Caledonia: Government And Tribal Management.**

**Sheila MCKENNA*[1]**, Stephen LINDSAY[2], Nathalie BAILLON[3], Henri BLAFFART[4], Edmond OUILLATE[5]

[1]Independent, Tuckers Town, Bermuda, [2]Consultant, Edgehill, Australia, [3]Direction de Developpement Economique et de Development et de l'Environnement, Province Nord, Kone, New Caledonia, [4]Dayu Biik Association and Conservation International, Hieghene, New Caledonia, [5]Tribu Panie, Hienghene, New Caledonia

Kanak tribes of the Hienghène and Pweevo communes of New Caledonia collect *Trochus niloticus* by hand or by free diving for subsistence and commercial purposes. Here, government and tribal laws regulate marine resource use and an official community based management plan is in development. For each commune, data on the amount of trochus extracted are recorded by year and no data exist for the populations *in situ*. To better understand their status, an assessment of the size (basal shell diameter) and density of trochus populations on 42 shallow (depth <12m) reef habitats was conducted using a transect method on three reef types of varying distances from shore. These included near shore fringing reefs, intermediate lagoon reefs and offshore barrier reefs. Given the artisanal nature of the trochus fishery, we tested *a priori* for significant differences in size and density for the three reef types. Twenty-one tribes were also interviewed regarding their perceptions and laws on marine resources. The mean diameter of trochus was significantly smaller ($p<0.01$) on the fringing reefs compared to the lagoon and barrier reefs. Only 129 individuals were observed during the survey and tribes noted more trochus in the past. Although the study was limited spatially and temporally, the findings suggest that government laws prohibiting extraction of trochus <9 cm in diameter are being followed. Greater mean size (>11cm) and population density on the lagoon and barrier reefs implies that accessibility is a factor in addition to trochus habitat preference. Trochus extraction data by commune in the previous year with the low population densities observed suggest that this species may be over-exploited. Size restriction as a managment tool appears to be effective, however more routine and extensive assessments are needed with continued collaboration between the tribes and government to determine appropriate management measures especially for extraction quotas.

## 23-31

**A Community Based Approach To Building A Regional Coral Reef Ecosystem Monitoring Program in The Freely Associated States Of Micronesia**

Shauna SLINGSBY[1], **Sebastian MARINO*[2]**

[1]Coral Reef Conservation Program, NOAA, Silver Spring, MD, [2]Palau International Coral Reef Center, Koror, Palau

From 2005-2007, NOAA's Coral Reef Conservation Program and Palau's International Coral Reef Center collaborated with local, regional, and international organizations to build capacity in coral reef ecosystem monitoring in the Freely Associated States of Micronesia. Micronesia has some of the most diverse and resilient coral reef ecosystems in the world and is arguably one of the better investments for coral reef conservation. A community based approach was emphasized over a period of three years, focusing on building capacity of local organizations and developing relationships between regional and international organizations. Forty-three members from Micronesia's governmental regulatory agencies (Marine Resources Division and Environmental Protection Agencies), local non-governmental groups, and academic institutions were trained in coral and fish taxonomy, reef sampling methods, experimental design, statistical analyses, database management, and reporting. The states of Chuuk, Kosrae, Palau, Pohnpei, Yap and the Republic of Marshall Islands (an area covering more than 30,000 square kilometers of shallow water habitat) are now using a standardized monitoring protocol to track changes in coral reef resources. This type of monitoring program, combined with traditional management practices in Micronesia, will provide long-term ecosystem-based management in this coral reef setting.

## 23-32

**Enabling Human And Reef Systems' Adaptation To Climate Change in Belize**

**Nadia BOOD*[1]**

[1]Belize, World Wildlife Fund, Belize, Belize

The health and integrity of Belize's reef complex is under increasing threat due to adverse anthropogenic activities, which will doubtless be compounded in the face of climate change. World Wildlife Fund is working on the ground in Belize to devise adaptation strategies that foster maintenance of reef-dependent livelihoods and reef ecosystem resilience to climate change. Efforts over the past two years focused on assessing the status of reefs and identifying healthy and potentially resilient reef systems, working with partners to advocate for conservation and management of identified healthy/resilient reefs through: raising awareness of key stakeholders and the broader public on climate change issues and the need for adaptation, and working with coastal communities to identify locally based strategies to promote resilience of reefs and adaptation of the community to the impacts of climate change. A total of 140 reef sites throughout Belize were selected based on reef habitat maps and assessed in 2006, offering a representative view of the status of reefs. A number of these reefs fell within or adjacent to existing marine protected areas or areas of conservation interest. The identification of particularly healthy reefs in surprising areas has facilitated a concerted commitment by such organizations to lobby for sustainable management of those healthy/resilient reef sites of interest. Furthermore, through the public outreach and community level work, locally based adaptation strategies are being developed through a participatory effort with community members. The proactive involvement of communities serves to foster ownership of identified strategies which is hoped will facilitate their legal adoption and potential scaling-up to the national level. The main strategies being explored are ecological and social systems' vulnerability reduction, social networking, and capacity building within the process of how to build resilience in both social and ecological systems; including coastal communities, coral reefs and mangroves.

## 23-33

**Integrated Research, Development, And Education Activities Enhance The Success Of Community-Based, Marine Resource Management in The Korolevu-I-Wai District, Fiji**

**Victor BONITO*[1]**, Bill AALBERSBERG[2], Kini RAVINALOA[3]

[1]Reef Explorer Fiji, Votua village, Fiji, [2]Institute of Applied Sciences, University of the South Pacific, Suva, Fiji, [3]FLMMA Representative, Votua Village, Votua village, Fiji

Community-based management is an effective means to accomplish biodiversity conservation and replenish depleted inshore fish stocks, particularly on Pacific islands whose indigenous communities have significant control over their resources. The Fiji Locally-Managed Marine Areas (FLMMA) Network involves the participation of over 200 communities across Fiji and covers approximately 30% of near-shore areas. Active participation in and contribution to FLMMA was complimented by a village-based coral reef ecologist who undertook and assisted with the implementation of a suite of research, development, and educational activities in the Korolevu-I-Wai district. Having an ecologist based on-site and living within the community boosted local initiative and support for resource management and conservation activities, as well as facilitated and improved the implementation of management actions, development activities, and research programs. Simultaneously targeting community development priorities and economic needs along with resource management strengthened support for resource management and conservation actions. Governance issues and the growing economic needs of traditional resource owners are perhaps the greatest obstacles to community support for management actions and resource management success. Poor land-use practices and waste from land-based development remain as major threats to marine resources. With considerable threats to resources coming from people who have no legal or traditional ties to the resources nor are under the influence of local traditional governance, compliance to and enforcement of community management initiatives remains a challenge to traditional resources owners.

## 23-34

**Reef Management Using Traditional Management Practices in Vanuatu**

**Zaidy KHAN*[1,2]**, Tevi MALTALI[3,4], Sompert RENA[3,5]

[1]Communites and Coast, Foundation of the People of the South Pacific International, Suva, Fiji, [2]Locally Managed Marine Area Network, Suva, Fiji, [3]Coastal Program, Foundation of the People of the South Pacific Vanuatu, Villa, Vanuatu, [4]Village Based Resource Managed Area Network, Villa, Vanuatu, [5]Department of Fisheries, Ministry of Agriculture,Forestry and Fisheries, Villa, Vanuatu

In 2005, the Foundation of the People of the South Pacific international ( FSPI) and its network partner FSP Vanuatu (FSPV) initiated pilot projects on community based coastal resource management together with the Vanuatu Department of Fisheries (VDF), and WanSmol Bag Theatre . In 1990 the VDF started a village based trochus (Trochusniloticus) management program which included a yearly harvest plan. This concept was favorably received by many villages and later extended by implementing control on other marine resource harvest by setting traditional "tabus" or Marine Protected areas (MPAs) to manage their reef resources. The MPAs were ceremonially demarcated by village chiefs.

Although the benefits of tradition protection is recognized by the government and other stakeholders in marine resource management, in recent years this management practices has faded due to loss of traditional and cultural values and limited government resources.

With the technical assistance from VDF, FSPV has been supporting indigenous communities in assisting reef management models and tools such as MPAs through developing community coastal resource management plans and reviving tradition practices during demarcation of MPAs. So far the project have launched management plans for Paunagisu and Marou in North Efate, Aneityum Mystery island after a 3 year community process through reviving their customary ceremonies on pig killing and turtle tagging together with national governments. This tradition and ceremonial launching of community based coastal management plans with national government has drawn a high level of respect, unity and recognition for village base MPAs and has highlighted spiritual importance of respect for chiefly governance systems. The traditional management approach by communities is spreading across Vanuatu, together with words of success of restocking and spill over benefits experienced from MPAs and is becoming a model and nation wide strategies for community based coastal management.

## 23-35

**Coral Reef Management in The Pacific Islands: Governance At Risk**

**Jean-Brice HERRENSCHMIDT*[1,2]**, Sven MENU[2], Pascal HÉBERT[2], Pascal DUMAS[1,3]

[1]IRD, Noumea, New Caledonia, [2]GIE Oceanide, Noumea, New Caledonia, [3]University of New Caledonia, Noumea, New Caledonia

The Pacific Islands populations rely on their coral reefs. Some Pacific countries are therefore involved in International and Regional initiatives to protect them at a large scale with the International Community support. The authors are in charge of the implementation of community-based management plans and of scientific assessments within the framework of two major initiatives: the nomination of the coral reefs of New Caledonia on the World Heritage List and the Coral Reef Initiatives for the Pacific (CRISP) in Vanuatu, Fiji and French Polynesia.

The integrated and participative approach developed aims at avoiding some traps from the predominant ideologies led by most of Marine Protected Areas (MPAs), community-based management and sustainable development processes. Pacific cultures and customs are rich and their linkages with marine resources management are real, but the predominant methodologies either phantasm about them, either promote ideological maladjusted and simple recipes, which reveals post-colonial Governance difficulties and risks.

The Pacific societies organisations, Coral reef ecosystems and the management of archipelago countries are extremely complex. Many Pacific countries are politically unstable and their colonial heritage is diverse. The World Heritage nomination process of New Caledonia coral reefs, in a political context of decolonisation and in comparison with other Pacific countries, contributes to imagine new directions for coral reef management effectiveness. Interdisciplinary approaches and Island management from the reach down to the reef help to handle complexity. The adaptation of legal tools, Public Service capacity building and collective critical discussions about the public vs private status of the marine environment are complementary actions needed to promote modern integration of skills and competences. Responsible Coral reef and marine areas management thus play an important role in integrating Pacific cultures and modern tools, and more generally, in strengthening citizenship and state policies in order to contribute to better governance and political stability.

## 23-36

**Conserving Ecological Integrity Only If "Absolutely Necessary" – How Florida and National Park Service Policies on Marine Reserves Threaten Coral Reef Ecosystems in Biscayne National Park, Florida**

David WHITE[1], **Jack SOBEL*[2]**

[1]Southeast Regional Office, Ocean Conservancy, St Petersburg, FL, [2]Strategic Conservation, Science & Policy, Ocean Conservancy, Washington, DC

When Congress created Biscayne National Park in 1980, healthy coral reefs in the park supported robust fish and invertebrate populations. In 1983, the National Park Service (NPS) adopted a management plan establishing intent to manage recreational and commercial fishing to "sustain a composition of native marine populations similar to that which existed prior to fishing pressure." A 2001 assessment of fisheries resources and habitats in the park concluded that, following decades of significant recreational and commercial fishing pressure and related habitat impacts, the extremely poor status of reef fish resources signaled "imminent resource collapse." In 2002, NPS and the State of Florida, which share jurisdiction over fishing in the park, agreed to jointly develop a plan to manage fishing for the next 10-15 years. The state/federal agreement, codified in a Memorandum of Understanding, establishes and adopts Florida's policy that marine reserves (no-take areas) are overly restrictive and will not be implemented unless both parties agree it is "absolutely necessary." This agreement was renewed until 2012, despite a draft environmental impact statement acknowledging that marine reserves would be required to protect and conserve ecosystem biodiversity, function, and services, and to begin to restore fishery-impacted ecosystems to natural levels. A policy of only considering marine reserves within the park if all parties agree it is "absolutely necessary" sets too high a bar for ecosystem management of coral reefs in urban areas, precludes efforts to protect natural resources from impairment in national parks in the United States, and undermines a "key conservation objective" of the United States Coral Reef Task Force to protect twenty percent of Florida's coral reefs as marine reserves by 2010.

## 23-37

**Challenges Facing An Mpa Management Authority in The Context Of A Rapidly Developing Tourism Industry**

**James FOLEY*[1]**

[1]Department of Research & Development, Roatan Marine Park, Roatan, Honduras

Roatan, the largest of the Bay Islands in Honduras, is located on the Meso-American Barrier Reef. While all coral reef ecosystems in the Bay Islands are a protected area under Honduran law, no governmental management authority protects or regulates the use of this natural resource. In response to concern over reduced coral reef species abundance, the Roatan Marine Park Authority (RMPA) was created in January 2005 by the diving community. Its initial objective was to prevent illegal fishing practices along a 13.5km long stretch of the protected area, known as the Roatan Marine Park (RMP) by facilitating police patrols. While this has been partly successful, new superimposed pressures on reef resources present new challenges to the RMPA in achieving its vision of conservation-based management. The Honduran Government is encouraging large scale development of Roatan for high revenue tourism; four new cruise ship docks will bring over one million tourists per year to the island. Rapid development is racing to meet demand for luxury vacation accommodation. Despite legislation to ensure proper management for conservation and exploitation of the marine environment, poor governance, corruption and a large national debt continually impede conservation efforts. Challenges for the RMPA include addressing sediment-rich runoff from land clearing and illegal mangrove cutting to make way for development, managing poorly treated sewage discharges, and educating large numbers of short-stay tourists to minimize their impact on the marine environment. Scientific knowledge of the interrelationships between rapidly changing ecological, economic and sociological dynamics is essential to developing an effective management programme that balances conservation and economic development objectives in the RMP. The RMPA is therefore seeking to support research efforts as a means to assess methods such as activity zonation to accommodate diverse and increasing demands on ecological resources.

## 23-38

**Community Involvement in Biophysical Monitoring And Evaluation Of Marine Protected Areas in Central Philippines: Generating High Resolution Data Using Standard Methods, Utilizing Local Materials And Employing Traditional Approaches**

**Roxie DIAZ*[1]**

[1]Research/Monitoring Team, Coastal Conservation and Education Foundation, Inc., Cebu, Philippines

Since the 1970's, over 500 marine protected areas (MPAs) have been established in the Philippines with only about 10-20% being effectively managed. This study illustrates the efforts of many individuals and institutions that over the last 5 years have contributed to the creation and development of the local monitoring teams. Specifically, this study shows the materials, methods, and results of the last 3 years of data collection by the local community monitoring teams highlighting their capacity to conduct technical surveys. Using appropriate technology - customized techniques from standard monitoring methods, utilizing local materials and employing traditional approaches, 50 MPAs in central Philippines were monitored by their respective local community monitoring teams. Results from these biophysical Monitoring and Evaluation (M&E) and the performance assessments have collectively gauge the status and effective management of the MPAs providing insight on the conditions and gaps in current MPA management.

## 23-39

**Mmas: A Network Experiment in Coral Reef Adaptive Management And Conservation.**

**Les KAUFMAN*[1,2]**, Leah BUNCE[3]

[1]Biology/Marine Program, Boston University, Boston, MA, [2]Conservation International, Arlington, [3]Conservation International, Arlington, VA

The Marine Management Area Science Program (MMAS) helps coastal societies to conserve coral reef and associated environments. MMAS has five key elements: (1) a network of communities in Brazil, Belize, the TEP, and Fiji that have area management schemes, treated here as a global adaptive management experiment; (2) a monitoring system for social and natural parameters with data stream tied to decision tools and policy options; (3) data comparison across nodes to detect global signals and measure effectiveness of local action in the face of global change; (4) new diagnostic and analytical methods to increase sensitivity to both process and state changes; and (5) targeted expeditions to fill key knowledge gaps. We report early progress on monitoring and diagnostics, the spatial dynamics of coral reef health and change, on society's relationships with coral reefs, the geographical ecology and connectivity of reefs, and a doubling of known reef habitat in the south Atlantic.

## 23-40

**Socioeconomic and Governance Monitoring of Marine Management Areas: A Work in Progress**

**Giselle SAMONTE-TAN*[1]**, Adele CATZIM[2], Diane HAYLOCK[2], Isabela CURADO[3], Rodrigo MOURA[4], Patrick Sakiusa FONG[5], Juan MATE[6], Osvaldo JORDAN[7], Lucia LASSO[7], Leah BUNCE[1]

[1]Center for Applied Biodiversity Science, Conservation International, Arlington, VA, [2]Belize ISIS Enterprises, Belize City, Belize, [3]Fundacao Getulio Vargas, Sao Paulo, Brazil, [4]Conservation International - Brazil, Caravelas, Brazil, [5]University of the South Pacific, Suva, Fiji, [6]Smithsonian Tropical Research Institute, Balboa, Panama, [7]Alianza para la Conservación y el Desarrollo, Panama City, Panama

Traditionally Marine Managed Areas (MMAs) have been established to achieve biodiversity conservation goals (e.g. protect endangered species, increase fish populations); yet increasingly social, economic and cultural objectives are being incorporated into MMA planning. To better understand these human effects, a cross-site study was designed to examine the socioeconomic and governance effects of MMAs in four countries (Belize, Brazil, Fiji and Panama) as well as ecological factors influencing these outcomes. A socioeconomic and governance monitoring survey is being conducted in each of the MMA coastal communities to understand conditions prior to MMA establishment compared with current conditions. The analysis will assess the MMA socioeconomic effects, including impacts on food security and health of coastal residents, livelihoods, human threats to the marine resources, and environmental awareness and knowledge as well as assess the governance effects, including impacts on management structures and strategies, stakeholder participation and representation, property rights and access to resources, management plan compliance by resource users. In addition, enabling factors for MMA effectiveness will be determined, such as leadership and long term support of local government, participation by community and all those affected, shared benefits among participants, alternative livelihoods that are appropriate in decreasing resource use pressures within MMAs. This project is within the Conservation International Marine Management Area Science Program, is a work in progress and demonstrates the application of monitoring and research to support improved understanding and adaptive management of coral reefs and related ecosystems.

## 23-41

**Water Quality Standards For Coral Reef Protection**

**William FISHER*[1]**, Aaron HUTCHINS[2], Leska FORE[3], Wayne DAVIS[4], Charles LOBUE[5], Heidi BELL[6]

[1]Office of Research and Development, U.S. Environmental Protection Agency, Gulf Breeze, FL, [2]Department of Planning and Natural Resources, U.S. Virgin Islands, Frederiksted, United States Minor Outlying Islands, [3]Statistical Design, Seattle, WA, [4]Office of Environmental Information, U.S. Environmental Protection Agency, Ft. Meade, MD, [5]Region 2, U.S. Environmental Protection Agency, New York, NY, [6]Office of Water, Office of Science and Technology, U.S. Environmental Protection Agency, Washington, D.C., DC

Resource managers have few tools to counteract the growing impacts of human coastal and watershed activities on coral reefs. Water quality standards for coral reef protection—including biological criteria (biocriteria)—have enormous potential but are not currently used by any U.S. jurisdiction. The Environmental Protection Agency is promoting coral reef biocriteria through collaborative development of bioassessment procedures and monitoring strategies suitable for regulatory activities. A rapid bioassessment protocol (RBP) for reef-building stony corals (Scleractinia) was developed and tested as an initial step. Scleractinia were selected because much of the ecological and economic value of coral reefs is directly attributable to the physical structure of stony corals. The RBP requires only three underwater observations but provides both colony and surface area characteristics and incorporates a three-dimensional approach to document colony size (indicator of ecosystem services) and the amount of live tissue (coral capacity for growth and reproduction). Preliminary testing in the Florida Keys showed that information gained through the RBP had relevance to coral reef management and sufficient precision to distinguish spatial and temporal differences. Further validation was completed in the U.S. Virgin Islands, where corals were sampled across human disturbance gradients to determine which indicators were responsive to anthropogenic stress, a requirement for regulatory enforcement. Several RBP indicators, including taxa richness, colony size, total and live surface area were found to be positively correlated with distance from human activity. These indicators also had sufficient precision to be effective in most monitoring programs, and are now considered strong candidates for application in a regulatory context. Implementation of enforceable biocriteria will depend on the application of responsive metrics in a defensible long-term monitoring program. Once established, such a program will provide valuable, long-term records of coral condition and regulatory compliance.

## 23-42

**Spillover Of Reef Fishes From No-Take Marine Reserves: An Evaluation Using The Before-After Control-Impact (Baci) Approach**

**Ronaldo FRANCINI-FILHO*[1]**, Rodrigo MOURA[1]

[1]Marine Program, Conservation International, Caravelas, Brazil

No-take marine reserves may promote recovery of exploited populations within their boundaries and spillover of fishes to adjacent fishing grounds, thus potentially benefiting the local fisheries. Although some studies have measured spillover by examining gradients of fish abundance and body size across reserve boundaries, there are no such studies to date including information from before reserve establishment, thus seriously limiting interpretation of results. We measured reef fish spillover from a no-take marine reserve in Eastern Brazil by estimating biomass and body size across the reserve boundary before (2001) and after (2002-2005) initiation of protection. Replicate sites were sampled inside and outside the reserve, with unprotected sites included in three distance categories from the reserve boundary: 0-400, 400-800 and 800-1200 m. This latter category surpass the scales over which spillover is expected to influence patterns of fish abundance outside reserves (generally < 500 m), thus acting as a control for the reserve effect. Habitat measurements were undertaken at the same sites, from 2003 on. Biomass of the greenbeak parrotfish Scarus trispinosus, a major fishery resource and the dominant species in terms of biomass (37.4% of total biomass), was lower inside the reserve area before its establishment. During this same period, no individuals of two primary target species, the black grouper Mycteroperca bonaci and the gray parrotfish Sparisoma axillare, were recorded inside the reserve. Coral cover was consistently lower inside the reserve from 2003 on. Biomass and body size of M. bonaci, as well as biomass of the yellowtail snapper Ocyurus chrysurus, increased continuously inside the reserve after initiation of protection, with no similar increases recorded in control sites. Evidences of spillover (i.e. higher biomass inside the reserve and in unprotected sites closer to its boundary) were obtained for M. bonaci, O. chrysurus and S. trispinosus, although this pattern was only marginally significant for O. chrysurus. Despite the aforementioned positive signs, recovery and spillover of S. trispinosus were probably inhibited by increased poaching from 2003 on. Our results indicate that the no-take reserve at Itacolomis Reef was established a priori on poor quality habitats. Thus, future spatial comparisons between protected and unprotected sites would underestimate changes due to protection. These findings highlight the importance of baseline information and continued monitoring for adequately understanding the effects of no-take marine reserves.

## 23-43

**Modularizing Coral Reef Monitoring Methodologies for Better Management Effectiveness**

**Karenne TUN*[1]**, Eugene GOH[2], Loke Ming CHOU[1], Tom FOSTER[2]

[1]Biological Sciences, National University of Singapore, Singapore, Singapore, [2]DHI Water & Environment, Singapore, Singapore

To a large extent, effective management of coral reefs depends on access to relevant reef monitoring data, and their translation into useful management indices. Several globally established monitoring methodologies are currently used by coral reef monitoring practitioners (eg, AIMS LIT, Reef Check, AGGRA and Vitareef), with many modifications or enhancement to suit local situations and needs. The fact is that there is no shortage of methodologies that practitioners can employ to monitor coral reefs – yet there is little compelling evidence to demonstrate a link between monitoring and management. In many instances, monitoring results appear to be no more than a cursory tool used in management. Analysis of a variety of documents (manuscripts, technical reports, management papers, etc) that link monitoring and management show a general lack of tools that effectively translate monitoring information into useful management indices to support management decisions. Most monitoring outcomes are reported as percent benthos cover, which is not an ideal index for assessing coral reef condition, and even less ideal as a management tool for making management decisions. This paper addresses the issue of translating monitoring outcomes into relevant indices for more effective coral reef management in a highly urbanized environment with extensive anthropogenic influences. The approach focuses on identifying key management questions for the specific area being managed, which are then addressed in the form of add-on modules that are linked to existing reef monitoring methodologies,. In essence, we propose that monitoring programmes retain their existing coral reef monitoring methodologies, but tackle specific management questions by appending relevant monitoring modules to their existing protocols.

## 23-44

**Community-Based Monitoring Of Marine Ecosystem Health For St. Kitts And Nevis, Lesser Antilles: Development Of A Relational Database Based On Local And Scientific Marine Stakeholder Knowledge.**

**Raphaela STIMMELMAYR*[1]**, Mike KAPLAN[2], Jose JUGEREY[2], Nikki BANFIELD[2], Maureen SULLIVAN[3]

[1]Ross University Veterinary School, Basseterre, Saint Kitts and Nevis, [2]RUSVM, Basseterre, Saint Kitts and Nevis, [3]St.Kitts Reef Ecology Watch Group, Basseterre, Saint Kitts and Nevis

A current comprehensive assessment of coral reef health, distribution of marine species including sea turtles and coral reef fishes that occur in the waters of St. Kitts-Nevis does not exist. Tourism in the wider Caribbean is the most important economic sector, having largely replaced the formerly important agricultural economy (i.e. banana and sugar cane). Ecotourism activities such as diving and other non-consumptive resource uses such as whale and sea turtle watching are an important local tourism component. Local marine stakeholder knowledge is a largely untouched and valuable source of information relevant to Caribbean marine ecosystem health and resources. Marine data was collected from roving diver surveys (dive masters and recreational divers) and snorkel surveys using standardized fish survey sheets. Local fish names have been compiled from semi-directed interviews. Coral reef photo data (1992/93 and 2006/2007) has been digitized and a registry created. Both can be linked to survey site data. The constructed relational database allows for seamless integration with local available geographical information systems. Community based approach to marine ecological monitoring is a viable, sustainable and economical tool for the generation of scientifically valid ecological baseline data for small island developing states that otherwise lack infrastructure and resources to engage in marine research needed for development of management guidelines. Furthermore the integration of local traditional knowledge provides insight into the local shifting baseline syndrome and can generate evidence for new hypotheses.

## 23-45

**Assessing Global Coral Reef Management Using Interdisciplinary Measures Of Conservation Success.**

**Venetia HARGREAVES-ALLEN*[1]**, EJ MILNER-GULLAND[1], Jamie OLIVER[2], Trond BJORNDAL[3]

[1]Imperial College London, London, United Kingdom, [2]WorldFish Centre, Penang, Malaysia, [3]Portsmouth University, Portsmouth, United Kingdom

Donors increasingly need information to help them chose how to optimise investment for conservation and management in marine protected areas (MPAs). In this study I use a questionnaire to managers and researchers of coral reef marine protected areas to assess the factors influencing perceived conservation success. A range of indicators of conservation success have been used in the literature, including management inputs, evidence of conservation outputs and threat reduction. In my study I compare the results of using each of these measures, which encompass ecological, economic and social components of success. I place emphasis on the counterfactual through the use of geographical 'inside versus outside' measures and temporal 'before versus after' measures. I will present the results of the survey, which encompasses 80 MPAs from all over the world, from those less than 1km2 to the Great Barrier Reef Marine Park in Australia. A focus of the survey is to explore the issue of equity in terms of the distribution of management and opportunity costs and use and non-use benefits. An analysis of the financial and management strategies that are linked to more successful MPAs enables me to identify recommendations for management. Global trends in regulations, funding strategies, budgets and management actions and their impact on conservation targets will also be discussed, along with an assessment of the challenges and limitations of this research.

## 23-46

**Linking Monitoring and Management- Lessons Learned at the Sapodilla Cayes Marine Reserve, Belize**

**jocelyn FINCH*[1]**, Christina GARCIA[1], Jason GUY[2], Godwin HUMES[2]

[1]Toledo Association for Sustainable Tourism and Empowerment, Punta Gorda, Belize, [2]Belize Fisheries Department, Punta Gorda, Belize

Located at the southern terminus of the Belize Barrier Reef, the Sapodilla Cayes Marine Reserve (SCMR) was declared a marine reserve in 1996 and is a part of the Belize Barrier Reef World Heritage site. The SCMR protects important reef ecosystems, is home to essential fishing grounds, and is visited by tourists from Belize, Guatemala and Honduras. With these diverse uses and values in mind, the Fisheries Department began on-site management at the SCMR in 2001. Today the SCMR is co-managed by the Belize Fisheries Department and the Toledo Association for Sustainable Tourism and Empowerment (TASTE). In 2006 TASTE, in collaboration with the Fisheries Department, developed a basic monitoring plan for the SCMR. In 2007 the partners began implementation of this monitoring plan. The goal of the monitoring plan was to ensure consistent biological monitoring and to better link the emerging data and its analysis to management decision making. Now after a full year of monitoring with careful evaluation of the monitoring techniques and the data collected; the co-managers have gained useful insight into the strengths and weakness of this monitoring strategy. In order to guarantee that quality biological data is being applied to adaptive management a number of key gaps in monitoring and analysis must be addressed including: insufficient funding of the monitoring plan, need for trained personnel, in-depth statistical analysis training and the ability to translate scientific evidence into management action. TASTE and the Fisheries Department need to work together to develop capacity in these key areas and maintain a consistent monitoring of these important biological resources. Through continued cooperation, improved implementation of the monitoring plan and better use newly collected data, it will be easier to balance the diverse management goals of the SCMR and ensure effective adaptive management.

## 23-47

**The Science Behind Adaptive, Ecosystem Based Management in The Great Barrier Reef Marine Park**

**David WACHENFELD*[1]**

[1]Science, Technology & Information Group, Great Barrier Reef Marine Park Authority, Townsville, Australia

The Great Barrier Reef is a vast, complex mosaic of different habitats including coral reefs, sponge and soft coral gardens, algal meadows, seagrass meadows, mangrove forests, islands, pelagic and deep sea environments, which are all ecologically inter-connected. The Reef is a significant source of economic, social, cultural and spiritual values for all Australians, and is a global environmental icon. The major threats to the Great Barrier Reef are climate change, degraded water quality and fishing. These threats do not operate in isolation of one another, but rather in synergy. The Great Barrier Reef Marine Park Authority takes a holistic view, protecting the entire ecosystem, its diversity of habitats, their inter-connectivity and their associated human values from the range of threats. The Authority has specific programmes targeted at protecting biodiversity, delivering sustainable industries (particularly tourism and fishing), improving water quality and responding to climate change. With the threat from climate change rapidly increasing, there is greatly increased urgency for local management to address other threats, and focus on measures to maximise the resilience of the ecosystem. The Authority partners closely with scientists to deliver sound information to form the basis of Reef management. In particular, we have developed significant monitoring programmes for our major management initiatives, so that we can track their effectiveness and continue to adaptively manage the Marine Park into the future.

## 23-48

**Spatial Footprint And Temporal Variability Of Recreational Usage At A Remote Fringing Reef in North-Western Australia**

**Claire SMALLWOOD*[1]**, Lynnath BECKLEY[1], Sue MOORE[1]

[1]Environmental Science, Murdoch University, Perth, Australia

Worldwide, studies investigating recreational usage of coral reefs have not previously been a priority for research. However, increased visitation and documented impacts from these activities have highlighted the importance of collecting relevant usage data at a scale appropriate for management. Ningaloo Reef is a remote fringing reef which extends 300 km along the coast of north-western Australia and supports several diverse ecosystems. Although located in an isolated arid region with a permanent population of only 10 000 people, this is supplemented each year by ~ 200 000 visitors. The fringing nature of the reef, which encloses a sheltered lagoon area with an average width of 2.5 km, results in a high level of accessibility for visitors participating in marine recreational activities. Planning for the future sustainable development of the Ningaloo coast is ongoing and a project to map the spatial footprint of marine resource usage in the lagoon is underway. Part of this study included ~1 100 face-to-face questionnaire interviews with recreational participants collected throughout 2007 along the length of the reef system. Snorkelling, fishing, diving, kayaking, surfing as well as charter tours for coral viewing and manta rays were some of the popular activities recorded. As well as seasonal variation in recreational usage, demographics, visitation patterns and origin of visitors, there was also spatial variation in these patterns along the coastline. Although studies of recreational activity have been undertaken previously in the region, this is the first study that clearly displays the spatial relationship between these activities, access points and various accommodation types. The study has also allowed popular usage nodes, which could be vulnerable to impacts from recreational activities, to be identified. The fine-scale resolution and geo-referenced nature of this dataset makes it particularly pertinent to site-specific planning and management of Ningaloo Reef and the adjacent coastline.

## 23-49

**Integrating Coral Reef Data For Marine Protected Area Decision Support**

James HENDEE[1], **Frank MULLER-KARGER*[2]**, Villy KOURAFALOU[3], Lew GRAMER[4]

[1]Atlantic Oceanographic and Meteorological Laboratory, National Oceanic and Atmospheric Administration, Miami, FL, [2]School for Marine Science and Technology, University of Massachusetts Dartmouth, New Bedford, MA, [3]Rosenstiel School for Marine and Atmospheric Sciences, University of Miami, Miami, FL, [4]Cooperative Institute for Marine and Atmospheric Studies, University of Miami, Miami, FL

Since 1997 NOAA's Atlantic Oceanographic and Meteorological Laboratory (AOML) in Miami, Florida, has been engaged in continuing development of expert systems as a tool both for researchers and for managers of Marine Protected Areas (MPA). Recently AOML has updated this system with powerful new software called G2, which forms the heart of the new Integrated Coral Observing Network (ICON) of in situ stations and virtual monitoring sites around the world. The ICON/G2 system integrates data from in situ, satellite, radar and other measurements in near real-time, and couples that data with decision support products for over 90 coral reef locations around the world. Many ICON sites are situated within MPAs; however, the needs of MPA managers require environmental monitoring with regional as well as local coverage, thus prompting the need for extensive satellite data. Also, requirements analyses of MPA managers highlight the need for basic research to support effective decision making; one area in particular--hydrodynamic modeling, applied to forecast the delivery of nutrients and larvae to the reef--is a common need for most MPAs. This paper discusses ongoing efforts to extend our data coverage to support these promising areas of research at the most visited site in the Florida Keys National Marine Sanctuary (FKNMS), Molasses Reef. This work can serve as a model for additional sites within the FKNMS, and eventually at other MPAs in the Caribbean Sea, Pacific Ocean and Indian Ocean.

## 23-50

**Maredess: Marine Resources Decision Support System**

**Laura DAVID*[1]**, Erlinda SALAMANTE[1], Eileen PENAFLOR[1], Kathleen SILVANO[1], Kristina CORDERO[1], Marites MAGNO-CANTO[1], Irene ALABIA[1], Victor TICZON[1], Ma. Bernadette DE VENECIA[1], Roselle BORJA[1], Rommel MANEJA[1], Cesar VILLANOY[1]

[1]Marine Science Institute, Univ. of the Philippines, Quezon City, Philippines

Republic Act 8550 marked the devolution from the national to the local government of the stewardship of coastal marine resources. Although this made sense in as much as it is the local stakeholders that are in the best position to ensure sustainability of use and management, nevertheless we argue for a need for a comprehensive national strategy. This study makes use of various remotely sensed products and numerical model simulations to propose a strategy for prioritizing sites for protection. Taken into consideration are presence/absence of reefs and related habitats; entrainment/ connectivity features; variability of environmental exposure; perceived threats and vulnerability. The recommendations include prioritizing offshore reefs that are less vulnerable to thermal stress and storms; reefs that have withstood thermal fluctuations through decades; and prioritizing series of reef areas to ensure a sustainable of connectivity corridors. A map of priority sites is given for the Philippines.

## 23-51

**Software Tools For Ecosystem-Based Management Of Coral Reefs**

Sarah CARR[1], **Lindsay ELDER*[1]**, Patrick CRIST[1]

[1]EBM Tools Program, NatureServe, Arlington, VA

Ecosystem-based management (EBM) of coral reefs requires the integration of information about a vast array of environmental and human systems, including the coral reef ecosystems themselves, pollutants from land-based sources, and human uses of the ecosystems such as tourism, recreation, fishing, and shipping. A variety of software tools have been developed to help policymakers and managers collect, visualize, and analyze this information and engage stakeholders in the EBM decision making process. For example, tools can:

- predict ecosystem response to natural and anthropogenic disturbances
- help select optimal areas for conservation or restoration
- help managers and stakeholders visualize the impact of development and resource-use scenarios on ecosystems and the human communities that depend on them
- help collect local knowledge about how resources are used
- facilitate stakeholder participation in evaluating management alternatives.

Using tools can improve environmental decision making by helping resource managers incorporate science into decisions, address multiple objectives, and build consensus for management actions among stakeholders.

Navigating through the vast array of tools and determining what tools do and how they should be used can consume a great deal of a manager's time. This presentation will provide information on an array of technology tools for EBM of coral reefs and the benefits and limitations of using technology tools. We will also describe an on-line resource for comprehensive information on EBM tools (www.ebmtools.org) and provide information on relevant training opportunities.

## 23-52

**Development And Implementation Of Coral Reef Biocriteria in U.s. Jurisdictions**

**Patricia BRADLEY*[1]**, Wayne DAVIS[2], William FISHER[3], Bell HEIDI[4], Valerie CHAN[5], Buddy LOBUE[6], Wendy WILTSE[7]

[1]Office of Research and Development/NHEERL/AED, U.S. EPA, Key West, FL, [2]Office of Environmental Information, U.S. EPA, Ft. Meade, MD, [3]Office of Research and Development/NHEERL/GED, U.S. EPA, Gulf Breeze, FL, [4]Office of Water, U.S. EPA, Washington, DC, [5]Office of Research and Development/OSP, U.S. EPA, Washington, DC, [6]Region 2, U.S. EPA, New York, NY, [7]Region 9, U.S. EPA, Honolulu, HI

U.S. coral reef ecosystems are threatened by a variety of anthropogenic activities (e.g., pollution, over fishing, vessel groundings, excess nutrients, coastal development, etc.), natural stressors (e.g., tropical storms), and natural stressors that have been exacerbated by anthropogenic activities (e.g., climate change).

Biological communities are dependable indicators of the health of aquatic ecosystems because they are responsive to effects of low-level, chronic, and non-point source pollution, and to interactive stressors not captured by physical and chemical water quality standards. Under the Clean Water Act, states may adopt water quality criteria based on biological, physical, and chemical criteria. The President's Ocean Action Plan directs the U.S. Environmental Protection Agency (EPA) to develop biological assessment methods and biological criteria for evaluating the health of coral reefs and associated water quality.

Biocriteria are narrative descriptions or numeric values representing the biological condition of biological communities. Rigorous biological assessments are needed to identify metrics for a monitoring program and to set expectations for the water body. These are used to develop a scoring system to indicate the health of the water body and to develop biocriteria for each class or designated use.

EPA is fostering development of coral reef biocriteria through focused research, evaluation, and collaboration with U.S. states and territories. To date, EPA has produced and validated a Stony Coral Rapid Bioassessment Protocol for application to biocriteria and a Coral Reef Bioindicators Website (http://www.epa.gov/bioindicators/coral/coral_biocriteria.html) for dissemination of information.

EPA and the collaborating states and territories have a wide variety of ongoing activities to conduct systematic coral bioassessments, develop metrics, design monitoring programs, and work toward adoption of protective and defensible biocriteria.

## 23-53

**Developing A Model For Ecosystem Based Management in The Tropical South Pacific -Initial Results From A Case Study in Fiji**

Kathy WALLS[1], Aaron JENKINS[2], Kesaia TABUNAKAWAI[3], **Daniel EGLI*[3]**

[1]Wildlife Conservation Society - South Pacific Program, Suva, Fiji, [2]Wetlands International - Oceania, suva, Fiji, [3]Worldwide Fund for Nature - Fiji Country Program, Suva, Fiji

The Vatu-i-Ra Reefs and Great Sea Reef of Fiji are globally recognized for their outstanding biodiversity. In 2005, three NGOs collaborated to investigate ecosystem based management approaches in this area.

The scope of the project is at the seascape scale with the inclusion of the adjacent watersheds. The project focus is on two traditional fisheries management areas and their adjacent watersheds on the island of Vanua Levu. Fish caught in the management areas are important for both sustenance and income for the local communities, but some land-use practices at the sites, such as logging, widespread land clearance and sugar-cane farming, may adversely affect the marine ecosystem through sedimentation and nutrient enrichment from runoff.

Thus far, project initiatives at both sites include: establishment of marine protected areas (MPAs) through close collaboration and consultation with the local communities; active resource management committees; draft management plans and enforcement training. Marine biophysical and socio-economic surveys have provided important baseline information on the marine habitats and the local communities of the sites. A biological monitoring program has been initiated to investigate effectiveness of the MPAs. Watershed conservation has begun through development of a management plan for a forest reserve at one site, resulting in increased awareness for watershed conservation. New information on the watersheds of both sites has been obtained through development of a preliminary runoff model that demonstrates the potential impacts of sediment and nutrient runoff on the marine habitats of both sites.

The work undertaken to date has highlighted the vital roles of both local communities and science-based approaches to ecosystem assessments in managing coral reef ecosystems.

## 23-54

**Genetic structure of Heliofungia actiniformis (Scleractinia: Fungiidae) populations in the Indo-Malay Archipelago: implications for live coral trade management efforts**

**Leyla KNITTWEIS*[1]**, Wiebke KRÄMER[2], Janne TIMM[2], Marc KOCHZIUS[2]

[1]Centre for Tropical Marine Ecology, Bremen, Germany, [2]Biotechnology and Molecular Genetics, Bremen University, Bremen, Germany

The fungiid *Heliofungia actiniformis* is one of the most popular scleractinian coral species in the growing live aquarium trade, with the majority of specimens originating in Indonesia. Details on population connectivity may potentially provide important information with regards to fishery management efforts. Phylogeographic structure was examined, using ribosomal ITS1, 5.8S and partial ITS2 sequences on a small scale among populations in the Spermonde Archipelago, South Sulawesi (up to 65 km distance), and on a large scale throughout the Indo-Malay Archipelago (up to 2,900 km distance). Significant genetic structuring was found at both scales. Within the Spermonde Archipelago isolation by distance as well as local oceanographic features shaped patterns of genetic connectivity. On the large scale, the data revealed genetically distinct populations in Tomini Bay, New Guinea and the Thousand Islands near Jakarta, and a lack of genetic differentiation among populations lying close to or directly in the path of the Indonesian throughflow: from the central Visayas to the Flores Sea. Whilst the influence of both historical and present day processes on genetic structuring of *H. actiniformis* populations was revealed, large scale results further emphasised the importance of current dynamics on larval dispersal patterns in this species. Potential for larval input from surrounding populations, and the increased vulnerability of upstream as well as isolated populations should be taken into consideration when setting future harvest quotas.

## 23-55

**Conservation Of Elkhorn (Acropora Palmata) And Staghorn (A. Cervicornis) Corals Through Two Proposed Rules Under The Endangered Species Act**

**Jennifer MOORE*[1]**, Sarah HEBERLING[1]

[1]Protected Resources Division, NOAA Fisheries Service, St. Petersburg, FL

The Endangered Species Act (ESA) listing of elkhorn and staghorn corals in 2006 has necessitated the development of two rules to provide for their conservation. The NOAA Fisheries Service is responsible for the development and implementation of these rules. A proposed rule under ESA section 4(d), called a (4(d) rule, extends ESA prohibitions to the threatened corals. The 4(d) rule also provides exceptions to those prohibitions for specific activities that provide for the conservation of the species. A proposed critical habitat rule designates specific geographic areas within U.S. jurisdiction on which are found physical and biological features essential to the species' conservation and which require special management. The specifics of the two rules, their conservation goals, and effects on public will be discussed.

## 23-56

**De Facto Marine Protected Areas: Coral Reef Conservation Inside The Danger Zone**

**Charles WAHLE*[1]**, Rikki DUNSMORE[2], Lisa WOONINCK[2,3], Mimi D'IORIO[1], Lauren WENZEL[4], Claudia MAKEYEV[2]

[1]Natl. MPA Center, NOAA, Monterey, CA, [2]Natl. MPA Center, NOAA, Santa Cruz, CA, [3]Southwest Fisheries Science Center, NOAA Fisheries, Santa Cruz, [4]Natl. MPA Center, NOAA, Silver Spring, MD

Effective ocean management requires a broad understanding of spatial patterns of human use. To this end, and with support from NOAA's Coral Program, the Marine Protected Areas Center has inventoried the De Facto MPAs (DF-MPAs) in U.S. waters: areas of the ocean where access and/or use are restricted for reasons other than conservation. Many DF-MPAs are located in coral reef ecosystems, potentially providing valuable but previously undocumented conservation benefits to these often remote areas. Presently, more than 1,000 DF-MPAs occur in U.S. waters, covering 3 percent of the nation's Exclusive Economic Zone (EEZ). In the Pacific Islands, a small area (< 0.01 %) is contained in 59 DF-MPAs. A large portion (95 %) prohibit access, at least part of the time. However, for 2/3 of this area, access is restricted only temporarily, with most of this area contained within one site during intermittent target practice. In contrast, approximately 500 km2 of marine waters are off limits year round in Pacific Islands DF-MPAs, contained primarily within three sites with coral reef habitats: Barking Sands, Kaula Rock and Kahoolawe Island. Coral reef resources within these areas are afforded year-round protection from extractive activities (e.g. fishing), yielding demonstrable increases in abundance and density of commercially-important reef fishes and invertebrates. A small portion of the Caribbean waters (<0.008%) is contained in 22 DF-MPAs, distributed throughout coral reef ecosystems of Puerto Rico (14) and the U.S. Virgin Islands (8). Within the next few years, the DF-MPA area in the Caribbean region will drop by 90 percent following the decommissioning of several military installations that encompass some of the region's healthiest coral reef habitats. Although often overlooked in conservation planning, De Facto MPAs are prevalent in U.S. coral reef ecosystems and may pose real opportunities for meaningful conservation in concert with other forms of place-based management.

## 23-57

**Management And Monitoring For Coral Reef Conservation in One Of The World's Busiest Ports**

**Nigel GOH*[1]**

[1]National Parks Board, Singapore, Singapore

Between the founding of modern-day Singapore in 1819 and today, the island nation has lost an estimated 60% of its coral reef area. Most of this loss may be attributed to pressures from land-use necessitated by an increasing population and a fast-growing economy. Nevertheless, high species diversity remains on its coral reefs, with 256 species of scleractinians still extant in Singapore. This number represents more than a quarter of all hard coral species worldwide, a statistic made more noteworthy as Singapore's total land area is only 700km2. In earlier years, conservation of coral reefs was fortuitous, contrasting with a more intentional approach seen in recent years.

A major pillar of this new approach towards managing the nation's coral reef natural heritage involves the setting of strict environmental quality objectives and use of real-time feedback monitoring processes. These rigorous environmental monitoring and management plans (EMMP) allow the mitigation of impacts while allowing coastal development that is often necessary in a land-constrained situation. In Singapore, the universal problem of having many stakeholders in coastal areas is exacerbated by the intensity of use brought about by its very limited availability of land and coastal areas. Besides traditional approaches to coral reef conservation, newer approaches like active habitat enhancement measures are necessary to ensure the long-term sustainability of coral reefs in the face of these pressures.

This paper describes these measures, as well as the EMMP process in Singapore that minimizes collateral damage to coral reefs arising from coastal developments, even when these developments are in close proximity to such reefs.

## 23-58

**Science To Action For Coral Reef Conservation**

**Sebastian TROENG*[1]**, Leah BUNCE[2], Michael WELLS[3], Guilherme DUTRA[4], Lindsay GARBUTT[5], Scott HENDERSON[6], Loraini SIVO[7]

[1]Regional Marine Strategies, Conservation International, Arlington, VA, [2]Center for Applied Biodiversity Science, Conservation International, Arlington, VA, [3]Consultant, Lier, Norway, [4]Conservation International-Brazil, Salvador, Brazil, [5]Friends of Nature, Placencia, Belize, [6]Conservation International - Eastern Tropical Pacific Seascape, Puerto Ayora, Ecuador, [7]Conservation International - Fiji, Suva, Fiji

A major conservation challenge is how to best use cutting edge science results to inform effective policies and best practices for coral reef conservation. Conservation practitioners may not have access to the latest information and researchers may not always reach key decision-makers with practical and useful science-based recommendations to inform policy and best practices. Conservation International's Marine Management Area (MMA) Science Program, a four-year initiative funded by the Gordon & Betty Moore Foundation, aims to bridge this gap between science and practical conservation and to simultaneously identify the key factors responsible for influencing the success of these "Science to Action" (S2A) efforts. The program is currently supporting over 40 studies on management effectiveness, connectivity, resiliency, economic and cultural values, conservation incentives and enforcement related to MMAs. To guide the S2A efforts and to allow for posterior assessment of success, a framework has been developed that specifies the desired marine conservation outcomes (long-term goals), outputs (short-term goals), outreach and influencing activities to reach these goals, and the conditions (e.g. level of participation in research design) that may have influenced whether or not the research results contributed to achieving the conservation goals. Science to Action workshops have been held in Belize, Fiji, Brazil and Panama with the participation of the principal investigators, and with practitioners and decision-makers from each of the countries and their broader region to identify the priority activities and goals. We hypothesize that this participatory approach will ensure that science results are fed into local decision-making processes and hence increase the probability of science results informing conservation policy and practice. We anticipate that this analysis of the S2A component of the Marine Management Area Science Program will allow us to identify the key success factors for scientists and conservationists to consider when planning and implementing conservation research programs.

## 23-59

**Making Research Matter: Best Practices And Common Barriers To Applying Research Findings**

**Ruth KELTY*[1]**

[1]National Ocean Service, NOAA, Silver Spring, MD

Successful realization of coral reef ecosystem management goals depends on the ability to transition research and information out of the laboratory and into the hands of decision-makers. This talk describes best practices for increasing the impact of research investment (as identified by the U.S. Ocean Research and Resources Advisory Panel), common barriers to transition, and coral reef ecosystem cases studies in which those barriers were overcome. Collaboration between researchers and intended users of the research is essential. The most successful collaborations are launched early in the process, facilitated by a neutral third party, and engage the end users in problem formation as well as application development. Consensus documents presenting the best available science are useful in convincing users that the research/solutions are accepted. Research funding agencies can help by creating incentives for integrating application into research programs, fully funding the transition (i.e. development, validation, and training), and valuing collaboration and transition along with publication. An institutional culture that values the timely transition of relevant research will contribute to the most effective use of science in societal decision-making.

## 23-60

**Designing A Resilient Network Of Protected Areas in The Republic Of Palau, Micronesia**

**Eric VERHEIJ*[1]**, Sean AUSTIN[2]

[1]Micronesia Program, The Nature Conservancy, Koror, Palau, [2]Micronesia Program, The Nature Conservancy, Koror, Papua New Guinea

In November 2003, the Protected Areas Network (PAN) Act was passed and signed into law. The PAN Act, which has dual objectives of protecting biodiversity and natural resource management, provides a framework for Palau's national and state governments to collaborate to establish a resilient nationwide network of terrestrial and marine protected areas. As part of the design process, a number of workshops have been organized to bring together relevant government institutions, non-government organizations, community representatives, and individuals. The aim of these workshops was to ensure that decisions related to evaluating and prioritizing marine and terrestrial biodiversity are based on the most up-to-date and accurate scientific information available. In May 2006, the PAN Office, supported by the Nature Conservancy and the Palau International Coral Reef Center, sponsored a series of two workshops attended by nearly 50 participants from National and State Governments, communities and non-governmental organizations, to comprehensively review and assess the latest biodiversity and socio-economic information available for the country. Following this information/data review, maps and data layers were updated and modeled using MARXAN software to provide varying design scenarios for Palau's PAN. These scenarios will serve to enable decision makers to determine how to effectively protect and manage Palau's natural resources. At the end of the second workshop the existing 28 MPAs, of which 26 were established using the natural resource management objective, were overlaid on the map with the biodiversity priorities. The result of the overlay was an almost perfect match and therefore demonstrates that conservation of biodiversity and natural resource management can be complementary.

## 23-61

**Mitigating The Effects Of Coral Bleaching Through Improved Methods Of Marine Reserve Design**

**Ian ELLIOTT*[1]**, Helen EDWARDS[1], Peter MUMBY[1], Claire PARIS[2], William SKIRVING[3], Mark EAKIN[3]

[1]Biosciences, University of Exeter, Exeter, United Kingdom, [2]University of Miami, Miami, FL, [3]NOAA, Townsville, Australia

Conventional methods of selecting locations for marine reserves have not fully addressed the impacts of climate change and disturbance events upon coral reef ecosystems. Here we present a new approach that combines ecosystem models, climate change predictions and reserve selection tools in order to provide greater sophistication and resilience to marine reserve networks in areas prone to coral bleaching.

Reserves are chosen from potential sites in the Bahamas. The conservation value of a site is determined by its current status (dependent upon the species and habitat it contains), and by the temperature characteristics of that location. Future sea surface temperatures are projected using data from a model that incorporates IPCC climate predictions. We consider both the average summer temperature and the variability in temperature at each location and in each decade until 2100. We prioritise sites that suffer less thermal stress and are less likely to experience bleaching. Sites are further prioritised if they have strong connectivity, allowing for coral larvae recruitment from hot-variable sites with resistance to bleaching.

An optimisation algorithm returns the configurations of reserves that minimise the losses to the fishing industry whilst meeting user-defined conservation and habitat-connectivity targets. The summed irreplaceability, defined as the number of all the reserve systems to which a site belongs out of the total number of reserve systems generated, is used to identify the most frequently selected sites. Reserve system efficiency and cost are compared under different bleaching scenarios and for different biodiversity targets. Incorporating the risk of future bleaching events modifies the influence of biodiversity criteria and has a profound influence on the distribution of reserves. Our results demonstrate that an increased awareness of the impacts of disturbance events can enable more effective management of coral reef ecosystems.

## 23-62

**Management Of The Florida Keys National Marine Sanctuary As Impacts Of Climate Change Strengthen**

**Brian KELLER*[1]**

[1]NOAA/SE Region/National Marine Sanctuary Program, St. Petersburg, FL

Coral reefs within the Florida Keys National Marine Sanctuary have experienced bleaching events of increasing spatial extent and severity over the past 25 years. Live coral cover has decreased over the past decade, associated primarily with the 1997-1998 mass bleaching event and the passage of Hurricane Georges in 1998. Projections of the Intergovernmental Panel on Climate Change suggest that stressors on reef-building corals, such as ocean temperature, acidification, and tropical storm severity, will increase during the next few decades. "Adaptations" to climate change are fast gaining the attention of managers of marine protected areas. Management adaptations include four categories of actions: 1) ameliorating existing stressors in coastal waters; 2) protecting apparently resistant and potentially resilient areas; 3) developing networks of marine protected areas; and 4) integrating climate change into marine protected area planning, management, and evaluation. The National Marine Sanctuary Program has formed a Climate Change Working Group that is initiating a systematic approach to develop practical strategies for resource protection in the context of climate change. Application of these strategies in the Florida Keys National Marine Sanctuary includes: the continued use of fully protected marine reserves; continued improvements to wastewater treatment and stormwater management through the sanctuary's Water Quality Protection Program; considering further protection of apparently resistant and potentially resilient areas identified by the Florida Reef Resilience Program; planning and implementing networks of these areas; and working closely with the National Marine Sanctuary Program's Climate Change Working Group as it helps implement practical climate change strategies at each national marine sanctuary. For the Florida Keys, implementing recommendations of the Reef Manager's Guide to Coral Bleaching will be a major part of incorporating climate-change impacts into sanctuary management.

## 23-63

**Do Marine Protected Areas Mitigate Coral Cover Decline?**

**Elizabeth SELIG*[1]**, John BRUNO[2], Kenneth CASEY[3]

[1]Curriculum in Ecology, University of North Carolina, Chapel Hill, NC, [2]Department of Marine Sciences, University of North Carolina, Chapel Hill, NC, [3]National Ocean and Atmospheric Administration, Silver Spring, MD

The global decline of corals has intensified the need for management strategies that can restore coral health, particularly in the face of climate change. Marine protected areas (MPAs) have clearly been effective for fisheries management, but their effects on coral health at regional scales are not well understood. MPAs could have positive indirect effects on corals by increasing resistance through the mitigation of stressors like overfishing and nutrient run-off if there is a terrestrial component. In addition, MPAs could increase the resilience or recovery rate from disturbance events by increasing herbivore abundance through better fisheries management. Using spatial databases of MPAs and surveys from more than 3800 reefs around the world, we analyzed how MPAs and MPA duration affected the rate of change of coral cover. We found a weak positive effect of MPAs on coral cover and a positive effect of the number of years of protection on the rate of coral cover change within MPAs. We also used a 21-year satellite temperature anomaly database to specifically test whether MPAs could lessen the effects of rising temperatures and if MPAs could be better designed to maximize benefits. Although our results suggest that MPAs can increase coral resilience, the weakness of the effect underscores the need for additional and more direct conservation measures including those aimed at reducing climate change.

## 23-64

**Ecological Effects Of No-Take Marine Reserves: Tests Of Latitudinal Variation And Adult Spillover And Comparison To Partial Protection**

**Sarah LESTER*[1]**, Benjamin HALPERN[2], Kirsten GRORUD-COLVERT[3]

[1]Institute of Marine Sciences, University of California, Santa Cruz, Santa Cruz, CA, [2]National Center for Ecological Analysis and Synthesis, University of California, Santa Barbara, Santa Barbara, CA, [3]Partnership for Interdisciplinary Studies of Coastal Oceans, Oregon State University, Corvallis, OR

The study and implementation of marine reserves has increased rapidly over the past few decades, providing ample data on the biological effects of reserve protection for a wide range of geographic locations and organisms. Reserves have been shown to support more intact communities, with a greater abundance and biomass of key species compared to areas outside. Nonetheless, numerous questions remain about their potential benefits and management utility. We conducted a survey of peer-reviewed scientific literature to compile a global database of studies documenting biological effects for multiple taxa in no-take marine reserves. We show that on average reserves generate strong positive effects for the biomass, density, species richness, and size of organisms within their boundaries and we explore how these results vary across different taxa. We then address several core issues in marine reserve science. First, we compare the performance of marine reserves in tropical and temperate environments and show that reserves have parallel positive effects across latitude. Second, we present emerging evidence that spillover of adults into unprotected waters is a general and quantifiable phenomena and likely scales with reserve size. Lastly, we evaluate the relative benefit of partial protection versus full protection (no-take reserves) and show that while partial protection affords some ecological benefits over open-access, on average greater responses are likely to be found for fully protected areas. These results have important implications for future efforts to design and implement marine reserves.

## 23-65

**Development Of Resilience-Based Management Strategies For Florida's Coral Reefs**

**Chris BERGH*[1]**, Phillip KRAMER[2], William CAUSEY[3], Mark EAKIN[4], David SCORE[3], Chantal COLLIER[5], Kent EDWARDS[6], Stephanie BAILENSON[7], Peter CONE[8], Paul MARSHALL[9], Eric MIELBRECHT[10], Frank MULLER-KARGER[11], Robert VAN WOESIK[12], David VAUGHAN[13], David LOOMIS[14], Robert LEEWORTHY[4], Joanne THOMAS[2], Brian KELLER[3]

[1]Florida Keys Program, The Nature Conservancy, Sugarloaf Key, FL, [2]The Nature Conservancy, Sugarloaf Key, FL, [3]NOAA, Key West, FL, [4]NOAA, Silver Spring, MD, [5]Florida DEP, Miami, FL, [6]Florida DEP, Key West, FL, [7]Florida DEP, Tallahassee, FL, [8]Commerical Fisher, Key West, FL, [9]Great Barrier Reef Marine Park Authority, Townesville, Australia, [10]Emerald Coast Environmental Consulting, Washington, DC, [11]University of South Florida, Tampa, FL, [12]Florida Institute of Technology, Melbourne, FL, [13]Mote Marine Laboratory, Summerland Key, FL, [14]University of Massachusetts, Amherst, MA

The Florida Reef Resilience Program (FRRP) is a collaborative effort among managers, scientists, conservation organizations and reef users to develop resilience-based management strategies for coping with climate change and other stresses on Florida's coral reefs. In 2004 the 400 km long reef tract from Martin County to Dry Tortugas was classified into 59 discrete reef zones. A "Disturbance Response Monitoring (DRM)" procedure, consisting of a probabilistic sampling design and a stony coral condition monitoring protocol, was developed and applied across these zones during the annual period of peak thermal stress in 2005, 2006 and 2007. DRM results show spatial and temporal patterns in coral bleaching and colony size frequency distribution, indicating that some zones and coral species may be more resilient to stress than others. Data on water quality parameters, volunteer observations of bleaching occurrence and remotely-sensed sea-surface temperature and accumulated thermal stress were analyzed to help explain variability in stress responses. This biophysical analysis of reef resilience was paralleled by social science research focused on reef users' perceptions of reef condition, reef management strategies and the economics of reef-dependent recreational and commercial activities. Results of FRRP research and other relevant studies were communicated with stakeholders during a series of workshops designed to gather input about optimization of existing reef management and reef use strategies and to identify novel strategies. The resulting recommendations are wide ranging and include; preferred anchoring methods, voluntary avoidance of stressed reefs, timing of coastal construction activities to minimize cumulative stress on corals, changes in fishing practices and new goals for spatial coverage, distribution and type of marine protected areas in the region.

## 23-66

**Hurricane Dean impacts on Chinchorro Bank coral reefs, Mexico: Bases to implement ecosystem-based fisheries management**

**Alvaro HERNÁNDEZ*[1]**, Fabián RODRÍGUEZ-ZARAGOZA[2], Gilberto ACOSTA-GONZÁLEZ[3], Miguel RUIZ-ZARATE[4], José CASTRO-PÉREZ[5], Alicia MEDINA-HERNANDEZ[6], María GARCÍA-RIVAS[7]

[1]Mesoamerican Reef, World Wildlife Fund, Cancun, Quintana Roo, Mexico, [2]Ecology, Universidad de Guadalajara, Zapopan, Jalisco, Mexico, [3]Recursos del Mar, CINVESTAV-Merida, Mérida, Yucatan, Mexico, [4]Quimica y Biologia, Instituto Tecnologico de Chetumal, Chetumal, Quintana Roo, Mexico, [5]Quimica y Biologia, Intituto Tecnologico de Chetumal, Chetumal, Quintana Roo, Mexico, [6]Mesoamerican Reef Program, World Wildlife Fund, San José, Costa Rica, [7]Reserva de la Biosfera Banco Chinchorro, Comision Nacional de Areas Protegidas, Distrito Federal, Mexico

As part of the activities to implement the ecosystem-based fisheries management in Chinchorro Bank Biosphere Reserve (ChBBR), Mexico, an inter-institutional work team initiated a systematic monitoring to evaluate its coral reef conditions. In April 2007, the team, integrated by World Wildlife Fund, ChBBR administration, and Chetumal Technologic Institute, in collaboration with local fishermen collected data through 120 transects in five sites. This information allowed us to calculate biodiversity and ecosystem functionality. On August 2007, the eye of Hurricane Dean (category 5) hit ChBBR. In September 2007, the inter-institutional team organized a second monitoring to assess the impact of this hurricane in three sites with highest biodiversity: 1) La Caldera, 2) La Baliza and 3) Chancay.

The community parameters of fish assemblages and the conditions of habitat structure were estimated through visual census; topographic complexity ("chain" technique); Horizontal heterogeneity (video-transects); and benthic groups and type of substrate (point intercept).

The comparison of the community parameters before and after the hurricane showed a higher impact on the benthic community of La Baliza. In this site, there were significant differences in both, shallow and deep habitats due to a coverage reduction of the following groups: sand, macro-algae, and hard coral. On the other hand, in La Caldera and Chancay the impact was moderate; which registered a significant reduction of macro-algae and large reef extensions covered by mold. In the three sites, fish biodiversity and biomass was similar before and after the hurricane, but the structure of fish assemblage was significantly different. After the hurricane, key invertebrates abundance increased significantly, particularly Panulirus argus, Strombus gigas, and Diadema antillarum. These results suggest that fish resources as well as invertebrates maintained a similar biomass, although we recommend that further fisheries exploitation must be cautious to enhance natural resilience and avoid a potential collapse of the resources.

## 23-67

**Climate Change Leads: Linking Environmental Analysis To Decision Support in Florida**

Alex SCORE[1], Eric MIELBRECHT[2], Daniel WAGNER[3], Debra HARRISON[1], **Lara HANSEN*[4]**

[1]World Wildlife Fund, Marathon, FL, [2]Emerald Coast Environmental Consulting, Washington, DC, [3]Biological Sciences, Florida Institute of Technology, Melbourne, FL, [4]World Wildlife Fund, Washington, DC

Coral reefs were one of the first ecosystems where the effects of climate change were readily apparent. As a result of their high vulnerability to climate change there is a pressing need for coral reef resource managers, including those in Florida, to manage for climate change. Florida's stakeholders and decision-makers urgently need targeted research, clear communications, and accessible tools to better understand the impacts of climate change and coral bleaching so they can develop and implement successful management and mitigation initiatives. The Climate Change: Linking Environmental Analysis to Decision Support (LEADS) initiative brought together scientists, natural resource managers and decision-makers at the local, state and federal levels, with a full range of stakeholders to analyze patterns in coral resilience to climate change and transform these findings into effective management strategies. A GIS based tool was created that illustrates patterns of coral resilience within the Florida Keys National Marine Sanctuary and allows users to manipulate layers of environmental data in prescribed and unique ways. The creation of this management tool, which promotes a better understanding of local environmental parameters that are associated with assemblages of resilient coral, was based on research that synthesized existing and emerging coral bleaching and water quality data for the Florida Keys in a GIS framework and identified patterns in bleaching occurrence and recovery with respect to environmental variables. The resource management applications of this GIS-based tool will be presented along with a description of the stakeholder and decision-maker outreach process utilized in the Climate Change LEADS initiative in the Florida Keys.

## 23-68

**Large Scale Transplantation Of Corals in A Small Island State**

Stephanie DOORN-GROEN[1], **Eugene GOH*[1]**, Karenne TUN[1], Thomas FOSTER[1], Clint TIWOL[1]

[1]DHI Water & Environment (S) Pte. Ltd., Singapore, Singapore

Singapore is a small, highly urbanized and industrialized island state, with extensive marine industries fringing most of her Southwestern coast and offshore islands which are fringed by coral reefs. Land intensive port operations and petrochemical industries have played a pivotal role in the island's economic success. As these industries expand, increased demand for land has lead to land reclamation works. While some of Singapore's reef habitat has been lost as a result of this development, coral species extinctions are not evident. Moreover, although reef area has been reduced and population abundance decline is apparent, the rate of this decline also appears to have been reduced through increased management and awareness of the importance of the reef habitats.

While the transplantation of corals as a compensation measure is viewed as a poor alternative to the conservation of entire reef communities, it provides an essential management tool whenever direct impact is inevitable. In 2006, one of the largest transplantation programs ever undertaken in Asia led to the relocation of about 4,200 mature coral colonies in Southwest Singapore with diameters up to 2m. Subsequent monitoring indicated a high survival rate; 12 months after the transplantation, about 80% of the monitored corals continue to thrive in their new home. This is a positive contrast to the survival reported in previous relocation programs in Singapore during the 1990's.

This paper reports on the key elements and processes that influenced and led to the successful execution of the transplantation exercise. The paper also discusses the systematic approach undertaken as well as the selection criteria used for the receiving site, which is considered the key to the success of the transplantation works.

## 23-69

**Restore Or Not To Restore?**

**Vladimir KOSMYNIN*[1]**, Alison MOULDING[2], Richard DODGE[2], David GILLIAM[2]

[1]Bureau of Beaches and Coastal Systems, Florida Department of Environmental Protection, Tallahassee, FL, [2]National Coral Reef Institute, NOVA Southeastern University, Dania, FL

Most coral reef scientists and managers would agree that coral reefs are degrading at ever increasing rates from a multitude of natural and anthropogenic stressors occurring at global, regional, and local scales. However, there is less agreement on the circumstances that warrant restoration and if costs outweigh benefits. In many cases observed recovery rates are slow, and new communities often have compositions differing from the original. Requirements for restoration of human-induced local damages often differ widely among countries. Efforts may involve reattachment of corals or their propagation (enhancement of recruitment) using various methodologies. The success of such local restoration is variable and depends on many natural and human induced factors. Nevertheless, published data and experimental results of projects in Southeast Florida demonstrate a high probability of success. Some would argue that restoration is insufficient to address large-scale degradation issues and, consequently, that limited funds should instead be directed at reducing impacts. While it is true that regional damages resulting from hurricanes, tsunamis, disease outbreaks, and bleaching events may involve areas too large for full-scale restoration, smaller scale restoration is an important management tool that could potentially benefit local and regional coral populations and speed recovery. Locally restored areas may serve as sources of coral propagation and stepping stones in connectivity between reefs. Restoration projects are also important in generating public awareness and support of conservation efforts. Additional research efforts directed at finding and testing new coral reef restoration methodologies should be continued. Unaided recovery of injured coral reefs now represents a much less likely scenario given the considerable local, regional, and global stressors.

## 23-70

**The Management Of Coral Reefs – Where We've Gone Wrong; How We Can Fix It**

**Peter F SALE*[1]**

[1]International Network on Water, Environment and Health, United Nations University, Hamilton, ON, Canada

Ecologists studying coral reefs long ago shifted from an assumption that these were ecosystems essentially untouched by humans, to a recognition that human impacts have become pervasive and severe, but they have meanwhile been party to a disastrous separation of science from management – a separation that keeps their growing understanding from being integrated into management action. Managers, when they have moved beyond the wishful thinking of paper parks and public awareness campaigns, have put undue faith in the effectiveness of Marine Protected Areas while ignoring both the lack of scientific underpinning of many management practices and the elephant which is rampant and growing over-exploitation of reef resources. The result is a sad history of progressive decline. Reefs suffer a diversity of often synergistic stresses. There is a way forward if we first decide that we really want to have sustainable coral reef systems in our future. This path requires that we firmly embrace the precautionary principle, that we recognize and reduce over-exploitation, and that we vigorously apply the science we have in hand to improve management now. Along the way we need to develop new science to provide a basis for more sophisticated management than is now possible. There is hope for a future for coral reefs, but only if scientists and managers act now to reduce controllable stresses, freeing these ecosystems to better cope with less manageable pressures of climate change. Achieving this future will require far more effective demonstration than yet achieved of the value of coral reefs to coastal populations.

## 23-71

**Are There "Ten Commandments"for Coral Reef Management?**

**Barbara BEST*[1]**

[1]Office of Natural Resources Management, U.S. Agency for International Development, Washington, DC

In an effort to capture the essential management actions required for Ecosystem-Based Fisheries Management, several fisheries scientist have proposed 10 guiding principles or "commandments". Could coral reef management benefit from a similar effort to capture critical management guidelines? To initiative a discussion within the coral reef community, an initial draft set of guidelines are presented. These commandments are based largely upon experience in less-consuming countries with weak governance and institutions but are widely applicable.

The first cluster of guidelines involves spatial attributes: 1. look upstream – take a watershed approach. 2. look down -- establish depth refugia. 3. look near then far -- include associated habitats then other functionally-connected reefs.

The second cluster focuses on the management process: 4. Understand the cultural, social, economic and governance context and work accordingly. 5. Focus on the consultative process early -- the science process should not outpace the stakeholder process. 6. Build management resilience – provide redundancy in leadership and capacity, strengthen management entities and organizations, and ensure revenue streams. 7. Address sea tenure and access rights – create incentives for environmental stewardship through clearly defined access and use privileges. 8. Focus on the decision-making process so that sound information and science is incorporated into decisions. 9. Create local economic incentives for conserving biodiversity and ecosystem services. 10. Address the drivers of international trade that threaten reefs, from fishing to tourism to other extractive industries.

## 23-72

**Ecological Criteria For Prioritizing Wider Caribbean Reefs in Need Of Protection**

**Judith LANG*[1,2]**, Robert GINSBURG[3,4], Kenneth MARKS[4,5]

[1]Independent, Ophelia, VA, [2]Marine Geology & Geophysics, RSMAS, University of Miami, Miami, [3]Marine Geology & Geophysics, RSMAS, University of Miami, Miami, FL, [4]Ocean Research and Education Foundation, Coral Gables, [5]Independent, Boca Raton, FL

Reefs with an abundance of healthy corals (including some that are large), ample crustose coralline algae and little macroalgae, are obvious candidates for protection and conservation. (Large corals provide habitat space for other organisms as well as larvae for future generations of framework builders or possible remediation efforts; abundant crustose corallines and sparse macroalgae signify the probable availability of larval recruitment sites.) To determine whether or not reefs with these characteristics are actually being protected, an easily calculated benthic condition index (BCI) based on the AGRRA project's coral and algal indicators has been developed. BCI values have been calculated for the over 700 surveys conducted between 1998 and 2004 on reefs in the wider Caribbean that had been stratified by zone (as bank, crest, fore, patch). This information will be posted online at www.agrra.org to help guide difficult decisions regarding where to focus local protection and management efforts. For example, sites rated overall as "well above average" (WAB) occurred in 15 of the 22 nations or territories and on 29 of the 50 insular or continental shelf units that were surveyed. Nearly half of these WAB sites are presently located in a marine protected area (MPA) of some designation. High priority should be given to protecting the remaining WAB sites, particularly those in areas with few or no established MPAs. Sites with high values for the macroalgal indicator signify overfishing of herbivorous fishes or nutrification, and could be further examined for potential causes and remediation strategies, the efficacy of which could be assessed during future surveys. In the absence of recent hurricanes or other mechanical damage, a paucity of large corals indicates poor environments for net reef growth, although other reasons may exist for their conservation.

## 23-73

**Caribbean Coral Reefs: Reversing The Slippery Slope To Slime**

**John OGDEN*[1]**

[1]Florida Institute of Oceanography, University of South Florida, St. Petersburg, FL

Coral reef monitoring and research programs, such as the Caribbean Coastal Marine Productivity (CARICOMP) network of marine laboratories and many others, have provided rich documentation of the continuing decline of Caribbean coral reefs and linked coastal ecosystems of the past 50 years. While science and management have achieved some local successes, particularly at the political level, in implementation of management plans largely based on small marine protected areas, there is little evidence that this effort has increased reef resistance and resilience to human disturbances. In spite of considerable depth of scientific understanding that the Caribbean Sea functions as a large marine ecosystem with coherent, region-wide ecological responses, there has been only one attempt to implement a regional management, scientific and governance scheme across a large coral reef region. Drawing on this experience, I suggest that a familiar land-use planning approach be implemented in a demonstration project within the contiguous Exclusive Economic Zones of several island countries. Within this large coral reef ecoregion, existing environmental and scientific information as well as traditional knowledge and human use patterns will be organized in a geographic information system format. This will allow stakeholders to apply management tools, particularly zoning, to separate conflicting human activities and plan for protection of critical conservation areas. Unlike land-use planning, ocean-use planning can be implemented on a trial basis with the plan adjusted over time with new knowledge. It will also provide new scientific information at more appropriate, large geographic scales on the resilience of coral reefs. It is past time to act. Coral reefs require comprehensive planning within ocean ecoregions if they are to sustain future human use and the beauty, wonder and lifting of the spirit that they so uniquely provide.

## 23-74

**Shifting Baselines, Local Impacts, And Global Change On Coral Reefs**

**Jeremy JACKSON*[1,2]**, Nancy KNOWLTON[3]

[1]Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, [2]Smithsonian Tropical Research Institute, Balboa, Panama, [3]Invertebrate Zoology, National Museum of Natural History, Smithsonian Institution, Washington, DC

The lush coral reefs of the remote, uninhabited and protected atolls of the Central Pacific raise basic questions about the importance of local impacts versus global change for the health of coral reef communities worldwide. Despite increased warming and high numbers of degree heating weeks that cause coral bleaching, these reefs still support extraordinarily abundant fish populations dominated by apex predators and living coral ranging from 44 to 56% live coral cover. This is as true of atolls in areas of intense upwelling and high productivity like Jarvis, Howland, and Baker, where nutrient concentrations greatly exceed those supposed to cause coral disease and mortality, as for atolls like Kingman and Palmyra in areas of much lower productivity. Detailed, long-term studies are lacking to determine whether these reefs somehow resisted bleaching or, as we believe more likely, have recovered from bleaching due to high recruitment and rapid growth of corals coupled with lower levels of macroalgal overgrowth, coral disease, and outbreaks of coral predators. Regardless, the simple persistence and obvious resilience of these reefs contradicts the widespread belief that the effects of global change are so overwhelming that local human impacts such as fishing and pollution can be safely ignored. More importantly, the quasi-pristine reefs of the Central Pacific are invaluable as monitoring stations for consequences of global change under ecologically optimal conditions of minimum local human impact, and as sites for observations of ecological processes and experiments on reefs that have not experienced the extreme degradation typical of other reefs worldwide. Experimental confirmation that local protection increases coral resilience to global change would provide the concrete evidence necessary to promote costly changes in management to more stringently regulate exploitation and pollution of reef ecosystems elsewhere.

## 23-75

**Plan B For The Anthropocene**

**Roger BRADBURY*[1]**, Robert SEYMOUR[2,3]

[1]Resource Management in Asia-Pacific Program, Australian National University, Canberra, Australia, [2]Department of Mathematics, University College London, London, United Kingdom, [3]CoMPLEX, University College London, London, United Kingdom

The Earth system is in transit from its current state, the Holocene, to a new one, the Anthropocene. The transition is being forced by the relentless process now called globalisation – really just the most recent half-century of the last few millennia of the transformation of the planet by human beings. The change is now locked in and is irreversible. Global warming is not the cause, but merely one of the more obvious symptoms of an inexorable process.

We don't know the details of the Anthropocene but we can now see its shape emerging clearly. The land, where people live, is becoming a new single, tightly interconnected, and greatly simplified agro-ecosystem whose contradictions – in terms of energy and mass fluxes and balances – will be resolved in the sea, where people don't live. The sea, already a single system, will host a vastly simplified ecosystem whose closest historical analogue will be the pre-Cambrian seas dominated by life forms such as jelly animals and algae.

Both the land and the sea will be inherently unstable and so need to be tightly managed. The management implications are profound. We may need to manage coral reef ecosystems through the transition into a reduced future shape, preserving what we can of their ecosystem function, perhaps at the expense of their current biodiversity and structure. Because most policy settings and management strategies are focussed on preserving reefs in something like their present Holocene state, they are, to that extent, unrealistic and unworkable. We will sketch the elements of an alternative policy and management framework – a Plan B – for the reefs of the Anthropocene.

## 24-1

**Fates Of Restored Acropora Palmata Fragments At The M/v Fortuna Reefer Grounding Site, Mona Island Puerto Rico: Lessons Learned Over 10 Years**

Andrew BRUCKNER[1], Ron HILL[2], **Robin BRUCKNER*[3]**

[1]NOAA Coral Reef Conservation Program, NOAA, Silver Spring, MD, [2]Southeast Fishery Science Center, NOAA Fisheries, Galveston, TX, [3]Office of Habitat Conservation, NOAA Restoration Center, Silver Spring, MD

Restoration of detached Acropora palmata fragments generated by the M/V Fortuna Reefer grounding off Mona Island (18°02'N; 67°51'W) was completed on October 14, 1997, three months after the grounding. Fragments (n= 1857) were secured to either reef substrates or dead standing A. palmata skeletons using stainless steel wire. Fragments experienced high rates of early mortality (57% surviving after 2 years) primarily attributed to wire breakage and removal during winter storms, overgrowth by bioeroding (clionid) sponges, disease, and predation by Coralliophila abbreviata (gastropods). Fewer than 10% (n=166) of the fragments were alive after 10 years. Most survivors resembled adult colonies with tissue covering their upper skeletal surfaces, extensive branching (mean= 5 branches, 89 cm in length), and a substantial increase in height (mean = 39 cm tall). Survivors included representatives of all size classes originally attached (15-340 cm), although the mean length of survivors (78 cm) was significantly larger than dead fragments (62 cm). Most surviving fragments were secured to the reef (70%) and oriented upright (>80%). These were 13% larger (mean=79 cm original length; current length= 120 cm) and had grown upward 14% more than fragments attached to skeletons. The most significant ongoing sources of mortality include snail predation (8%), overgrowth by sponges (6%), and disease (6%). While some fragment mortality can be directly attributed to the restoration approaches used at this site, most losses were due to disease and corallivory, two pervasive problems affecting acroporids throughout the region. Since 2001, we have documented an increase in corallivore abundance and a severe outbreak of disease; these primarily affected unrestored colonies, and have caused the loss of >95% of the colonies in surrounding areas. To improve our ability to recover and rebuild degraded acroporid populations, restoration approaches need to be combined with measures to mitigate disease and corallivory.

## 24-2

**Gardening Coral Reefs – New Insights For Coral Reef Restoration By Using Branching Corals As Ecosystem Engineering Species**

**Yael HOROSZOWSKI*[1,2]**, Jean-Claude BRETHES[3], Baruch RINKEVICH[1]

[1]National Institute of Oceanography, Israel Oceanographic & Limnological Research, Haifa, Israel, [2]ISMER, Universite du Quebec a Rimouski, Rimouski (Quebec), Canada, [3]ISMER, Universite du Quebec a Rimouski, Rimouski (Quebec), QC, Canada

Many of the world's coral reefs are experiencing a severe degradation due to anthropogenic activities that have significantly weakened the reefs' ability to cope with disturbances. Due to the ineffectiveness of traditional measures, active restoration has now become the premiere method of rehabilitation. In past efforts, coral colonies were taken from healthy localities and transplanted into denuded areas. This, however, resulted in low survival rates and inflicted stress on donor colonies. With the aim of overcoming these pitfalls, we tested the application of the "gardening coral reefs concept," a method inspired from forest restoration guidelines. This method involves generating and farming large stocks of new coral colonies in an *in situ*, floating nursery prior to their transplantation into degraded reefs.

The experiment targeted a degraded zone of Eilat's Reef, Israel. Two transplantation events were carried out: In November 2005, 550 nursery-grown colonies of two branching scleractinians (*Stylophora pistillata*, *Pocillopora damicornis*) were transplanted on five denuded knolls. In May 2007, 330 nursery-grown colonies of three branching species (*S. pistillata*, *P. damicornis*, *Acropora sp.*), one massive species (*Favia favus*) and one hydrozoan (*Millepora dichotoma*) were added.

The first two years of monitoring revealed low mortality rates of the new transplants. The new ecological and spatial niches resulting from the autogenic engineering characteristics of the transplants were immediately colonized by coral-obligatory invertebrates. When following influences on local fish community we witnessed an increase in the habitat's carrying capacity, reflected by higher fish abundance with no modification of the species composition. *S. pistillata* colonies from both transplantations released planula larvae. Thus, the nursery-grown transplants are not only reinforcing the local coral community but are also contributing to larval pool by participating in the local coral reproduction.

## 24-3

**Coral Transplantation in a Degraded Lagoon Environment: Differential Results of Three Species**

**Edgardo GOMEZ*[1]**, Patrick CABAITAN[1], Helen YAP[1]

[1]The Marine Science Institute, University of the Philippines, Quezon City, Philippines

A major challenge to restoration ecologists concerning reef corals is the determination of the appropriate species to use, and how to deploy them in the field to ensure good survival and growth. We transplanted three coral species which represent different life history strategies, viz., *Montipora digitata, Porites cylindrica, and Pavona danai.* Our study aims to establish viable coral populations within a range of conditions in a degraded lagoon environment (Bolinao, northwestern Philippines). The basic assumption is that prevailing environmental factors are still favorable for scleractinian survival, growth and reproduction, but that limitations probably exist in terms of potential recruitment, substrate suitability, and competition with other, established, benthic species. Degraded bommies along a gradient from sheltered to exposed conditions were used as platforms for the transplantation of branch fragments of the three species mentioned above. There was variable success ranging from high mortality for a usually fragmenting species, *M. digitata*, to virtually no mortality for *P. cylindrica*, with *P. danai* towards the more positive end. Growth of the transplants appeared to be better in environments that resembled more closely those of their naturally established (source) populations. The experimental treatments included variations in density and orientation of the transplants (attachment to horizontal and vertical surfaces), for which there appear to be no statistically significant differences in terms of growth and survival.

## 24-4

**Coral Transplants As Rubble Stabilizers: A Technique To Restore And Mitigate Damaged Reefs**

**Pablo ROJAS*[1]**, Laurie RAYMUNDO[1], Roxanna MYERS[1]

[1]Marine Laboratory, University of Guam, Mangilao, Guam

Developing workable stabilizing techniques to mitigate the effects of coastal construction, ships groundings and destructive fishing have been challenging well-informed decision makers for the past 30 years. Coral communities reduced into rubble are less likely to provide potential substrate for recruits due to instability and have slim chances to recover. We tested the efficacy of using two species of corals with contrasting morphologies as rubble consolidators. Three experimental plots were established in a 14 m2rubble field at 15 m depth in Sumay Mound, Apra Harbor, Guam. Eighteen fragments each of *Porites rus*, a submassive species that forms basal plates and *Porites cylindrica*, an upright branching species were transplanted to each plot in June 2006. We cemented each fragment to pieces of rubble to provide minimum stability and monitored for consolidating ability, measured in survival and basal growth and branching. We hypothesized that *P. rus*, which is hardy and forms extensive basal plates like forming plate would be superior as a consolidator to *P. cylindrica*. After 13 months, growth and overall survival varied significantly between species. Survival of *P. rus* was 99% and 80% for *P. cylindrica*. Monthly mean basal growth was 0.76 mm for *P. rus* and 0.16 mm for *P. cylindrica*. *Porites rus* proved superior as a stabilizer due to its plate-like forming base that enhanced fragment stability. *P. cylindrica* failed to attach to substrate and its mortality was higher. Transplants required occasional recementing in the early stages and cleaning of seasonally abundant macroalgae. Our study demonstrated that a morphologically complex, hardy, plate-forming coral species can be used to stabilize coral rubble. With minimum maintenance at post-transplantation, *Porites rus* established themselves within one year and showed positive growth, high survival and attachment to the substrate.

## 24-5

**How Quickly Do Coral-Fragments Of Different Species 'self-Attach' After Transplantation?**

**James GUEST*[1]**, Rommi DIZON[2], Chiara FRANCO[3], Alasdair EDWARDS[1], Edgardo GOMEZ[2]

[1]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]Marine Science Institute, University of the Philippines, Diliman, Philippines, [3]Department of Marine Science and Technology, Newcastle University, Newcastle upon Tyne, United Kingdom

Although corals regularly undergo colony fragmentation, mortality of unattached coral fragments can be high. Consequently the speed at which fragments 'self-attach' to substrata is likely to be critical to survival. During reef restoration interventions, coral transplants are often attached using epoxy or other adhesives, however self-attachment by growth of coral tissue onto the substrate is likely to provide a more secure and lasting bond. While it is known that coral fragments can generate new tissue to bond to the substratum within a few weeks of transplantation, surprisingly little is known about the speed of self-attachment. In this study, self-attachment times as well as growth rates and survival of transplanted fragments from thirteen coral species on replicated calcium carbonate substrata were examined experimentally in north-western Philippines. Two independent experiments were carried out. The first examined self-attachment, growth rates and survival in eleven species from different families representing a range of morphologies over approximately two years, whereas the second examined self-attachment times of three fast-attaching *Acropora* species in detail over one month. In the first experiment, *Acropora muricata* was significantly faster to self-attach (median time 39 days) compared to all other species, while *Echinopora lamellosa* was slowest to self-attach (median time 167 days) and was significantly slower than all other species except *Porites lutea* and *Pavona frondifera*. In the second experiment, *A. muricata* (branching) was significantly slower (median time 24 days) than *A. hyacinthus* (tabular) and *A. digitifera* (digitate)(median time 16 days). Results reveal that *Acropora* species have significantly faster attachment times than the other coral taxa studied. However branching *Acropora* species - which tend to fragment more frequently - do not necessarily have faster self-attachment times than other morphologies.

## 24-6

**Restoration Of Threatened Acropora Cervicornis Corals: Clone As A Factor in Mortality, Growth, Branching, And Self-Attachment**

**Austin BOWDEN-KERBY*[1]**

[1]Counterpart International, Suva, Fiji

The potential of farming *Acropora cervicornis* corals to restore this threatened species to Caribbean reefs was investigated, with particular emphasis on genetic factors relating to the relative success of culture methods. Clones from both high and low energy areas were sampled, to determine the relative importance of intraspecific variability and source environment on experimental outcomes. Corals were sampled from eight isolated *Acropora cervicornis* populations; thirty 10cm coral fragments obtained from each. Half of the samples were obtained from reef front coral thickets, and half were obtained from back reef areas. Fragments were attached to wire frames using colored ties to distinguish between clones, six branches per clone per frame. Sites were located in shallow back reef areas <2m deep, on five different reefs in the La Parquera reef system, Puerto Rico, with each frame placed on sand. Measurements were taken at one year for mortality, growth, branching density, and self attachment. Analysis was done separately for clones obtained from back reef and reef front areas. Results indicate that clone is a highly significant factor for all of the variables studied: mortality, growth, branch density, and attachment. There was up to a six-fold difference in relative growth based on clone alone. Back reef and reef front clones of *A. cervicornis* differed significantly in branch diameter, relative growth, and attachment ability after growing together for one year, suggesting a genetic basis to morphology and adaptation to specific environments. Frame culture was effective as a culture method, with mean growth rates ranging from 7-fold to 21-fold during the year. The application of this information to *A. cervicornis* restoration work ongoing in the Dominican republic and Honduras is also presented.

## 24-7

**Survival, Growth, And Fecundity Of Acropora Muricata And Hydnophora Rigida After Fragmentation And Transplantation**

**Kareen VICENTUAN*[1]**, James GUEST[2], Porfirio ALIÑO[1], Andrew HEYWARD[3]

[1]The Marine Science Institute, University of the Philippines, Quezon City, Philippines, [2]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom, [3]Australian Institute of Marine Science, University of Western Australia, Crawley, Philippines

Coral transplantation is seen as one way of rapidly restoring coral cover and structural complexity to degraded reefs. However little is known about the potential negative affects on the health of the donor colonies due to removal of fragments. In this study, we examined the effects of fragmentation and transplantation on the survival, growth and reproductive effort of donor colonies and transplants of *Acropora muricata* and *Hydnophora rigida* using 2 fragment sizes (ca. 5 and 10 cm long). Fragments were removed from replicate donor colonies and attached to replicated calcium carbonate substrata (dead giant clam shells) at an *in situ* nursery in a protected lagoon site in north-western Philipines. A second set of control colonies were tagged but left untouched. A replicate set of control fragments was also collected and transplanted beside the donor colonies. The annual pattern of reproduction of natural colonies was also examined over a period of 1 year. Survival, growth and reproductive output of half of the donor colonies and transplants were examined 4 months after fragmentation and transplantation (in March 2007, prior to the predicted spawning dates) The remaining replicates were to be examined after 17 months, however most of the remaining colonies and transplants died due to a coral bleaching event and an outbreak of *Acanthaster planci* at the study sites. Thus, only results of the four months post-manipulation will be presented here. Preliminary results indicate that their reproductive effort is significantly higher in donor colonies compared to transplanted fragments and that large fragments have higher (albeit not significant) reproductive effort than small transplants. Reproductive output of the donor colonies was not significantly different from control colonies suggesting fragment removal did not negatively affect the health of the donor colonies.

## 24-8

**Use Of A Mechanical Removal Device To Control Alien Algal Blooms On A Coral Reef in Kane'ohe Bay, Hawai'i**

**Eric CONKLIN*[1,2]**, D. Eric CO[1], Brian HAUK[2,3], Cynthia HUNTER[4], Anthony MONTGOMERY[3], Brian PARSCAL[5], Celia SMITH[5]

[1]The Nature Conservancy of Hawai'i, Honolulu, HI, [2]Hawai'i Institute of Marine Biology, University of Hawai'i, Kaneohe, [3]Department of Land and Natural Resources, State of Hawai'i, Honolulu, HI, [4]Biology Program, University of Hawai'i, Honolulu, HI, [5]Botany Department, University of Hawai'i, Honolulu, HI

Coral reefs around the world are increasingly undergoing shifts from coral to algal domination in response to anthropogenic stressors. These "phase shifts" are most often attributed to increased nutrient inputs and/or decreased grazer abundance. On many reefs in Hawai'i, they are at least partially the result of a third contributing factor, the introduction of alien macroalgae. On reefs in Kāne'ohe Bay, O'ahu, these alien algae are rapidly spreading, overgrowing and killing reef building corals and associated benthic species. The objective of this study was to determine if the use of an underwater vacuum cleaner ("Super Sucker") to remove accumulations of algal biomass is an effective management tool to reverse the trend towards algal domination of reefs. The Super Sucker removed 8298kg of the alien alga *Gracilaria salicornia* from two sites on a fringing reef over several months, reducing algal cover from ca. 65% to ca. 15% and increasing rugosity and the availability of coral settlement substrata. Expectations were that alien algal biomass would slowly increase following removal due to intrinsic growth of remnant algae and the importation of algae from adjacent reef flat habitats, necessitating continued removal efforts. However, alien algae continued to decrease several months after removal until they were effectively absent from the removal sites. The Super Sucker appears to have reduced algal abundance below a tipping point at which the existing herbivore populations can control algal abundance. These encouraging results suggest that, at least under some circumstances, mechanical removal of alien algae from overgrown reefs may be a viable remediation technique that has the ability to produce long-lasting changes to benthic communities.

## 24-9

**Sponge-Mediated Coral Reef Restoration: Efficiency, Sustainability And Relative Performance**

**Brendan BIGGS*[1]**

[1]Biological Sciences, Florida State University, Tallahassee, FL

Physical disturbances damage coral reef three-dimensional structure, leaving behind unstable debris. Reef recovery is dependent, in large part, on coral reestablishment, and substratum stability is critical to the success and survival of live fragments and coral recruits. Coral reef sponges, whose attachment can anchor live coral and stabilize loose carbonate, help mediate the process of reef rejuvenation by providing time for the consolidation of coral skeletons by crustose coralline algae. Restoration efforts currently employ epoxy and cement to secure rubble and upended colonies, but these agents are unnatural, possibly less attractive, and potentially unfavorable to coral larvae. Utilizing organisms that naturally bind and stabilize rubble to help restore reefs has largely been overlooked. On shallow, fringing reefs in Curacao, four treatments varying substratum and binding agent -- coral rubble alone, coral rubble seeded with sponge fragments, coral rubble bound by cement, and cement rubble bound by cement -- were used to assess the performance of sponges relative to cement as a binding agent and to investigate preference of coral larvae for natural vs. artificial substrata. Regrowth of branch tips removed from sponges (*Niphates erecta*, *Aplysina cauliformis*, and *Aplysina* sp) for seeding coral rubble was also measured to evaluate the sustainability of sponge use. Sponge fragments attached to rubble readily, stabilizing and anchoring piles rapidly. Rubble piles with sponges had significantly more coral recruits, and were taller and tighter in shape, than coral rubble alone. Recruitment was heaviest to coral rubble bound by cement, but did not differ significantly for natural vs. artificial substrata. Regrowth was slowest for *N. erecta*, while both *Aplysina* species replaced tissue rapidly. Results indicate that using sponges to boost reef recovery is both feasible and sustainable and would be an effective natural addition to current restoration techniques.

## 24-10

**Species Specific Sensitivities Of Transplanted Coral Fragments From Eleven Species To Predation And Bleaching**

**Romeo DIZON*[1]**, James GUEST[2], Edgardo GOMEZ[1], Alasdair EDWARDS[2]

[1]The Marine Science Institute, University of the Philippines, Quezon City, Philippines, [2]School of Biology, Newcastle University, Newcastle upon Tyne, United Kingdom

The selection of appropriate coral species is critical to the success of restoration interventions involving coral transplantation. Knowledge about the tolerance of species to various stressors, e.g. predation, disease and bleaching, is essential in deciding which are most suitable for transplantation. In this study, the performance among species and between two fragment sizes (3 to 5cm and 5 to 11cm) was compared for 11 coral species (*Acropora muricata*, *Echinopora lamellosa*, *Hydnophora rigida*, *Heliopora coerulea*, *Montipora digitata*, *Pocillopora damicornis*, *Pavona frondifera*, *Porites cylindrica*, *P. lutea*, *P. nigrescens* and *P. rus*). A total of 100 fragments of each species were attached to a standard calcium carbonate substrate (dead *Tridacna* shells) at five sites in a shallow lagoon (3-4 m depth) near Bolinao, north-western Philippines during December 2005 and February 2006. The survival and status of the 1100 transplants were monitored fortnightly for the first 6 months and semi-annually subsequently. On each occasion, mortality, partial mortality, predation and bleaching were noted for each transplant. Early mortalities were due to the predation of the muricid gastropod, *Drupella* sp., on *A. muricata* and the nudibranch, *Phestilla* sp., on the *Porites* transplants. Elevated water temperatures during June and July 2007 caused total or partial bleaching in 62% of the living transplants. Subsequently, survivorship of the transplants dramatically decreased. Periodic monitoring from July to November 2007 revealed inter-specific differences in their relative resistance to, and recovery from bleaching. *P. frondifera* was the most resistant species while *H. coerulea*, *P. lutea* and *M. digitata* were the fastest to recover. Although some species were generally susceptible to bleaching, some genotypes within a species showed remarkable recovery after bleaching.

## 24-11

**Assessment Of Gorgonian Transplantation Techniques Offshore Southeast Florida, Usa**

**Vanessa BRINKHUIS*[1]**, Alison MOULDING[1], Vladimir KOSMYNIN[2], David GILLIAM[1]

[1]National Coral Reef Institute, Nova Southeastern University Oceanographic Center, Dania Beach, FL, [2]Florida Department of Environmental Protection, Tallahassee, FL

Due to continuing anthropogenic degradation of coral reefs worldwide, there is need for effective and experimentally tested reef restoration protocols. Much effort has been spent on scleractinian coral transplantation. However, less attention has been directed towards effective techniques for the transplantation of gorgonians (Coelenterata: Octocorallia). This study used clippings from healthy adult *Pseudopterogorgia acerosa* and *Plexaura flexuosa* gorgonian colonies to test the effectiveness of several gorgonian attachment techniques. In April 2007, 40 donor colonies of each species were tagged. A total of 80 clippings (25cm) were collected from each species (2-3 clippings from each donor colony). A ship grounding site offshore Broward County, Florida was chosen as the transplantation site. Forty clippings from each species were attached with cement, and 40 were attached with epoxy (attachment material treatments). In addition, 40 clippings from each species had 10 cm of their base tissue removed from around their proteinaceous axis, and 40 clippings did not undergo base stripping (base treatment). Donors and clippings were monitored 1, 2, 3, and 6 months post-transplantation. Within the first month all clip wounds on the donor colonies were completely healed. By 6 months species specific differences in success were evident. The highest percent attachment and survival was 100% for both *P. flexuosa* base treatments attached with epoxy, and the least successful treatment, with the highest percent missing and lowest survival at 60%, was the *P. acerosa* non-base-stripped treatment attached with cement. It appears that for *P. acerosa,* tissue that had not been stripped became necrotic and sloughed off, resulting in a loose attachment which prevented the clippings from growing over the attachment material. This project provides resource mangers with quantitative evidence that gorgonian transplantation can be an effective part of reef restoration activities.

## 24-12

**Staghorn Corals Transplantation, a Method to Increase Axial Polyps (AP) Quantities of Transplants Using Cicatrisation Tissues High AP Generation Potential. Applications on Acropora microphtalma, Acropora muricata and Acropora pulchra**

**Cedric GUIGNARD*[1]**, Thomas LE BERRE[1]

[1]Seamarc Pvt Ltd, Male', Maldives

High growth rates and availability of broken fragments have made staghorns the most commonly transplanted hard coral species. During the first 3 months after transplantation, Axial Polyps Generation (APG) is an important factor to consider for the future transplant's shape and productivity. Then avoiding any damage of Initial Axial Polyps (IAP) seems logical to preserve the "branching" fragments potential. However, recent observations made in the Maldives indicate that cicatrisation tissues covering broken sections, here named "Cuts", had a higher APG potential than IAP themselves. To verify this hypothesis, an initial experiment using 80 fragments of *Acropora muricata,* has been set up to compare APG of the fragments with at least one IAP to those without. After 3 months the results showed a significant difference. Transplants with IAP presented an average of 3,0 AP (+/- 0,5 at 95% CI) while transplants without IAP presented an average of 5,9 AP (+/- 0,6 at 95% CI). To investigate a practical application of this result, several experiments including also *Acropora pulchra* and *Acropora microphtalma* species have been launched following different protocols where fragments where especially damaged to increase the quantity of cicatrisation tissue areas. These damages are named "Extra Cuts" and aims at producing Extra Axial Polyps (EAP), this to valorise fragments Radial Polyps (RP) areas which have been proved to have a low APG potential in the first experiment. This permitted to develop a method able to produce EAP and then to increase transplants AP quantities without causing any significant mortality. This method was found easy and productive to valorise a fragment stock.

## 24-13

**Using Reef Resilience Principles To Improve Staghorn Coral (Acropora Cervicornis) Restoration in The Florida Keys**

**Meaghan JOHNSON*[1]**, Phil KRAMER[1], Ken NEDIMYER[2]

[1]The Nature Conservancy, Summerland Key, FL, [2]Healthy Reefs Inc., Tavernier Key, FL

Significant declines in living coral coverage within the Florida Keys National Marine Sanctuary (and worldwide) have occurred in recent decades due to local, regional, and global threats. In particular, populations of the important reef building branching staghorn coral, *Acropora cervicornis*, have declined 80-90% throughout the Caribbean and western Atlantic since the late 1980's, and has recently been listed as threatened under the Endangered Species Act in May 2006. This project aims to restore degraded reefs in the Upper Keys by transplanting fragments of naturally occurring, and wild staghorn coral. Approximately 25 staghorn coral colonies naturally settled onto a privately owned live rock farm within Sanctuary waters in the Upper Keys. In addition to these 25 parent colonies, 22 wild colonies were collected, fragmented, and brought back to the live rock farm (coral nursery). All of these colonies were fragmented, and cemented to small cement casts, that remain on platforms within the coral nursery. The genotypic identity of these corals was also determined within the first six months. This genetic marker will serve as a tool that allows for long term tracking of recruitment and proliferation. In November 2006, these fragments were outplanted to four different restorations sites, located within different reefs zones determined by the Florida Reef Resilience Program. These restoration sites will be monitored for coral growth rates, mortality, and the recolonization of reef-dwelling organisms. We expect to create a series of localized staghorn thickets following the rapid growth and expansion of the transplanted fragments. This project has now been expanded to three more sub-regions( Lower Keys, Miami transition, Broward), with future plans to expand to the Caribbean region.

## 24-14

**Coral Recovery And Rehabilitation From Blast Fishing in Indonesian Rubble Fields**

**Helen FOX*[1]**, Roy CALDWELL[2], Sangeeta MANGUBHAI[3]

[1]Conservation Science, World Wildlife Fund-US, Washington, DC, [2]University of California, Berkeley, Berkeley, CA, [3]P.T. Putri Naga Komodo, Labuan Bajo, Indonesia

Although fishing with explosives (dynamite or homemade bombs) continues to impact reefs throughout Indonesia and beyond, there are success stories where blasting has been halted and the surviving reefs protected, such as in Komodo National Park. Here, we report results of long-term research (10 y) examining natural recovery from blast fishing and the efficacy of rock piles as a low-tech, locally-available reef rehabilitation method. Comparative studies in North Sulawesi of acute single blasts of known age showed that this rubble slowly stabilized, and craters filled in with surrounding coral and new colonies. After five years, coral cover within craters no longer differed significantly from control plots. In contrast, the large rubble fields created by chronic blasting in Komodo remain devoid of corals despite adequate supply of coral larvae, with no appreciable natural recovery over 10 years, hence the need for rehabilitation research. After pilot studies of different methodologies (1998-2002), locally quarried rocks were chosen to scale up. In 2002, four different configurations of rock piles were installed at four sites, covering ~6000$m^2$total. Rock piles stabilize the rubble, attenuate water currents, re-create the three-dimensional structure of an intact reef, and provide surfaces for coral recruitment and refuges for other invertebrates and fish. Coral recruitment was considerable and coral colonies grew at the rate of 15-20 cm/year at some sites, but rubble encroachment remains a problem at the highest current sites. Thus, this rehabilitation method is feasible at these scales at lower cost than most, although this work highlights the need for comparative studies. Furthermore, it would likely be cheaper and more efficient to prevent the damage in the first place.

## 24-15

**Lessons for Minimizing Impacts to Coral Reef and Other Ecosystems from the 2004 Tsunami**

**Dwayne MEADOWS*[1]**

[1]Office of Protected Resources, National Marine Fisheries Service, Silver Spring, MD

The 2004 Indian Ocean tsunami left a vast amount of destruction in its wake on land and in the sea. About 60% of coral reefs in affected areas of Thailand were damaged. Many damaged reef areas in Thailand and Sri Lanka were high value tourist attractions or provided other important ecosystem goods and services. We were part of a fortuitous partnership of people with experience in reef restoration, coral reef science, marine debris removal, construction, professional SCUBA diving, business, marketing, and environmental NGOs. We helped organize and funded multiple restoration and cleanup projects that restored damaged and detached sea fans in Similan Islands Marine National Park, restored hard corals, removed over 400 tons of marine debris, and provided sustainable management advice to local stakeholders and decision-makers. We later became involved in advising emergency management agencies on tsunami preparedness and response. We report on lessons learned for re-attachment of large sea fans, triaging and organizing large-scale volunteer marine debris recovery and coral ecosystem restoration efforts, and mitigating and planning for future natural disaster impacts on fishery ecosystems. We argue that "natural" disasters can cause significant damage to reefs, and much damage results from human sources that are not "natural" and can be mitigated or prevented (such as siting and land use decisions that lead to debris affecting reefs). Thus we disagree with those who say natural events like hurricanes or tsunamis "are not appropriate for reef restoration". Further, governments need to recognize the economic and inherent values of ecosystem goods and services in natural disaster response legislation and policies (e.g., The Stafford Act in the U.S.) to improve outcomes. We also argue that ecosystem advocates need to adopt the language of emergency management and become more involved in emergency management disaster planning.

## 24-16

**Sea Fan Recovery after the Tsunami 2004 at Mu Ko Similan National Park, Andaman Sea, Thailand**

**Sakanan PLATHONG*[1]**, Charles BENZIES[1], Fumihito IWASE[2]

[1]Coral Reef and Benthos Research Unit, Department of Biology, Prince of Songkla University, Hat Yai, Songkla, Thailand, [2]Kuroshio Biological Research Foundation, Tokyo, Japan

At the Similan Islands, Thailand, one of the biggest impacts from the tsunami was on the gorgonian sea fan where approximately 250 individual colonies were found to have fallen from their substrate. As part of the reef recovery efforts following the tsunami, a project aimed at sea fan reattachment was launched in January 2005 and continued through the year. Many fallen sea fan colonies were lying on the sea floor for 2 weeks - 4 months, where they suffered tissue damage. Initially the sea fans were temporarily supported in the flowing current to enable feeding while methods of permanent reattachment were investigated. Fallen sea fans were reattached using a variety of methods. One hundred sixty four colonies were cemented to a rock substrate aboard a boat and then replaced by divers back in the floor. Wooden wedges were used to hold 54 sea fans into cracks in the rock substrate. Iron rods hammered into the sand, rocks placed at the base of the sea fan and cable ties were also used to support sea fans temporarily. Many large sea fans had to be cut into segments to make them more manageable. In total, about 450 whole sea fans or colony fragments have been recovered and reattached. Recovered sea fans showed a high occurrence of infected tissue due to an unknown microbial infection, often resulting in severe or total tissue loss and death of the colony. The infection, characterised by white matter spreading rapidly over the axial skeleton, was shown to be Aspergillosis. As of February 2006, about 80% of recovered sea fans found and about 50% of the total number of colonies recovered has survived.

## 24-17

**Coral Community Restorations Following Vessel Groundings in Broward County, Florida: A Review Of Efforts And Future Needs**

Bruce GRAHAM[1], **Erin HODEL*[1]**, Anne MCCARTHY[1]

[1]CSA International, Inc., Stuart, FL

Frequent vessel groundings have impacted coral communities offshore Broward County, Florida, causing structural and biological impacts of variable severity and areal extent. To accelerate natural recovery processes of damaged habitat, CSA International, Inc. (CSA) has conducted restoration following six of these groundings. Restoration included reattachment of displaced and fractured biota, re-establishment of structural complexity, rubble stabilization, and removal of material that may impede natural recovery. In total, over 2,000 scleractinian corals, gorgonians, and sponges were reattached, and approximately 147 tons of rubble were stabilized to restore the three-dimensionality of the habitat. Post-restoration monitoring has only been conducted at several restoration sites. CSA conducted monitoring of re-attached coral colonies, coral recruitment, and other epibenthos at multiple-year intervals after restoration of the *M/V Firat* grounding. Monitoring of epibenthos and ichthyofauna was performed 6 months after restoration of the *M/V Eastwind* grounding. Together, these data indicate high survivorship of reattached biota (≥90%), successful recruitment of corals and other epibenthos to restored substrates, and re-established abundances of reef fishes. Furthermore, CSA has tagged and mapped over 1,000 biotal specimens and conducted baseline biological surveys from the six restoration sites to facilitate potential monitoring. Future monitoring of biotal reattachment success and health, coral recruitment and survivorship, succession of epibenthos, and reef-fish assemblages at these restoration sites would greatly benefit evaluation of their long-term success. These restorations offer a unique opportunity to examine biotal succession and recovery times of coral communities following vessel groundings in southeast Florida. CSA is currently seeking means to continue monitoring these restoration sites to evaluate their long-term success and gather data to support future decision-making about restoration actions and inputs into Habitat Equivalency Analyses, an important tool in determining lost ecological services.

## 24-18

**Large Coral Transplantation in Bal Haf (Yemen): An Opportunity To Save Corals During The Construction Of A Liquiefied Natural Gas Plant Using Innovative Techniques**

**Olivier LE BRUN*[1]**, Eric DUTRIEUX[2], Fannie SEGUIN[3], Robert HIRST[4], Ibrahim AL-THARY[4,5]

[1]CREOCEAN, LA SEYNE SUR MER, France, [2]CREOCEAN, Montpellier, France, [3]CREOCEAN, St Pierre d'Oléron, France, [4]Yemen Lng Company, Sana'a, Yemen, [5]Yemen Lng Company, St Pierre d'Oléron, Yemen

As part of a mitigation measure associated with the construction of a Liquiefied Natural Gas (LNG) plant, four large coral transplantation missions were carried out in Bal Haf (South of Yemen), About 1,500 selected coral colonies were removed from four areas to be damaged with a surface area of 900, 2,700 and 3,500 m2.respectively. The coral colonies were transported and cemented in five new sites of 300 to more than 500 m2 surface area. They belong to more than 40 species and 23 genera, with a dominance of massive forms such as *Platygyra daedalea*, *Porites lobata-lutea*, *Favites sp* and *Echinopora lamellosa.*

These transplantations included moving 130 large *Porites lutea-lobata* weighing from 200 kg up to 4 tonnes, using new transplantation techniques.

Growth, *in situ* mortality and health condition of the transplants were monitored over nine months on a quarterly basis and will be followed for another 2 years at least. Photo quadrats, close up pictures of single remarkable colonies and growth measurements for *Acropora* species and a selection of large *Porites* were carried out during each of the three operations.

Overall survival of corals nine months after transplantation was an encouraging 95%. Most losses of transplants were due to sedimentation of fine particles in the transplanted areas, fish predation, fishermen activity and hydrodynamic effects. Evidence of new growth was observed, especially on *Acropora* species, *Porites lobata-lutea* and, to a lesser extent, on some faviids.

These transplantations carried out on a large scale clearly demonstrate the capacity of corals to adapt to a new environment, in favourable conditions. They prove that carefully designed coral reef rehabilitation strategies can be part of industrial development processes, whenever necessary.

## 24-19

**Coral Relocation For Impact Mitigation in Northern Qatar**

**Deborah KILBANE*[1]**, Bruce GRAHAM[1], Robert MULCAHY[1], Dr. Ali ONDER[2], Mark PRATT[2]

[1]CSA International, Inc., Stuart, FL, [2]Safety, Health, Environmental, & Risk Management, Qatar Liquefied Gas Company Ltd., Doha, Qatar

A large-scale, long-distance coral relocation project was conducted as mitigation for potential impacts to hard coral habitat associated with marine construction activities offshore Ras Laffan Industrial City, Qatar. Working under the guidance of the Supreme Council for the Environment and Natural Reserves, Qatargas Operating Company Limited and its Expansion Projects engaged in a project to transplant over 4,500 corals from proposed pipeline corridors. Corals were transported 46 km from the north coast of Qatar to a fasht coral habitat along the east coast. This project represents an option for off-site mitigation and is an excellent example of proactive environmental regulation, corporate responsibility, and advanced field technology applied in concert to reduce impacts to a viable hard coral habitat.

Hard coral relocation, which salvages and utilizes hard corals to accelerate natural coral habitat recovery in other areas, was implemented to reduce impacts associated with pipeline construction activities. Proven techniques for coral reattachment and newly developed methods designed to enhance coral survival were used for the efficient mass recovery, transport, and deployment of the corals. The relocation site was selected from 7 candidate sites based on local stakeholder consultation, the presence of an existing coral population, relative similarity of physical characteristics to the impacted area, and availability of suitable substrate for coral reattachment. Hard corals were transported in a specially designed, flow-through seawater holding pool during the single day transit to the relocation site and reattached using concrete. Within the reattachment site, temperature data loggers were deployed and approximately 5% of the reattached corals and control corals were selected and uniquely tagged for subsequent monitoring. Initial monitoring indicated high survival rates and habitat enhancement based on assessment of coral, epibiota, fish, and urchin populations. Future long-term monitoring will provide information on coral community dynamics in the Arabian Gulf.

## 24-20

**Lessons Learnt From Applied Restoration Projects**

**Sandrine JOB*[1]**

[1]Reef Restoration, CRISP, Noumea, New Caledonia

The talk aims at presenting some lessons learnt from 4 restoration projects that have been conducted in the Indo-Pacific (Mayotte, New Caledonia, Fiji and Tuvalu; the 2 last projects being conducted under the CRISP Program).

A brief overview of these projects, their objectives, methods used and general results will be given. An analysis of what went right or wrong will lead to possible recommendations on how the projects could be redesigned to enhance their results.

Based on this specific work, a best practices guideline for conducting applied restoration projects will be discussed and general key instructions to follow while designing a restoration project will be proposed. This work is currently being performed for the writing of a Manual on Reef Restoration, a joint venture between CRTR and CRISP.

## 24-21

**Mass Culture Of Reef Building Corals in Open Water At Akajima Marine Science Laboratory**

**Makoto OMORI*[1]**, Kenji IWAO[1], Hiroki TANIGUCHI[1], Minoru TAMURA[1]

[1]Akajima Marine Science Laboratory, Okinawa, Japan

Since establishment in 1988, Akajima Marine Science Laboratory made effort to study reproduction and evolution of corals at Akajima Island, Okinawa. Based on the knowledge acquired in the process, the scientists are now developing techniques to culture *Acropora* corals from eggs using sexual reproduction. They have overcome a number of hurdles, including 1. prediction of spawning date and time, 2. collection of larvae from the sea or fertilization of gametes in the laboratory, 3. mass culture of planula larvae, 4. introduction of the larvae to substrate, and 5. cultivation of juvenile corals in cages in open water. The juvenile corals were cultured together with juvenile top shells, *Trochus niloticus*, which were used to control macroalgal growth. In June 2005, *Acropora tenuis* was cultured from eggs and by December 2006 the juvenile corals had grown to an average diameter of 5.8 cm in cages suspended 2 m above the seafloor in open water. About 2,000 colonies were then transplanted onto nearby degraded bommies and fixed in place using pegs and underwater glue. Six months later, in June 2007, 89% of the colonies were alive, firmly attached to the substrate, and had increased in size to an average diameter of 9.1 cm. After further development, this technique promises to be an economical and effective way to culture corals for restoration of damaged reefs.

## 24-22

**Mass Culturing Of Corals Using Sexual Reproduction Technique In Thailand**

**Suchana CHAVANICH*[1]**, Voranop VIYAKARN[1], Chalothon RAKSASAB[1], Pataporn KUANUI[1], Kenji IWAO[2], Makoto OMORI[2]

[1]Marine Science, Chulalongkorn University, Bangkok, Thailand, [2]Akajima Marine Science Laboratory, Okinawa, Japan

Recently in Thailand, mass culturing of spawning corals using sexual reproduction technique was developed. Gametes of 4 coral species (*Acropora millepora*, *Acropora hyacinthus*, *Acropora humilis*, and *Platygyra daedalea*) were collected from natural habitats and fertilized on a land-based rearing system. Then, planula larvae were induced to settle on substrates, and were reared in this system for 2 weeks to 6 months before transferred to floating cages in the sea. In the rearing system, the rates of fertilization of each species ranged between 92.1 – 97.0%. Meanwhile, the self fertilization rates of the same colony in each coral species ranged between 1.9 – 3.3%. After the fertilization, the survival rates of larvae were between 83.4 – 94.2%, and the settlement rate of planula larvae were 49.5 – 75.2%. In all species, the embryo developed into a planula stage within couple days, and settled on the substrates within 4 – 5 days after the gametes were released from the parental colonies. The results from the experiments showed that high numbers of larvae settled on the bottom of the settlement plates compared to the top or sides of the plates. In addition, planula larvae of *Pocillopora damicornis* were collected and reared in the rearing system. The settlement rates of *P. damicornis* larvae were 62.8%, and the survival rate of juvenile corals after the settlement was 71.9%. The growth rates of five species ranged between 1.5 – 3.7 mm per month. This is the first time that Thailand has success in the mass coral culturing using gametes. At present, juvenile corals were about 6 months old and the maximum size was about 1 cm in height.

## 24-23

**Implementing *acropora Spp.* larval Settlement Techniques And A Coral Hatchery System To Gain Insights Into The Survivorship Of Juvenile Acropora Spp. Polyps**

**Charles BOCH*[1]**, Aileen MORSE[2]

[1]Interdepartmental Graduate Program in Marine Science, University of California Santa Barbara, Santa Barbara, CA, [2]Marine Biotechnology Center, University of California Santa Barbara, Santa Barbara, CA

A pilot study was conducted (2006) at the Palau International Coral Reef Center (PICRC) to compare the efficacy of several types of "larval flypaper" for settlement of some common regional *Acropora spp.* larvae in a controlled laboratory setting and to determine and compare the survivorship of newly settled *Acropora spp.* polyps in a coral hatchery. For the first experiment, we used coralline algae (*Hydrolithon sp.*) derived "larval flypaper" in 6-well culture plates to settle *A. digitifera* larvae. For the second experiment, we used small (~1-2 mm) coralline algal chips in 6-well culture plates to settle *A. tenuis* and *A. digitifera* larvae—however, species were not distinguishable after settlement. Newly settled polyps in the culture well plates were placed facing up or down in the hatchery. A subset of each experiment was transplanted to Ioul Luke's Reef to compare the over-all survivorship. At 44 days from the initial start of the experiments, total survivorship in the coral hatchery ranged from 57 – 87%. After 70 days, total survivorship dropped to 30 – 31% before dropping to a final survivorship of 0% at the end of the 126-day experiment. For the reef experiment, after 126 days, total survivorship ranged from 8 to 9%. A rise in phosphate level, a steep temperature drop and significant algal fouling in the hatchery system were recorded about two months into the experiment. The decline in survivorship with this increase in algal fouling led us to conclude that, at this location, it would be advisable to hold newly settled polyps in the hatchery for a period of approximately two months before polyps become negatively impacted by algal fouling. We conclude "larval flypapers" are an efficient method to settle some *Acropora spp.* larvae and coral hatcheries provide valuable insights into the factors that may determine juvenile polyp survivorship.

## 24-24

**Assessing The Efficacy Of *in Situ* Coral Larval Seeding Under High Rates Of Early Post-Settlement Mortality**

**Wade COOPER*[1]**, Diego LIRMAN[1], Megan PORTER[1], James HERLAN[1], John PARKINSON[1]

[1]Division of Marine Biology and Fisheries, RSMAS, University of Miami, Miami, FL

For degraded reef systems with low natural recruitment, active restoration techniques to seed larvae directly onto the reef may provide the impetus to replenish adult stocks. However, *in situ* seeding techniques have only been attempted in a handful of known studies, and the success has been limited in most cases. The goals of this study were to assess the efficacy of seeding larvae directly onto denuded reef substrate and explore techniques to improve the success of this active seeding strategy. In addition, this study compared the success of this direct *in situ* seeding approach to an *ex situ* approach where larvae were settled onto small substrate chips, reared in the laboratory for different periods of time (1 week and four months), and then transplanted onto the reef. Overall, survivorship from *in situ* seeded larvae of the brooder *Porites astreoides* followed an exponential decline with typically less than 10% surviving after two weeks, and in one case survivorship of a cohort was less than 1% after 17 days. In some trials, survivorship was dependent on the general substrate type on which they settled, and survivorship improved when potential predators were excluded by cages. However, the magnitude of these effects was minimal when compared to the improved survivorship of those larvae settled and reared in the lab and then transplanted to the reef at a later age. Given these high rates of early post-settlement mortality within the first few days and weeks, *ex situ* settlement with later transplantation to the reef may be a more efficient use of resources for seeding efforts.

## 24-25

**Development Of A Coral Nursery Program For The Threatened Coral Acropora Cervicornis in Florida**

**James HERLAN*[1]**, Diego LIRMAN[1]

[1]Marine Biology and Fisheries, University of Miami, Miami, FL

Acroporid corals were among the most abundant reef-building corals on Caribbean reefs until a drastic decline resulted in losses of up to 95 % at many locations. This regional decline prompted the listing of *Acropora* as 'threatened' under the U.S. Endangered Species Act in 2006. In response to the need for localized efforts to protect and recover surviving populations of staghorn coral, *Acropora cervicornis*, an underwater nursery was established in Biscayne National Park, Florida. The goals of this nursery, one of four such nurseries established in Florida, are to develop effective fragmentation and propagation methodologies and to evaluate the role of genetics on coral resilience.

In June 2007, branch clippings (10 cm) were collected from *A. cervicornis* colonies and fragmented into 3-7 cm sections that were glued onto cement bases in vertical and horizontal orientation. The bases were glued onto cinder blocks and placed in the nursery established at 6 m of depth. The fragmentation and transplantation methods used were very efficient and resulted in limited fragment mortality;14 % of fragments died within the first month, but subsequent mortality has been minimal.

The growth of fragments was influenced by time after transplantation, size, and orientation. The growth rate of fragments was 0.6 cm/month during the first 6 weeks after transplantation and increased to 0.9 cm/month in the subsequent 6 weeks. Growth was positively related to initial fragment size, and fragments in horizontal position grew significantly faster (0.9 cm/month) than fragments in vertical position (0.6 cm/month) due to the ability of these fragments to grow from both ends. The fast growth of this species makes it an ideal candidate for restoration programs and it is expected that the staghorn fragments kept in Florida nurseries will provide an expanding coral stock to be used in future reef restoration and scientific experiments.

## 24-26

**Comparisons between Directly Transplanted and Nursery-reared Coral Fragments in Bolinao, Northwestern Philippines**

**Dexter DELA CRUZ*[1]**, Baruch RINKEVICH[2], Edgardo GOMEZ[3], Helen YAP[1]

[1]The Marine Science Institute, University of the Philippines, Quezon City, Philippines, [2]Israel Oceanographic and Limnological Research, National Institute of Oceanography, Haifa, Israel, [3]The Marine Science Institute, University of the Philippines, Quezon CIty, Philippines

Direct transplantation is the current method of choice in reef restoration efforts worldwide, though with varying degrees of success, probably due to the stress imposed on the fragments or whole colonies used. The alternative method of rearing fragments in coral nurseries located at sheltered reef zones is now used as an intermediate step with the goal of producing robust transplants that will survive better than directly transplanted fragments. These two methods are compared in field experiments in Bolinao, northwestern Philippines using 2 common species, *Echinopora lamellosa* and *Merulina scabricula*. The first experiment compares the survival of wild nubbins (~3-4 cm) that are maintained in a field nursery versus similar fragments that are transplanted directly to dead coral bommies. The second experiment compares the performance of nursery-reared coral nubbins with that of similar-sized fragments (~5 cm) collected from the wild by attaching both types of transplants to natural substrates. Survival was monitored monthly. Three end points were selected, namely, 7 months after transplantation (normal conditions), a month after the June 2007 bleaching event (elevated water temperature) and 3 months after bleaching (post-bleaching recovery phase). Kaplan-Meier survival analyses (employing Gehan's-Wilcoxon pairwise test) showed that the three end points yielded consistent results. There were significant differences between the two methods for *E. lamellosa* in the first experiment, while there were no significant differences between wild and nursery-grown corals for both species in the second experiment. These results indicate that some species fare better when maintained in nurseries; however, this advantage is not necessarily carried over after they are transplanted to natural substrates.

## 24-27

**Use Of Aquacultured Coral Fragments For Restoration Activities in The Florida Keys: Culture Techniques And Health Certification**

**Ilze BERZINS*[1]**, Craig WATSON[2], Roy YANONG[2], Kathy KILGORE[2], Casey COY[1], Ryan CZAJA[1], Lauri MACLAUGHLIN[3], Billy CAUSEY[3]

[1]The Florida Aquarium, Tampa, FL, [2]Tropical Aquaculture Laboratory, University of Florida, Ruskin, FL, [3]Florida Keys National Marine Sanctuary, Key West, FL

Many species of Atlantic Scleractinia can be fragmented and grown successfully in aquaculture systems, but can they be reintroduced to the wild? This study addressed two primary questions concerning the use of aquacultured fragments for restoration: 1) whether culture techniques affect survival and growth of reintroduced fragments, and 2) could these fragments be a vector for disease when returned to a restoration site?

Addressing the first question, 210 fragments were cut from 7 species (30 per species) of coral collected from the Truman Annex site in Key West Harbor. The fragments (*Siderastrea radians*, *Solenastrea bournoni*, *Montastrea annularis*, *Montastrea cavernosa*, *Diploria clivosa, Dichocoenia stokesii*, and *Stephanocoenia michellini*) were distributed to two culture locations and one open reef site. The land-based fragments were grown in culture for 7 months prior to transplantation in the field. Transplantation of corals to Miss Beholden grounding site, Western Sambo Reef, occurred in December, 2006. Monitoring of the site will follow 3 month intervals for 2 more years.

To answer the second question, a standard best management practice was developed to ensure that corals intended for reintroduction are healthy prior to restoration. These procedures and other diagnostic methods were used to develop criteria for issuance of a federal health certification before reintroduction of corals to restoration sites.

## 24-28

**Genet Considerations in Acropora Cervicornis Propagation in Restoration**

**Andrew ROSS*[1]**

[1]Life Sciences, University of the West Indies, Montego Bay, Jamaica

Coral restoration, propagation and gardening are concepts gaining interest and impetus in research and backing in conservation, aesthetics and politics as the plight of corals gains popular visibility, particularly in the specter of global climate change. In investigating propagation it is important to understand the how choice of parent material influences final outcomes. Significant differences in growth rate, branching morphology and resistance to bleaching were recorded between genets of Acropora cervicornis propagated in buoyant-line nurseries in Montego Bay, Jamaica in 2005 through 2007. In 2005 differences between genets were noted in growth rate, branch number and overall branched growth rates. In 2006 final length differences were noted between genets at all depths without differences within genets between depths. Branch number and overall branching length were different between depths however, with higher overall branching length and branch number at shallower depths. Strong genet differences were also seen in susceptibility to bleaching at all depths. These patterns continued through the 2007/8 experiments using ramets produced in the 2006 growth trials, though bleaching was driven largely by re-fragmentation and nursery fouling organism contact and stinging stresses. Although some level of adaptation or hardening to stress-related bleaching was observed, genets with faster growth and branching were always relatively more resistant to bleaching and associated death indicating generally stronger or weaker genets. It is apparent that choice in genet for propagation must be carefully considered in any restoration programme, particularly considering the monetary costs involved and the potential rarity of the species concerned. Similarly, the long-term goals of any propagation programme must be considered such as breadth of genetic differentiation for effective sexual reproduction or long-term success through associated human gardening or other water quality and ecosystem management programmes when choosing the genets invested in.

## 24-29

**A Land-Based Resource For Ecologically-Important Western Atlantic Corals**

**Thomas CAPO*[1]**, Phillip GILLETTE[1], Daniel DIRESTA[2], Richard CURRY[3], Chris LANGDON[1], Andrew BAKER[1], Diego LIRMAN[1], Iliana BAUMS[4]

[1]MBF, University of Miami RSMAS, Miami, FL, [2]Department of Biology, University of Miami, Coral Gables, FL, [3]Biscayne National Park, Homestead, FL, [4]Department of Biology, Pennsylvania State University, University Park, PA

Coral reefs in the continental US show their greatest development along the SE coast of the state of Florida. The northern portion of the reef tract is found within Biscayne National Park, where it is of high intrinsic value for both scientific and recreational reasons. The state of the reef has declined over recent years due to both natural and anthropogenic stressors. Given these threats, the loss of corals within the park due to accidental boat groundings represents a significant impact on an already dwindling resource. In 2000, we initiated a collaborative research program to evaluate rehabilitation of damaged areas based upon coral fragments recovered from these areas. Orphaned fragments were collected from grounding sites and relocated to a field-nursery in BNP as well as the University of Miami's land-based Coral Resource Facility. Research over the past four years has focused on the initiation of clonal lines to produce uniform ramets for manipulative experiments and on factors controlling *ex situ* growth rate. Continuing trials are targeting four key parameters of coral growth and survival: fragment size, supplemental feeding, water movement, and light. The UM Coral Resource Facility now houses over two dozen coral species, of which five have been targeted for intensive culture and mass growout: *Acropora cervicornis, A. palmata, Montastraea faveolata, Oculina* sp.*,* and *Porites furcata*. To ensure genetic diversity, five independent clonal lines of each species are in the isolation process. Presently we are providing microcolonies, nubbins, and macrocolonies with a known environmental history and documented genetic profile to investigators for studies in coral physiology, epidemiology, ecotoxicology and restoration research. Incorporating advances in coral propagation and building on our successful growout, we are expanding the present UM facility to hold more than 10,000 coral fragments of the 5 target species in support of coral research.

## 24-30

**Spatial and Temporal Patterns In The Recruitment And Settlement Behaviour Of Scleractinian Coral Larvae On Artificial Substrata: Applicability And Implications For Coral Reef Restoration**

**Cristiana DAMIANO*[1,2]**, Peter HARRISON[1]

[1]School of Environmental Science and Management, Southern Cross University, Lismore, Australia, [2]National Marine Science Centre, Coffs Harbour, Australia

The discipline of coral reef restoration through larvae reseeding remains in its formative stage. While preliminary studies have indicated the viability of inducing laboratory-cultured coral larvae to settle on reefs, almost no work has been done to determine their subsequent growth and survival, or the extent to which such 'reseeding' facilitates the rapid and efficient recovery of coral communities. This latter information is a prerequisite for reseeding techniques as a mechanism for promoting the restoration of corals. Equally importantly, identifying the key factors influencing the fate of coral recruits is an essential component of coral reef ecology that will ultimately assist management agencies to define clearer protocols for their future conservation throughout the world. Here we present results of research done from 2003/06 to assess the applicability, benefits and disadvantages of scleractinian coral larvae rearing and reseeding techniques on artificial substrata under laboratory conditions at Heron Island Research Station, Australia. Gravid colonies of *Acropora millepora* and *Platygyra daedalea* were collected and the predictable annual mass spawning provided access to large quantities of larvae, which were reared in aquarium facilities for six days and transferred to 70-l plastic tanks, containing three replicates of two preconditioned ceramic tile orientations (horizontal and 45°). After seven days, settled spats were taken back to the reef and monitored for growth and survival via a repeated-measure sampling technique. High rates of settlement and recruitment were observed for *A. millepora* planulae, supporting the viability of using laboratory-reared larvae for coral reef rehabilitation and restoration programs. However, longer-term survival rates were low, particularly after a widespread bleaching event that affected Heron Island's reefs during summer 2006/07. Although these results are preliminary, they nevertheless support the need for ongoing research to more fully describe the ecological processes contributing towards planulae recruitment and survival as a prerequisite for restoration programs.

## 24-31

**Reef Restoration—The Good And The Bad**

**Jere LIPPS*[1]**

[1]Integrative Biology & Museum of Paleontology, University of California--Berkeley, Berkeley, CA

Little good and a lot of bad come from reef restoration. Reefs damaged by humans and nature are "restored" using unnatural materials as substrata quickly occupied by corals and fish. This is commonly considered good, for seemingly the reef has been returned to a "healthy" state; fish can be caught again and tourists return for the "beautiful reefs". Restoration, the act of restoring to a former state, has never been accomplished on a reef; rather reefs have been manipulated to conform to particular human values without regard for the entire reef--its ecology, trophodynamics, hydrodyamics, physical or chemical characteristics of pseudo-substrata, geochemistry, nutrient supply, and even reef aesthetics among a multitude of others. People seemingly cannot leave well enough alone when it comes to reefs that have been noticeably damaged. Yet, that is exactly what reefs need—time without interference. Emotional reactions without careful analysis of the total consequences of various methods are ill-advised. Reefs evolved over millions of years in one of the harshest environments on earth—the air-water interface. They are well adapted to recover from physical damage of almost any sort. Reefs are not fragile. Thoughtful assistance would help, using materials occurring naturally within reef systems, by involving regional stakeholders in natural processes of restoration, and by stringent protection regulations and agreements. Opportunistic "restoration" by well-meaning, misguided or avaricious people without careful consideration of what really constitutes a reef is a major mistake that will eventually need restoration itself. Do we need more junk on our reefs?

## 24-32

**Reef Rehabilitation At Maiton Island: The Prototype Of Rehabilitation By Using Artificial Substrate in Thailand**

**Hansa CHANSANG*[1]**, Nalinee THONGTHAM[1], Ukkrit SATAPOOMIN[1], Niphon PHONGSUWAN[1], Pitul PANCHAIYAPHUM[2], Vipoosit MANTACHITRA[3]

[1]-, Phuket Marine Biological Center, Phuket, Thailand, [2]-, Phuket Marine and Coastal Resources Conservation Center, Phuket, Thailand, [3]Burapha University, Faculty of Aquatic science, Chonburi, Thailand

A pilot project on rehabilitation was carried out at reef of Maiton Island using triangular concrete modules as artificial substrate for coral settlement. The reef was physically damaged by storm and no noticeable recovery was observed after 8 years. Two hundred and twenty-five modules of 50x50x50 cm were placed covering area of 225 $m^2$. The structural design for the modules was based on the objective of study complexity of module structures to reef fish colonization and coral settlement. Monitoring on development of colonization of sessile organisms especially coral and fish population have been carried out periodically.

The modules had successfully increased coral recruitment. Complexity of substrate surface increased chances of coral recruitment. After 7 years, there were 16 genera of coral settled on the surfaces. The total coral cover was about 53-60% of module surface. For fish recruitment, early colonization of fishes in term of number of species and individuals were rapid with in the first 4 months. Fish assemblages did not differ among different complex modules. The fish assemblages stabilized after 7 years and 88 species of 23 genera were sighted. The development of fish assemblages correlate with increasing coral coverage on module surfaces.

At present, there are 1280 modules in the reef covering the minimum area of 1280 $m^2$. This artificial reef will continue to evolve and increase in community complexity. It is evaluated as a successful project considering the outcome and cost effective including labor input.

## 24-33

**Transplantation of *Porites lutea* to Rehabilitate Degraded Coral Reef at Maiton Island, Phuket, Thailand**

**Nalinee THONGTHAM*[1]**

[1]Phuket Marine Biological Center, Phuket, Thailand

*Porites lutea* is among the most common coral species found in Thai waters. Its solid, hard structure enables it to withstand storms and strong waves. It is also tolerant to heavy sedimentation, thus it is appropriate to be used as the main structure in rehabilitation of degraded coral reefs. However, as its growth rate is slower than branching corals, it is not often used for transplantation. The objective of this study, which began in December 2004, is to determine the survival and growth of different sizes of transplanted *P. lutea* at Maiton Island off Phuket, Thailand. Fragments in three different sizes, 4.5x4.5 cm, 3x3 cm and 2x2 cm, were detached from coral colonies and each size was replicated 45 times. Coral colonies of about the same size as the fragments were also collected for comparison. The fragments and coral colonies were cemented on concrete blocks and placed at the same depth as the reef where the corals were taken. Percentage of survival and detachment, as well as diameter and height of those corals were monitored every 3-4 months for 2 years. Survival of bigger fragments and colonies was higher than the small ones, which had more tendency (76%) to be detached from the substrate after ninth months. Mortality of all sizes was between 2 and 17%. Self-attachment of both fragments and colonies was apparent just after one month, but growth in height was slow. A study conducted over 10 years in an adjacent area found that it takes at least seven years for the concrete block to be fully covered and the coral blend with the natural environment. The study found that *P. lutea* could be used as the main structure in rehabilitating coral reefs.

## 24-34

**The Population Of Hard Coral Colonies Growing On Ecoreefs® Artificial Modules On Manado Tua Island, Bunaken National Park, North Sulawesi, Indonesia**

**Tries RAZAK*[1]**

[1]Research Consultant, EcoReefs Project at Bunaken National Park, Bandung, Indonesia

Bunaken National Park in North Sulawesi was established as a marine national park in October 1991 and is one of Indonesia's most well-known marine ecotourism and diving destinations. Unfortunately, many reef areas within the park have been decimated into fields of coral rubble from dynamite fishing that peaked around 30 to 40 years ago. A rehabilitation program was then implemented in December 2003 where 620 EcoReefs® modules were installed on a blast-damaged sloping reef area. In the present study, "returned" populations of hard corals were examined within two-and-half (June 2006) and three years (December 2006) after the installation. On the first trip, 138 modules were examined and a total of 5626 colonies belonging to 31 genera in 15 families were found. The second research trip was performed six months after the first one (December 2006) where 112 modules were studied; the same 112 modules studied on the first trip. Hard coral population on EcoReefs® modules was dominated by family Pocilloporidae, Acroporidae, Milleporidae and Poritidae; that altogether covered 91.4% (June 2006) and 85.4% (December 2006) of the total population. The number of corals per module ranging between seven to 122 colonies; and there was an increase in the average abundance with 45 colonies/module in December 2006 compare to 12 colonies/module (July 2004) and 41 colonies/module (June 2006). In regards to colonies' physical condition, up to 62.1% (December 2006) of the total population were alive and healthy; this number was higher in June 2006 with 77.6%. The remaining of the population (37.9% and 22.4% respectively) were dead colonies covered with algae/crustose coralline algae/sponge, bleached or infected by diseases. These findings showed that artificial reefs can be used as a catalyst in resurrecting marine life, still conserving the live reef ecosystems are easier and cheaper.

## 24-35

**Eco-Block As A Coral-Friendly Contrivance in Port Construction**

**Hidekazu YAMAMOTO*[1]**, Norikazu MAEKOUCHI[2], Takashi ANO[2], Megumi OOGI[2], Syuichi TSUDA[2], Kazuo KURITA[3]

[1]Coastal Environment Department, ECOH Corporation, Taito-ku, Japan, [2]Okinawa General Bureau, Cabinet office, Naha City, Japan, [3]Okinawa General Bureau, Cabinet office, Miyako City, Japan

We confirmed the natural attachment of coral colonies on breakwaters in Naha Port, Okinawa Prefecture in 1989. Having fixed 30 quadrates to the breakwaters, we have been monitoring the growth of corals every year since 1990. The results complied until 2003 were reported by Ooka et al. (2006).

Focusing on this phenomenon as a clue to afford a coral-friendly approach in port construction, we began the development of technology to enhance coral recruitment and growth on concrete armor blocks. The development concept centered on creating roughness on conventionally smooth block surfaces, thus imitating natural substrates as near as possible. The primary experiment began in Naha Port in 1990, followed by the second one in 1991. The findings from these experiments were then applied in the project of the Eco-block in 1999, a wave-dissipating block with abrasive protrusions on its surface. Since the installation of Eco-blocks in 1999, the growth and recruitment of corals on them have been monitored yearly in 36 fixed quadrates. With information obtained here, a similar attempt is underway in Hirara Port in Miyako Island. The surfaces of armor blocks were unevenly processed before their deployment to breakwaters, and their effectiveness has been continually monitored.

Eco-blocks with abrasions at depths of about 5mm and 10mm showed a greater effectiveness in coral settlement. The initial coral recruitment was found to be higher at depths of C.D.L. 5m and shallower. The same results were obtained from the experiment in Hirara Port.

Ooka, S. et al. (2006) Growth of coral assemblages on artificial structures and surrounding natural substrates. Proc. 10th Int. Coral Reef Symposium, Naha., p.91-98.

## 24-36

**Benthic And Fish Community Succession After The 2005 Red Tide Disturbance in The Eastern Gulf Of Mexico: Are Artificial Reefs Effective Mitigation Tools?**

**Jennifer DUPONT*[1]**, Pamela HALLOCK[1], Walter JAAP[2]

[1]College of Marine Science, University of South Florida, Saint Petersburg, FL, [2]Lithophyte Research, Saint Petersburg, FL

A harmful algal bloom (red tide) and associated anoxic/hypoxic event in 2005 resulted in massive fish kills and the collapse of epibenthic communities in depths less than 25 meters along the central west Florida shelf. An ongoing monitoring study provided a focused time series (2005 to 2007) of community successional stages at two natural hardbottom ledge sites and six artificial reef sites, situated in comparable depths (~20 meters), allowing us to assess the potential use of artificial reefs as benthic invertebrate and fish recruitment/recovery tools during future disturbances. Radical changes in community structure were observed at both the artificial and natural habitats after the red tide. Epibenthic invertebrate and fish diversities and abundances were significantly lower (t-tests: $p<0.03$) immediately after the peak of the red tide event (August through November 2005) compared to pre-red tide data. Coral community diversities at natural ledges were higher than artificial reef diversities during all samplings. Species including *Oculina diffusa, Solenastrea hyades, Stephanocoenia intersepta* and *Siderastrea radians,* appear to have bleached during the red tide disturbance, but recovered soon thereafter as large (>10 cm) colonies were recorded. Juvenile recruits were abundant on exposed substrate during post-disturbance samplings. Artificial reefs had much lower benthic diversities and were dominated by smaller *Cladocora arbuscula* and *Phyllangia americana* corals. Fish community diversities and abundances were higher at the artificial reef habitats. Successional stages tended to follow a predictable progression and revert to a pre-red tide state, corroborating previous predictions that the fluctuating nature of the shallow eastern Gulf of Mexico may limit the effective species pool of colonists. Artificial reefs appear to be significantly more effective in recruiting diverse and abundant fish populations, with less diverse benthic invertebrate communities, when compared to natural reef ledges along the West Florida Shelf.

## 24-37

**Restoration Of *acropora Cervicornis* At The Site Of The M/t Margara Grounding**

**Tom MOORE*[1]**, **Bruce GRAHAM*[2]**, **Sean GRIFFIN*[3]**, Kevin KIRSCH[4], Craig LILYESTROM[5], **Michael NEMETH*[6]**

[1]Restoration Center, NOAA, St. Petersburg, FL, [2]CSA International, Stuart, FL, [3]Lighthouse Technical Consultants, Aquadilla, Puerto Rico, [4]NOAA, St. Petersburg, FL, [5]Puerto Rico DNER, San Juan, Puerto Rico, [6]Lighthouse Technical Consultants, Boqueron, Puerto Rico

The M/T MARGARA, a 228-m (748-ft) tanker went aground on coral reef formation on 27 April 2006. The impacted reef is located approximately 1 mile south-southeast of Bahia de Tallaboa along the south coast of Puerto Rico. The coral reef feature supports a relatively healthy epifaunal assemblage visually dominated by soft corals, sponges, and hard corals. Rapid response by PRDNER, NOAA and the Responsible Party resulted in the salvage and reattachment of over 10,000 hard and soft corals displaced during the grounding.

A unique feature of the grounding location was the presence of a large thicket of *Acropora cervicornis* which has been designated as Threatened under the Endangered Species Act of 1972. Impact to the A. cervcornis thicket produced over 900 fragments ranging in size from 7.7 to 23 cm (3 to 9in) that were available for reattachment.

The *A. cervicornis* restoration strategy utilized various techniques at four distinct locations within the grounding site. Techniques included the reattachment of grouped *A. cervicornis* fragments to 1) stainless-steel bolts projecting from pooled cement, 2) natural coral rubble projecting from pooled cement, and 3) secured frame of plastic-coated wire mesh. In all three reattachment techniques, fragments were secured using plastic cable ties. Additionally, fragments were attached directly in cement and secured with epoxy at some locations.

Over the first year the reattached fragments grew vigorously, formed multiple new branches and generally had a high rate of survival. Branching fragments could be utilized for transplantation within the grounding site and/or as a source of fragments for additional reattachment locations. This talk will discuss initial results and lessons learned concerning these new field-tested techniques for restoring *A. cervicornis* resources.

## 24-38

**Survival Of Coral Recruits in Relation To Substrate Stability Within Ship Grounding Sites.**

**Stuart FIELD*[1]**

[1]University of Notre Dame, Perth, Australia

Ship groundings cause discrete, small scale disturbances with defined boundaries and are characterised by a mosaic of disturbed areas varying in the extent of damage and the stability of the remaining substrate. Following a disturbance resulting from a ship grounding event, recovery of the coral community is dependent on the recruitment of new individuals to the denuded substrate created as a result of the disturbance. In this study juvenile corals were investigated for 24 months at four sites associated with ship grounding sites adjacent to the Straits of Tiran, Egypt. The density of juveniles within and adjacent to areas of disturbance were considered along with the diversity and size distribution of the juvenile coral community at each site. This investigation has enabled a greater understanding of early life history processes in the recovery of disturbed reefs. Increased densities of juvenile corals were recorded in disturbed areas, supporting findings of recruitment to artificial settlement tiles, however, there were also higher rates of juvenile mortality in disturbed areas, particularly in areas with mobile rubble, indicating that smothering and abrasion were likely causes of decreased survivorship in these areas. However, these rates of recruitment and survivorship were variable across the four sites investigated. These results suggest that while we can improve predictions of recovery rates by defining the mosaic of substrate classifications that characterise a ship grounding site, site-to-site variability in settlement and post-settlement mortality prevents predictions based solely on these initial site surveys and long-term monitoring is needed at each site to follow recovery over time.

## 24-39

**Natural Resource Damage Assessment And Restoration in The National Park Service: Coral Reef Vessel Grounding Case Studies in Biscayne National Park**

**Amanda BOURQUE*[1]**

[1]Division of Resource Management, Biscayne National Park, Homestead, FL

Natural Resource Damage Assessment (NRDA) is a process that allows authorized resource trustees to identify injured resources, recover damages from responsible parties, restore habitats and resources to pre-injury/exposure conditions ("primary restoration"), and compensate the public for the loss of ecological and/or visitor use services ("compensatory restoration"). The National Park Service is authorized by several statutes to implement the NRDA process in resource injury cases. Biscayne National Park (BISC) pursues damage recovery in vessel grounding cases under the authority of the Park System Resource Protection Act (PSRPA, 16 USC 19jj). BISC is one of the largest marine parks in the National Park System, and protects the northernmost Florida Keys, seagrass meadows, mangrove forests, clear bay waters, and over twenty miles of the Florida reef tract. Submerged park resources holding significant ecological, cultural, and economic value are frequently impacted by vessel groundings. BISC is unique because it has the highest volume PSRPA cases in the National Park System, and these cases arise from one type of resource injury (i.e. vessel groundings). This presentation will provide an overview of how BISC applies the NRDA process in vessel grounding cases, with an emphasis on those cases that involve coral reef resources. Injury assessment techniques, injury classifications, restoration planning approaches, restoration alternatives for primary and compensatory projects, monitoring protocols, environmental compliance, and policy solutions will be discussed. Examples will be drawn from several BISC cases.

## 24-40

**Coral Reef Metrics And Habitat Equivalency Analysis**

**Shay VIEHMAN*[1]**, Steven THUR[2], Greg PINIAK[1]

[1]Center for Coastal Fisheries and Habitat Research, NOAA, Beaufort, NC, [2]Office of Ocean and Coastal Resource Management, NOAA, Silver Spring, MD

When coral reefs held in United States public trust are injured by anthropogenic injuries such as vessel groundings or oil spills, a natural resource damage assessment process is utilized to quantify the resource loss and determine the amount of restoration required to make the public whole from the injury. Habitat equivalency analysis (HEA) is used to equate resource losses from the injury with benefits from the compensatory project. Ecosystem services are represented in HEA using an indicator metric, typically coral cover for reef injuries. However, depending on the injury and habitat, alternative approaches such as composite metrics incorporating topographic complexity and other coral reef community members, or a resource-scale approach utilizing size-frequency distributions may more comprehensively represent lost services. We examine the robustness, flexibility, and application within HEA of these metrics to predict complex and compound (larger scale) results from the original injury. Careful selection of a metric appropriate to both the degree and extent of injury and of habitat type can serve as a vital link between the damage assessment, recovery modeling, compensatory calculations, and recovery monitoring.

## 24-41

**Scleractinian Coral Relocation From A Coastal Seawall To A Nearshore Hardbottom Habitat in The Northern Florida Keys.**

**Jeff ANDERSON*[1]**, J. Harold HUDSON, PH.D. [2], Bill GOODWIN[3], John ILIFF[4], Tom MOORE[4]

[1]Contractor to Florida Keys National Marine Sanctuary, I.M. Systems Group, Inc., Key Largo, FL, [2]Damage Assessment and Resource Protection, Florida Keys National Marine Sanctuary (Retired), Miami, FL, [3]Damage Assessment and Resource Protection, Florida Keys National Marine Sanctuary, Key Largo, FL, [4]NOAA Restoration Center, St. Petersburg, FL

During a permitted seawall reconstruction project, Scleractinian corals were found growing on the vertical face. For a coastal location, the seawall housed a large quantity, size, and distribution of healthy reef coral species generally found further offshore. Based on the seawall construction date, the corals had been growing in that environment for a maximum of 35 years. A total of 136 whole colonies and live coral fragments, with diameters ranging from 10 cm to 100 cm, representing 13 Scleractinian species, were harvested. Collected corals were temporarily housed in wire-mesh baskets *in situ*. To accommodate the lateral accretion typical for Scleractinians growing on vertical surfaces, the corals were attached to 30 flat-faced cement and fiberglass modules at the removal site, transported to an offshore site approximately one nautical mile east of the original seawall, and cemented on the seafloor. Two of the largest colonies, along with a number of fragments, were cemented directly to the substrate. The relocation site lies in 4 m of water, is comprised of hardground of Pleistocene Key Largo limestone bedrock overlain by a thin veneer of carbonate sediment, and is populated by numerous Octocorals, sponges, and occasional Scleractinian species. State of Florida biologists conducted an inspection and declared the modules were securely cemented to the bedrock and that all relocated corals appeared healthy as evidenced by their normal coloration and overall appearance. Ongoing monitoring of the site has demonstrated the relocated corals have grown new tissue and continue to survive three years after relocation. The project demonstrates that Scleractinian corals can be successfully collected from coastal construction sites and relocated in order that they can continue to contribute to the marine ecosystem.

## 24-42

**Coral Restoration Is Not Merely About Corals: Reef Fish Habitat Use Measures Coral Reef Restoration Success At The Fortuna Reefer Grounding Site, Mona Island, Puerto Rico**

**Ron HILL*[1]**, Michelle SCHÄRER[2], Michael NEMETH[2], Andy BRUCKNER[3]

[1]SEFSC, NOAA/NMFS, Galveston, TX, [2]Dept. of Marine Sciences, Univ. of Puerto Rico-Mayagüez, Mayagüez, Puerto Rico, [3]OHC Coral Reef Ecosystem Div, NOAA/NMFS, Sand Spring, MD

A multi-agency emergency restoration reattached over 1800 *Acropora palmata* fragments, following the grounding of the M/V Fortuna Reefer on Mona Island in 1997. Shortly after the grounding, we began monitoring the restoration using coral reattachment, survival, and growth and the recovery of fish assemblages as measures of success. Although no surveys were conducted before the grounding, we have neighboring undisturbed areas for comparison and we can analyze temporal changes within the site. In early surveys reef fish assemblages were significantly different from adjacent control sites. With almost a decade of monitoring complete, we are starting to see increases in species diversity, expansions of size distributions, and increases in abundances and diversity of juvenile haemulids, species known to be habitat selective. Additional monitoring will determine when the conditions can be considered "normative" however experimental approaches might be required to improve restoration of fish habitat and encourage the coral-fish interactions that can contribute to the effectiveness of coral reef restoration.

## 24-43

**Multivariate Responses Of The Coral Reef Fish Community To Artificial Structures And Coral Transplants**

**Sebastian FERSE*[1]**

[1]ZMT Bremen, Bremen, Germany

Reef rehabilitation efforts frequently employ the use of artificial structures or coral transplantation. Although several studies have addressed relationships between artificial structures or the natural habitat and associated fish communities, no attempt has been made to contrast the effects on the fish community of structures used alone and in combination with coral transplantation. In this study, repeated fish census over plots containing rubble [C], artificial structures [S], and structures together with coral transplants [S+C], was conducted over a time of up to two years at three sites in North Sulawesi, Indonesia. The results show an increase in fish abundance and number of species in the [S] plots, and a further increase in the presence of corals at two sites. Principal component analysis (PCA) emphasized differences between the three treatments in terms of fish abundance, number of species, and diversity (H' and H' max). Abundance, number of species and H' in the [S+C] plots was higher than that observed in the surrounding natural reef at one location, but lower at the other two sites. Cluster analysis revealed distinct communities at the three treatments and a low similarity to the natural reef at all three locations. Similarity to natural reefs was lowest in the rubble plots. Spearman-rank correlation of the similarity matrices for each treatment with model similarity matrices revealed increasing similarity among census replicates in the [S] and [S+C] treatments over time at all sites. Crossed three-way ANOVA of the average similarities among census replicates showed significant effects of treatment and the interaction terms location*treatment and location*time. The results underline the role that structures and transplants play in re-shaping and stabilizing the associated fish community, but also demonstrate that the effects differ markedly depending on the ambient reef.

## 24-44

**Effects Of Coral Transplantation And Giant Clam Restocking On The Functional Groups Of Fish On Degraded Patch Reefs**

**Patrick CABAITAN*[1]**, Edgardo GOMEZ[1], Porfirio ALIÑO[1]

[1]Marine Science Institute, University of the Philippines, Quezon City, Philippines

This study examined the effects of restoration treatments on different functional groups of reef fish that are important to the stability of a community. Fish on 25 degraded patch reefs were monitored monthly for 3 months before and every 1-2 months for 11 months after the application of the restoration treatments. The treatments were: 1) transplantation of *Acropora* spp. and *Pocillopora* spp. corals, 2) restocking of the giant clam *Tridacna gigas*, 3) restocking of *T. gigas* with coral transplantation, 4) deployment of *T. gigas* shells, and 5) control. The fish were categorized into 10 functional groups, defined by feeding habit and the relative size of their territory. For fish with large territory, the coral treatment increased the abundance of Omnivore, Zoobenthivore, and Carnivore, while the clam+coral treatment increased the abundance of Omnivore, Zoobenthivore, and Herbivore relative to the control. The clam treatment increased the abundance of Omnivore and Zoobenthivore. For fish with small territory, the coral treatment increased the abundance of Omnivore, Herbivore, and Carnivore, while the clam+coral treatment increased the abundance of Omnivore and Herbivore relative to the control. The Clam treatment increased the abundance of Carnivore, while the shell treatment increased the abundance of Herbivore. Only Zooplanktivore with small and large territories and Zoobenthivore with small territory did not achieve any significant increase in any of the treatments. This study shows the feasibility to restore reefs, although with different responses from the fish functional groups, which can be summarized into: 1) habitat-linked, 2) trophically-linked, and 3) cascading effects on the increase of certain functional groups.

## 24-45

**Alternate Benthic Assemblages On Artificial Reef Restoration Structures And Their Effects On Coral Larval Settlement**

**Margaret MILLER*[1]**, Abel VALDIVIA[2,3], K. Lindsey KRAMER[4], Benjamin MASON[5], Dana WILLIAMS[3,6], Lyza JOHNSTON[5]

[1]Southeast Fisheries Science Center, NOAA Fisheries, Miami, FL, [2]CIMAS, University of Miami, Miami, FL, [3]Southeast Fisheries Science Center, NOAA Fisheries, Miami, [4]US National Park Service, Hilo, HI, [5]Marine Biology and Fisheries, University of Miami, Miami, FL, [6]CIMAS, University of Miam, Miam, FL

Acute physical reef injuries are sometimes addressed by construction of on-site artificial structures to secure fractured framework and enhance architectural complexity of damaged sites. To characterize benthic assemblages, four restoration structures (RS) along with adjacent natural reef substrates (Reference) in the Florida Keys, USA (age range 6-13 yrs) were sampled via line-intercept transects. Multivariate clustering analysis indicated a high degree of divergence between RS and Reference samples, as well as among sites. RS had significantly higher cover of thick cyanobacterial turfs (up to 30% cover) than Reference substrates. Assemblage differences were primarily attributable to macroalgal and cyanobaterial groups with fast growth and turnover, rather than to slow-growing corals and crustose coralline algae. Thus, divergence of assemblages is not simply attributable to incomplete succession, but appears to be a persistent, possibly stable state.

Since cyanobacteria have known ill effects on adult and larval corals, we tested if exudates of these distinct algal assemblages (RS and Ref) chemically inhibit coral larval settlement. Seawater exudates were prepared from $1m^2$ of macroalgae, including turf, collected from RS and Reference substrates at two sites (Wellwood and Maitland). Competent larvae of three broadcast spawning scleractinian species were exposed to natural substrate in exudates or seawater controls and allowed three days to settle. *Acropora palmata* and *Diploria strigosa* larvae were subject to exudates from a single site (Wellwood) while *Montastraea faveolata* larvae were tested with exudates from both sites. Reference exudates from the Wellwood site displayed greatest settlement inhibition for all 3 species while, for *M. faveolata*, RS exudates from the Maitland site were more inhibitory than Maitland Reference exudates. *A.palmata* larvae displayed greater sensitivity than the other species with 100% mortality in the Wellwood Ref treatment. Both RS and Reference substrates in these locations appear to have compromised 'recruitment potential' for spawning corals.

## 24-46

**Natural And Enhanced Coral Reef Recovery After Injury**

**Alison MOULDING*[1]**, David GILLIAM[1], Vladimir KOSMYNIN[2], Richard DODGE[1]

[1]National Coral Reef Institute, Nova Southeastern University, Dania Beach, FL, [2]Bureau of Beaches and Coastal Systems, Florida Department of Environmental Protection, Tallahassee, FL

The coral reefs of Broward County, southeast Florida, USA are located offshore a highly urbanized area. Because of the close proximity of a major shipping port and its associated anchorage, Broward reefs have been impacted by more than 10 ship groundings over the last 15 years. These injuries usually require restoration to speed recovery and compensate for damage. However, the recovery process on injured sites is not well understood, and even less is known about how restoration aids in recovery. This study examines coral recruitment, growth, and mortality in permanent quadrats on injured sites to asses their potential for natural recovery. It also investigates substrate materials commonly used in reef restoration, including limestone, concrete, and terracotta, to determine their efficacy in attracting and retaining coral recruits. Lastly, transplantation of juvenile corals collected on settlement plates from areas of higher coral recruitment and of corals raised in the lab from the larval stage is examined as a potential method to enhance reef restoration. Preliminary results indicate coral recruitment rates to injured sites were higher compared to reference sites. Mortality rates at the injured sites were also higher than reference sites. After one year of deployment, more corals settled on limestone plates than on concrete or terracotta. Hence, recovery on injury sites may be hampered by high juvenile coral mortality rates, and the choice of substrate materials used in restoration may influence recovery.

## 24-48

**Recruitment Of The Temperate Scleractinian Coral, *oculina Arbuscula*, To Natural And Artificial Substrata On Reefs Of The South Atlantic Bight, U.s.a.**

**Daniel GLEASON*[1]**, Leslie SUTTON[1]

[1]Department of Biology, Georgia Southern University, Statesboro, GA

Similar to their tropical counterparts, temperate reefs have high biodiversity, but are in peril from anthropogenic impacts. Primary threats include commercial trawling, recreational fishing, ocean acidification, and increased sedimentation. *Oculina arbuscula* is a temperate, broadcast spawning coral and is the only structurally complex Scleractinian occurring on hard-bottom reefs of the South Atlantic Bight, U.S.A. *Oculina arbuscula* is an important contributor to reef rugosity in this ecosystem, but can be easily damaged by dredges and trawls. To investigate the sustainability of these coral populations on reefs off the Georgia coast we monitored recruitment of *O. arbuscula* to 30x30 cm plots over 3 years. Treatments consisted of 10 replicates of each of the following: 1) unmanipulated natural substrata, 2) natural substrata initially cleared of all encrusting organisms, and 3) artificial substrata consisting of concrete paving tiles. These plots were photographed at least 13 times between July 2004 and June 2007 using a digital camera mounted to a PVC frame to control for distance and exposure level. These images showed that *O. arbuscula* recruits throughout the year with peak recruitment exhibited in September/October. While recruitment rates were higher than death rates in all treatments and resulted in a net gain of *O. arbuscula* colonies, recruitment to artificial substrata far exceeded that found on natural surfaces. Competition with other sessile invertebrates, such as tunicates and sponges, appeared to contribute little to these differences because recruitment rates were similar on unmanipulated and cleared natural substrata. Likewise, the high recruitment rate observed on the artificial substrata rules out the possibility that maintenance of *O. arbuscula* populations is limited by larval supply. While the reasons are unclear currently, these results suggest that deploying artificial substrata, such as concrete paving tiles, may be useful as a mechanism of enhancing recruitment of *O. arbuscula* to damaged temperate reef structure.

## 24-49

**Brazilian Corals Early Growth And Survival**

**Clovis CASTRO*[1]**, Bruna CASTRO[1]

[1]Departamento de Invertebrados, Museu Nacional, Rio de Janeiro, Brazil

Early growth and survival of coral recruits are crucial for the renewal of coral populations and restoration initiatives. In order to assess these parameters, we set up experiments with different recruitment plates (plastic and ceramic) and environmental conditions (open sea and tanks). In the laboratory, coral spats were recorded using a dissecting microscope. Each individual spat was measured and its position recorded using a coordinate system. Plastic plates were deployed in January, 2004, and initially kept in the Itacolomis Reefs (16°54'S, 039°04'W) for circa 15 months. Censuses occurred in June, 2005 (T0) and March, 2006 (T1 – 9 months). This experiment started with 1762 live spats and ended with 574. Survival rates were higher in tanks (61%, excluding spats in lost plates, vs. 15% in open sea). Survival was also higher in larger spats, both in tanks and open sea. Growth rates were slightly higher in tanks. Larger spats grew faster than smaller ones. Ceramic tiles were deployed in March, 2006, and kept in the "Recife de Fora" (16°24'S, 038°59'W) for circa seven months. Censuses occurred in October, 2006 (T0), March (T1 – 5 months) and October, 2007 (T2 – 12 months). This experiment started with 1078 live spats. The last census showed 206 live spats, 19% of the original spats. Survival rates agreed with those from plastic plates. However, differences between tanks (T0-T1 = 48%; T1-T2 = 34%) and open sea (T0-T1 = 27%; T1-T2 = 5%), as well as in larger spat size classes, were more evident. Growth rates in tanks were substantially higher than in open sea (up to 7 times higher in the same size class). These preliminary results suggest that rearing coral recruits in captivity may become an alternative for coral reef restoration in the long term.

## 24-50

**Gametogenesis in Cultured Versus Wild *acropora Intermedia* Colonies: Fertilization, Survival, And Oxygen Consumption 10 Years After Fragmentation**

**Nami OKUBO*[1]**, Hiromi YAMAMOTO[2], Fumio NAKAYA[3], Ken OKAJI[4]

[1]Yokohama National University (present: Kyoto University), Yokohama, Japan, [2]Okinawa Expo Aquarium, Okinawa, Japan, [3]Ochanomizu University, Tokyo, Japan, [4]CoralQuest Inc, Kanagawa, Japan

In the late 1990s, the once prolific *Acropora intermedia* populations surrounding Okinawa, Japan, dramatically declined because of thermal stress and subsequent bleaching and mortality. Before the bleaching event, 72 fragments of approximately 15 cm in length were collected and transferred to the Okinawa Expo Aquarium. Through growth and repeated fragmentation, these original fragments developed into approximately 100 colonies, which spawned from 1999 to 2006. Here we compare gametogenesis, fertilization, survival, and O2 consumption in the cultured and wild offspring. Cultured *A. intermedia* had larger oocytes (volume), higher fertilization rates, higher embryonic O2 consumption, and higher survival rates compared to samples from wild colonies. These results suggest that the cultured *A.intermedia* and their offspring are more fit than wild colonies.

## 25-1

**Is 500 Ppm $Co_2$ And 2°c Of Warming The 'tipping Point' For Coral Reefs? If So, How Should We Respond?**

**Ove HOEGH-GULDBERG*[1]**

[1]Centre for Marine Studies, University of Queensland, St Lucia, Australia

The burning of fossil fuels is driving a rapid increase in the concentration of $CO_2$ in the atmosphere which is expected to exceed 500 ppm in the earth's atmosphere within 50 years. At this point, tropical sea temperatures will be 2°C warmer than 150 years ago and tropical carbonate ion concentrations will fall below 200 µmol $kg^{-1}$. These conditions differ markedly from those seen over the past 420,000 years during which time most extant species and communities evolved. Most importantly, the current rate of change in sea temperature and atmospheric $CO_2$ is 70 and 1,000 times faster, respectively, than the highest rates of change seen in the past 420,000 years. This is outstripping biological responses (adaptation, range migration) and is driving major changes in the distribution and abundance of tropical marine organisms. This paper will discuss scenarios associated with the future of coral reefs with the aim of visualizing the challenges that coral reef managers will face over the next few decades as we approach 500 ppm. The weight of evidence suggests that corals will be rare on tropical reefs which will enter a state of net erosion under atmospheric $CO_2$ concentration of 500 ppm or more. As a result, coral reefs are expected to be less diverse and reef frameworks to start to crumble and deteriorate. How can managers respond to these changes? Are there responses that managers should be taking today in preparation for changes projected a few decades from now? Should we contemplate moving vulnerable species or enriching the genetic diversity of species growing at a particular location? These issues will be discussed at the outset of this mini-symposium which anticipates a lively discussion around what is clearly one of the most important issues facing coral reef scientists and managers.

## 25-2

**Implications For Our Coral Reefs in A Changing Climate Over The Next Few Decades – Hints From The Past 22 Years**

**Alan E. STRONG*[1]**, Gang LIU[2], C. Mark EAKIN[1], Tyler R. L. CHRISTENSEN[2], Dwight K. GLEDHILL[2], Scott F. HERON[1], Jessica A. MORGAN[2], William J. SKIRVING[1]

[1]NOAA Coral Reef Watch, Silver Spring, MD, [2]IMSG at NOAA Coral Reef Watch, Silver Spring, MD

The NOAA/NASA Pathfinder sea surface temperature (SST) data from 1985 to 2006 are examined for variability and trends on both sides of the recent 1998 Pacific Decadal Oscillation (PDO) reversal for implications on tropical ecosystems. These twenty-two years of satellite observations reveal some noteworthy shifts that have quite different implications for each major ocean basin. In addition, the data reveal expected increasing SST trends toward higher latitudes, especially in the northern hemisphere, confirming the Intergovernmental Panel on Climate Change (IPCC) projections. Although several regions throughout the tropics have experienced decreasing SSTs over the 22-year timeframe, significantly more regions are showing rising trends. Most notable and worrisome is an obvious shift after the recent PDO reversal from cooling to warming in some specific tropical waters. More promising regions, also identified from our results, are presently experiencing cooling trends and thus decreasing pressure from thermal stress. What will be instructive for the future of our precious coral reef ecosystems is whether the dramatic regional shift in trends since the recent 1998 PDO reversal continues to persist into the second decade of the 21st Century or evolves into a signal of a changing climate.

## 25-3

**The Elephant In The Reef: Committed Warming And Coral Bleaching**

**Simon DONNER*[1]**

[1]Geography, University of British Columbia, Vancouver, BC, Canada

An increase in episodes of mass coral bleaching around the world in recent decades have been attributed to more frequent periods of anomalously warm ocean temperatures. Over the past fifteen years, a number of modeling studies have predicted that, left unchecked, human-induced climate change will further increase the frequency and intensity of these thermal stress events and threaten the survival of most of the world's coral reef ecosystems. As now near the end of the first decade of the 21st century, the questions need to change. Is the future happening now? How much of this projected climate warming can be avoided?

In this presentation, I use analysis of the 2005 coral bleaching event in the Caribbean to discuss the role of human-induced climate change in recent mass coral bleaching events and the effect of "committed" warming on the likelihood of future mass bleaching events. Simulations of background climate variability with the GFDL global climate models suggest that anthropogenic warming may have increased the probability of the 2005 coral bleaching events by an order of magnitude. The thermal stress that cause mass coral bleaching in the eastern Caribbean is expected to become a biannual event in 20-30 years regardless of the emissions scenario, due to the inertia in the climate system and the world economy. Thermal adaptation by corals and their symbionts could delay this forecast until the latter half of the century, possibly enabling time to reduce greenhouse gas emissions and change the climate forecast. Taken together, these results suggest that protecting coral reefs from climate change will require managing local stresses, to increase reef resilience to inevitable future warming, and immediate action to reduce greenhouse gas emissions.

## 25-4

**Climate-Scale Influences On The Development Of Coral Bleaching Conditions in The Great Barrier Reef**

**Scarla WEEKS*[1]**, Ana REDONDO-RODRIGUES[1], Andrew BAKUN[2]

[1]University of Queensland, Brisbane, Australia, [2]Pew Institute for Ocean Sciences, University of Miami, Miami, FL

A suite of available time series indicators of climatic and large-scale oceanographic properties and processes were evaluated with respect to providing (1) an appropriately representative climatological background for studying the factors leading to coral bleaching events, (2) a time-series record long enough to contain multiple independent realisations sufficient for valid hypothesis tests, and (3) a consistent baseline for normalising higher spatial and temporal resolution data obtained from more recent satellite sensors. These indicator series included NOAA OI SST (1° res., 1982-2007), the NCEP series (barometric pressure, wind, water vapor, air temperature, 1948-2007, 2.5° res.), and the NASA "Photosynthetically Active Radiation" product (9km res., 1997-2007). The study focused on three recent coral bleaching events in the GBR, the 1997-1998 "El Niño"-associated event, the 2005-2006 mild "La Niña"-associated event, and the most severe of the three, the 2001-2002 "ENSO-neutral" event.

Preliminary findings include: La Niñas (2005-06 in particular) are characterized by high regional-scale SST, while El Niños (1997-98 in particular) are typified by high solar radiation (PAR) incident on the sea surface. Accordingly, bleaching in the GBR may occur in either ENSO phase. The intense 2001-2002 event featured unusually high levels of both SST and PAR. The "linking factor" in all three major bleaching events was anomalously low wind mixing of the near-surface water column. The actual spatial variability of severe bleaching tends to be on scales smaller than resolved by the available climatic series, and seems to be governed by meso-scale and sub-meso-scale ocean flow. Examples are illustrated with 1-km MODIS satellite imagery.

An emerging consensus among climate models suggests that the Pacific trade wind circulation may slow and the Pacific system become chronically more El Niño-like. Thus besides direct greenhouse heating, there are additional El Niño-related possibilities of enhancement of PAR and reduction of near-surface wind mixing.

## 25-5

**Going, Going, Gone? Are 1998 And 2005 Signs Of The Future For Coral Reefs?**

**C. Mark EAKIN*[1]**, Jessica A. MORGAN[2], Scott F. HERON[2], Janice M. LOUGH[3], William J. SKIRVING[2], Gang LIU[2], Tyler R. L. CHRISTENSEN[2], Dwight K. GLEDHILL[2], Alan E. STRONG[4]

[1]Coral Reef Watch, National Oceanic and Atmospheric Administration, Silver Spring, MD, [2]Coral Reef Watch, IMSG at National Oceanic and Atmospheric Administration, Silver Spring, MD, [3]Australian Institute of Marine Science, Townsville MC, QLD, Australia, [4]Coral Reef Watch, AJH Environmental at National Oceanic and Atmospheric Administration, Silver Spring, MD

The 2005 Caribbean coral bleaching event was the most extensive and devastating on record for this basin. The greatest bleaching and mortality were seen along the Antillean Arc where the thermal stress exceeded any seen in the Caribbean during the previous 21 years of satellite data and 100 years of gridded, in situ temperature reconstructions. Coral bleaching exceeded 90% at many sites, and extended across most of the wider-Caribbean region; mortality exceeded 40% at many sites. The 2005 Caribbean bleaching rivals that seen in the Indo-Pacific in 1998.

Climate change is rapidly modifying the environmental envelope of coral reefs through both increased thermal stress and ocean acidification. Both the thermal and chemical limits that control coral survival and reef growth will likely be passed before 2100 assuming even conservative projections reported in the 4th Assessment Report of the Intergovernmental Panel on Climate Change. While local stresses currently dominate, coral reefs are increasingly confronted with global-scale changes due to rising greenhouse gas concentrations. The 1998 and 2005 bleaching events showed one of the key problems that climate change poses to coral reefs: warming oceans can kill corals in even the best-managed or most remote coral reefs. Global action to curb greenhouse gas emissions is certainly needed. However, because of the time delay between emission reductions and climate stabilization, emission curbs are not sufficient by themselves. Steps need to be taken to increase the resilience of coral reefs to survive bleaching, ocean acidification, and other climate change threats.

## 25-6

**Forecasting Storm-Mediated Changes in Reef Coral Assemblages**

**Joshua MADIN*[1,2]**, Michael O'DONNELL[3], Sean CONNOLLY[4]

[1]Department of Biological Sciences, Macquarie University, New South Wales, Australia, [2]National Center for Ecological Analysis and Synthesis, University of California, Santa Barbara, Santa Barbara, [3]Marine Science Institute, University of California, Santa Barbara, Santa Barbara, CA, [4]School of Marine and Tropical Biology, James Cook University, Townsville, Australia

Reef corals build physical structures that provide essential ecosystem services including substrate for settlement, protection from predators, and shelter from disturbances. Restricted to shallow-water equatorial regions, corals continually experience moderate wave forces and intermittent bombardment by severe hydrodynamic disturbances. Predicted increases in severity of tropical storms and hypothesized weakening of reef carbonate materials through seawater acidification will necessarily affect the ability of corals to mechanically withstand hydrodynamic disturbances, but how and to what extent these will change coral community assemblages remains unclear.

We use field measurements of colony mechanical vulnerability and an existing mathematical model to forecast changes in coral assemblage structure following tropical storms under two reef strength scenarios: present-day reef strength measurements and future estimates assuming a 50% weakening due to acidification. There are dramatic, morphological-specific differences in the expected numbers of remaining colonies. Larger disturbances result in dramatic decreases in the median size of the competitively dominant species. As a consequence, relative cover of the other species increases. At some point over the continuum of disturbance intensities each species dominates the post-disturbance assemblage both in relative cover and mean colony size, but absolute numbers of remaining colonies become sparse for all populations. Hypothetical halving substrate strength exacerbates these differences: certain populations lose up to 20% more colonies than present-day conditions and the dominance hierarchy shifts at lower disturbance intensities.

Both colony size and proportion cover have consequences for recovery following disturbances. For example, larger colonies tend to be more resistant physical abrasion and disease, have greater competitive and reproductive potential, and command greater proportions of limited substrate space. The number of associated species supported by a colony scales with both colony size and morphological complexity. Therefore, the forecasted dominance of mechanically robust, morphologically simple coral species in future reef environments will lead to decreases in whole-reef biodiversity.

## 25-7

**Seasonal To Decadal Changes in The Carbonate System Of The North Pacific Ocean**

**Richard FEELY*[1]**, Chris SABINE[2], Kathryn FAGAN[3]

[1]OCRD, PMEL/NOAA, Seattle, WA, [2]PMEL/NOAA, Seattle, WA, [3]University of Washington, Seattle, WA

The addition of fossil fuel carbon dioxide to the atmosphere is rapidly changing seawater chemistry and the calcium carbonate saturation state of the world's oceans as a result of the acidifying effects of CO2 on seawater. This acidification makes it more difficult for corals to build their skeletons. Repeat hydrographic and coastal cruises in the North Pacific show direct evidence for ocean acidification. The dissolved inorganic carbon increases, of about 10-15 µmol kg-1 in surface and intermediate waters over the past 15 years, are consistent with corresponding pH decreases of approximately 0.025 units over large sections of the northeastern Pacific. These dramatic changes can be attributed, in most part, to anthropogenic CO2 uptake by the ocean over the past decade. These data verify earlier model projections that the oceans are undergoing ocean acidification as a result of the uptake of carbon dioxide released as a result of the burning of fossil fuels. From these results we have estimated an average upward migration of the aragonite saturation horizon of approximately 1 m yr-1 in the North Pacific. Such shoaling is due to the effects of anthropogenic CO2, ventilation and biological respiration processes in the surface and intermediate waters. We have also instrumented a Coral Reef Instrumented Monitoring and CO2 Platform (CRIMP-CO2) in southern Kaneohe Bay in December 2005 and have been collecting data almost continuously since that time. The CO2 mooring collects air pCO2 and pO2 and surface water pCO2, pO2, temperature, and salinity data every three hours. The results show a seasonal trend in the pCO2 data with higher levels occurring during the summer months and lower levels occurring during the winter. Changes in water temperature had a small effect on surface water pCO2 levels and seasonal changes in pCO2 are driven mainly by changes in calcification.

## 25-8

**Marine Biocalcifiers Exhibit Mixed Responses To Co2-Induced Ocean Acidification**

**Justin RIES*[1]**, Anne COHEN[1], Daniel MCCORKLE[1]

[1]Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA

We have conducted 6-month laboratory experiments to investigate the effect of $CO_2$-induced reductions in seawater $CaCO_3$ saturation state on biocalcification by 21 aragonitic and calcitic (low-high Mg) taxa representing eight of the major marine calcifying groups: Chlorophyta; Rhodophyta; Crustacea; Bivalvia; Gastropoda; Annelida; Cnidaria; and Echinodermata. The $CaCO_3$ saturation states of the experimental seawaters, constrained by intercalibrated determinations of pH, alkalinity, and DIC, were attained with bubbled air-$CO_2$ mixtures of 380 (ambient), 560, 840, 2240 ppm $CO_2$, yielding $\Omega_{arag}$ of 3.2 (ambient), 2.4, 1.8, 0.8, respectively. Net calcification/dissolution rates obtained from buoyant weighing reveal that nearly half of the species exhibited reduced calcification, and even dissolution, in the elevated-$CO_2$ seawaters. However, each of the major taxonomic groups that we investigated contained at least one species (9 species in total) that exhibited increased calcification in the moderately (560 ppm) or extremely (840 or 2240 ppm) elevated $CO_2$ conditions. This surprising observation runs counter to the conventional belief that $CO_2$-induced ocean acidification necessarily reduces calcification rates in marine organisms. Rather, some calcifying organisms appear to benefit from the elevated DIC, either directly through photosynthesis or indirectly through calcification, which requires conversion of $HCO_3^-$ to $CO_3^=$ via proton-pumping from the organism's internal calcifying medium. No single trait governed the pattern of responses amongst the organisms. A confluence of factors, including skeletal mineral polymorph solubility, proton-pumping efficiency, and the utilization of photosynthesis, appears determinant of each organism's response.

## 25-9

**Carbonate Dissolution By Euendolithic Microorganisms Increases With Rising pCO2**

**Aline TRIBOLLET*[1]**, Marlin ATKINSON[2], Chris LANGDON[3]

[1]IRD, Marseille, France, [2]HIMB, Kaneohe, HI, [3]University of Miami, Miami, FL

Six months-old experimental blocks of the coral *Porites lobata* colonized by natural epilithic and endolithic organisms from an offshore oceanic site in Kaneohe Bay (Hawaii) were placed in experimental tanks with similar water quality as the oceanic site. After a further two months of acclimation, blocks were exposed to 2 different aqueous pCO2 treatments, one at ambient pCO2 (400 ppmv) and another at 750 ppmv (predicted pCO2 by the year 2100) for another 3 months. Before and after treatment, euendolithic microorganisms (i.e. boring cyanobacteria, algae and fungi), their distribution, abundance and bioeroding activity were determined using thin sections, scanning electron microscopy and image analysis. At the beginning of the pCO2 experiment, euendolithic communities comprised of 65-80% chlorophyte *Ostreobium quekettii,* and increased to 90% at the end of the experiment. There were no differences in the relative abundance of euendolithic species, nor any differences in bioeroded area at the surface of blocks (27%) between pCO2 treatments. The depth of penetration of euendolithic filaments of *O. quekettii* was however significantly higher under elevated pCO2 (1.4 mm) than ambient pCO2 (1 mm). Consequently, higher microbioerosion rates (biogenic carbonate dissolution) were measured under elevated pCO2 than ambient pCO2 (0.63 kg m-2 of planar reef y-1 versus 0.45 kg m-2 y-1). Based on these results, we estimate that carbonate dissolution by *O. quekettii* can increase by 30% with a doubling atmospheric pCO2. We conclude that biogenic dissolution by euendoliths can be a dominant mechanism of carbonate dissolution in a more acidic ocean and could have major negative consequences on the maintenance of coral reefs in a close future.

## 25-10

**Coral Reef Response To Climate Change – Addressing Complex Problems With A Simple Model**

**Robert BUDDEMEIER*[1]**

[1]Kansas Geological Survey, University of Kansas, Lawrence, KS

The COMBO model is a spreadsheet-based tool designed to be used by managers, conservationists, and biologists for projecting the effects of climate change on coral reefs at local-to-regional scales. The model calculates the effects on coral growth and mortality, and ultimately on coral reef cover, from changes in average sea-surface temperature and carbon dioxide concentrations, and from episodic high temperature mortality (bleaching) events. The model uses a probabilistic assessment of the frequency of high temperature events under a future climate to allow development and testing of local scenarios. COMBO offers data libraries and default factors for three selected regions (Hawai'i, Great Barrier Reef, Caribbean), but it is structured with user-selectable parameter values and data input options, facilitating modifications to reflect local conditions or to incorporate local expertise. Results of parameter sensitivity analyses and comparison of future scenarios for different regions in the North and South Pacific are used to demonstrate model applications to the complexities of assessing the relative importance of high temperature events, increased average temperature, and increased carbon dioxide concentration to the future status of coral reefs at local and regional scales.

## 25-11

**Scleractinian Corals Response To Ocean Acidification Conditions**

**Maoz FINE*[1,2]**, Dan TCHERNOV[3,4]

[1]Faculty of Life Sciences, Bar-Ilan University, Ramat-Gan, Israel, [2]Interuniversity Institute for Marine Science in Eilat, Eilat, Israel, [3]Department of Evolution, Systematics and Ecology, The Hebrew University, Jerusalem, Israel, [4]The Interuniversity Institute for Marine Science, Eilat, Israel

Anthropogenic-driven accumulation of CO2 in the atmosphere, and projected ocean acidification, has raised concerns regarding the eventual impact on coral reefs.

Little is known however about the physiological response of corals to increased pCO2 and ocean acidification and hence it is difficult to predict what shifts these ecosystems will experience. This study demonstrates that skeleton-producing corals grown in experimental acidified conditions are able to sustain basic life functions, in a sea anemone-like form and will resume skeleton-building when reintroduced to normal modern marine conditions. Coral species from the temperate Mediterranean and tropical Red Sea were subjected to pH 7.3-7.6 and 8.2 (ambient) for 3-18 months in an open flow-through system. Corals in decreased pH conditions demonstrated morphological changes such as dissociation of the colony form followed by complete skeleton dissolution. In encrusting corals the polyps remained attached to the undissolved substrate whereas living polyps of branching species descended to the aquarium bottom. Biomass of the solitary polyps under decreased pH conditions was 1.5 to 3-fold higher than the biomass of polyps in the control colonies. This may be explained by the higher primary productivity (Net and Gross Photosynthesis) that was measured in corals under higher pCO2. Changes in photosynthesis and calcification as a response to decreased pH were species specific with some species responding earlier than others. Gametogenesis in control and experimental corals developed similarly. Soft bodied corals calcified and reformed colonies when transferred back to ambient pH conditions. Hence, in the absence of conditions supporting skeleton-building, corals maintain basic life functions as a skeleton-less ecophenotype. This has far reaching implications for the understanding of the natural history of corals and their near future in an increasingly changing environment.

## 25-12

**Impacts Of Ocean Acidification And Warming On Calcifying Coral Reef Organisms**

**David I. KLINE*[1]**, Kenneth R. N. ANTHONY[1,2], Guillermo DIAZ-PULLIDO[1,2], Sophie DOVE[1,2], Selina WARD[1], Ove HOEGH-GULDBERG[1,2]

[1]Centre for Marine Studies, The University of Queensland, St Lucia, QLD, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, The University of Queensland, St Lucia, QLD, Australia

The world's oceans are predicted to become warmer and more acidic over the next century with potentially dramatic consequences for coral reef ecosystems. However, there is little known about the combined impacts of temperature and pH on coral reef organisms or about which species will be most vulnerable to these changed environmental conditions. Using a large custom-built, flow-through aquarium system we simulated 3 projected levels of CO2 concentrations at two ocean temperatures to simulate future reef conditions under high-emission scenarios. We compared a series of physiological responses (including growth rate, photosynthesis/respiration, and survivorship) of four major calcifying coral reef organisms from the southern Great Barrier Reef (massive corals, branching corals, calcareous algae and foraminiferans) to temperature and CO2 conditions in a highly replicated factorial design. Our results suggest that different reef calcifying organisms have varying susceptibilities to climate change with calcareous algae and branching corals projected to reach their physiological thresholds as early as 2050. Reefs of the future will likely undergo large ecological changes as some of the first species likely to be impacted by climate change are important coral reef framework builders.

## 25-13

**Combined Effects Of Elevated Temperature And Pco2 On The Photo-Physiology Of *symbiodinium* Spp. in Two Scleractinian Coral Species**

Andrew BAKER[1], **Paul JONES*[1]**, Ranjeet BHAGOOLI[2], Herman WIRSHING[1], Tom CAPO[1], Christopher LANGDON[1]

[1]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [2]Department of Biosciences, University of Mauritius, Reduit, Mauritius

Few studies have investigated how reef corals respond to the combined effects of thermal stress and elevated pCO2, yet these conditions are likely to be an environmental reality of the 21st century. To better understand how these factors interact, we undertook a 14-week pilot experiment using two Caribbean coral species, *Porites furcata* and *Montastraea faveolata*. We exposed replicate nubbins of each species to three pCO2 levels (360, 550 and 800ppm) and three temperatures (28, 30 and 32oC); conditions were maintained using CO2 bubblers and a computer-controlled heater-chiller system. Additionally, we used an outdoor system and neutral density screens to expose corals to ambient or 50% solar irradiance. Prior to the start of the experiment, coral nubbins were acclimated to different pCO2 levels at ambient temperature (28oC) for four weeks, before being heated at a rate of 0.3oC per day to the experimental temperatures (30 and 32oC). Temperatures were maintained (+/- 0.2oC) for nine weeks before being returned to ambient levels at the same rate. Corals were then monitored for five weeks during a recovery phase. Elevated pCO2 levels were maintained throughout the acclimation, exposure and recovery phases. Every 2-4 weeks chlorophyll fluorescence was analyzed using an Imaging-PAM (Walz, GmbH), and coral tissue samples were taken to determine algal symbiont densities, pigment concentrations, and *Symbiodinium* identity. Color-scaled photographs documented temporal changes in tissue pigmentation and health. Corals in the highest temperature and light treatments exhibited the most severe bleaching, regardless of CO2 levels. However, at control temperatures (28oC), elevated CO2 resulted in healthier corals, as evidenced by symbiont counts, photographs and fluorescence properties. *P. furcata* bleached more readily than *M. faveolata*, although these species also hosted different *Symbiodinium*. Together, these results suggest temperature and CO2 interact in unexpected ways to influence coral health.

## 25-14

**Ocean Acidification Changes The Early Life History Of Scleractinian Corals.**

**Selina WARD*[1]**, Sophie DOVE[2], david KLINE[2], kenneth ANTHONY[2], Ove HOEGH-GULDBERG[1]

[1]Centre for Marine Studies, The University of Queensland, Brisbane, Australia, [2]Centre for Marine Studies, The University of Queensland, brisbane, Australia

Predictions of doubling preindustrial carbon dioxide levels by the middle of this century create serious concerns for the future state of coral reefs. Reproduction and the early life history stages of corals have been shown to be particularly sensitive to adverse conditions. In experiments with four species of acroporid corals, settlement of larvae and early calcification of the newly settled corals were detrimentally affected by seawater with reduced pH. Gametes from these species were collected, fertilised and larvae reared at One Tree Island on the Great Barrier Reef, Australia in spring 2007. Eight thousand *Acropora millepora* larvae were placed in ambient seawater or sea water of pH 7.8 or 7.6 with preconditioned terracotta tiles for the settlement period. pH was maintained by bubbling carbon dioxide in to the seawater. Settlement success was significantly reduced at pH 7.6 and 7.8 compared to that in ambient seawater. In a separate experiment, larvae of four species were settled on terracotta tiles in ambient seawater. As soon as most of the larvae had metamorphosed, the tiles were scored for the number of larvae that had settled, calcified or were attached but not metamorphosed. Over 16 000 settled corals were used in the experiment. The tiles were then transferred to 250L chambers of either ambient seawater, pH of 7.8 or 7.6 for five days. Tiles were then rescored in a similar manner but stage of calcification was also recorded. Most coral spat in the pH 7.8 and 7.6 treatments did not calcify past the very early stages of calcification in all four species. These results represent crucial information for the future of recruitment on coral reefs.

## 25-15

**Effects Of Climate Change On Coral Reef Algae: Will Algae Be The Winners?**

**Guillermo DIAZ-PULIDO*[1]**, Kenneth R.N. ANTHONY[2], David I. KLINE[2], Laurence MCCOOK[3], Selina WARD[2], Ove HOEGH-GULDBERG[2], Sophie DOVE[2]

[1]Centre for Marine Studies and ARC Centre of Excellence for Coral Reef Studies, University of Queensland, Brisbane, St Lucia, Australia, [2]Centre for Marine Studies and ARC Centre of Excellence for Coral Reef Studies, University of Queensland, St Lucia, Brisbane, Australia, [3]Great Barrier Reef Marine Park Authority, Townsville, Australia

Climate change predictions imply that intensified levels of thermal bleaching and ocean acidification will lead to increasing rates of coral mortality. A general perception is that such coral reef degradation will result in a phase shift from coral to macroalgal dominance. However, the effects of ocean acidification and warming on tropical coral reef algae have rarely been studied and the vulnerabilities of this key group of organisms to climate change are poorly known. Here we explore the impacts of warming and ocean acidification due to rising atmospheric carbon dioxide emissions on a range of coral reef macroalgae, including crustose coralline algae (CCA) and fleshy macroalgae. We used controlled experimental conditions to simulate acidification and warming scenarios for the Great Barrier Reef, Australia (GBR) in the years 2050 and 2100. Preliminary results from the southern GBR indicate that both groups of benthic algae (calcareous and fleshy) are highly sensitive to climate change. Rates of calcification, photosynthesis, survivorship and recruitment of the CCA *Porolithon onkodes* were severely reduced with increasing CO2 levels and temperature. Similarly, the fleshy macroalga *Lobophora variegata* showed a 50% growth reduction under high levels of CO2 and temperature representative of levels predicted for 2100. Further experiments performed on Lizard Island (northern GBR), confirmed that other species of coral reef macroalgae have relatively low temperature thresholds for physiological stress. Our results suggest that the coral reef macroalgae studied are at least as vulnerable to ocean acidification and global warming as are corals. The high vulnerability of CCA is likely to lower the reef's recovery and cementation capacity, while a reduction in fleshy macroalgae may affect primary productivity with consequences for trophic relations and ecosystem function.

## 25-16

**Climate Change Thresholds And Coral Reef Degradation**

**Kenneth ANTHONY*[1]**, Guillermo DIAZ-PULIDO[1]

[1]Centre for Marine Studies, University of Queensland, St Lucia, Australia

The healthy functioning of coral reefs is underpinned by processes operating at organism, population, community and ecosystem levels. Current reef-resilience models provide excellent insight into the role of coral-algae-herbivore interactions. However, predictions of how coral reefs will behave under unprecedented climate conditions require information about stress responses across all organizational levels. Here, we explore coral community responses along gradients of ocean acidification and thermal stress using a new dynamic coral community model parameterized by organism and population responses to climate-change variables from experimental studies. Model runs for years 2050 and 2100 indicate that key framework builders such as crustose coralline algae and Acroporid corals will gradually diminish in reef communities on the Great Barrier Reef. Contrary to general assumptions, transitions from healthy to degraded reefs are not triggered by the exceedence of distinct threshold values, but show a gradual decline to depauperate states. Whether corals will be replaced by macroalgae depends on the physiological responses of the algal species, and model runs based on recent data suggest that shifts to barren rather than algal-dominated reefs are likely outcomes.

## 25-17

**Climate Change And Reef Development in The Tropical Eastern Pacific**

**Richard ARONSON*[1]**, Ian MACINTYRE[2], Steven VOLLMER[3], Jennifer HOBBS[4], Anke MOESINGER[1]

[1]Dauphin Island Sea Lab, Dauphin Island, AL, [2]Department of Paleobiology, Smithsonian Institution, Washington, DC, [3]Marine Sciences Center, Northeastern University, Nahant, MA, [4]School of Marine and Atmospheric Science, Stony Brook University, Stony Brook, NY

Understanding how biotic turnover controls the development of coral reefs will be critical to projecting their future in a rapidly changing world. How well reefs keep up with rising sea level will determine the extent to which they protect adjacent land masses from coastal erosion. In the tropical eastern Pacific, populations of *Pocillopora damicornis*, the dominant constructor of reef framework, were bleached on a regional scale by the 1982–83 El Niño event. Subsequent coral mortality and bioerosion suggested that centennial-scale recurrences of extreme thermal anomalies associated with the El Niño–Southern Oscillation have slowed accretion rates of eastern Pacific reefs by killing *Pocillopora* episodically. Off the Pacific coast of Panamá, *Pocillopora* recovered rapidly after 1983 in some places but not in others. Where it did not recover, the *Pocillopora* rubble was colonized by another coral species, *Psammocora stellata*, which is not a framework-builder. Coring studies in the Gulf of Panamá showed that *Pocillopora* kills and shifts to *Psammocora* occurred episodically over the past 6000–7000 years; however, *Pocillopora* growth was suppressed for centuries to millennia, depressing vertical reef accretion for intervals far longer than the return time of strong El Niño events. These protracted intervals of suppressed coral growth can be used to parameterize models of reef accretion under scenarios of biannual to annual coral bleaching, predicted to commence in the next several decades. Oceanic acidification will further inhibit reef accretion, especially in the tropical eastern Pacific where upwelled waters already expose *Pocillopora* populations to elevated concentrations of dissolved carbon dioxide.

## 25-18

**Fragile Reefs Of The Eastern Pacific: A Model For Reefs in A High $Co_2$ World**

**Derek MANZELLO*[1]**, Joanie KLEYPAS[2,3], David BUDD[4], Mark EAKIN[5]

[1]Cooperative Institute for Marine and Atmospheric Studies, Rosenstiel School, University of Miami, Miami, FL, [2]Institute for the Study of Society and Environment, National Center for Atmospheric Research, Boulder, CO, [3]Institute for the Study of Society and Environment, National Center for Atmospheric Research, Boulder, [4]Dept. of Geological Sciences, Univ. of Colorado, Boulder, CO, [5]Coral Reef Watch, NOAA NESDIS, Silver Spring, MD

Ocean acidification describes the progressive, global reduction in seawater pH that is currently underway due to the oceanic uptake of increasing atmospheric $CO_2$. Acidification is expected to reduce coral reef calcification and increase reef dissolution, and the relative rates of change will likely be a function of $pCO_2$ (the partial pressure of $CO_2$) in seawater, which is directly proportional to $pCO_2$ in the atmosphere. Little is known about the effects of acidification on syndepositional processes that affect the persistence and preservation of carbonates (i.e., early marine diagenesis). Newly analyzed samples agree with previous studies showing that only trace amounts of inorganic cements occur in modern day coral reefs that exist naturally under low ambient pH in the eastern Tropical Pacific (ETP). The variation in cement abundance and rates of bioerosion between sites in Panamá and Galápagos appears to be related to differences in the saturation state of $CaCO_3$ ($\Omega$); suggesting a link between $\Omega$, inorganic cementation and coral reef development in the ETP. ETP reefs may thus provide a real-world model of coral reef growth in low $\Omega$ waters and provide insights into the role of decreasing $\Omega$ on reefs beyond the prediction of reduced $CaCO_3$ production.

## 25-19

**Phase Shifts in Coral Reefs – Comparative Investigation Of Corals And Benthic Algae As Ecosystem Engineers**

**Christian WILD*[1]**, Andreas HAAS[1], Malik NAUMANN[1], Christoph MAYR[2]

[1]Coral Reef Ecology (CORE) Work Group,GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany, [2]GeoBio-Center, Ludwig-Maximilians-Universität München, München, Germany

Global climate change and direct anthropogenic stress factors do strongly affect the benthic community structure in coral reefs. It is reported from the literature that hermatypic corals are gradually replaced by benthic micro- and macro-algae at many reef locations around the world, a process which is commonly referred to as phase shift. Recent research showed that hermatypic corals via the release of organic matter and concomitant effects on cycles of matter can act as engineers of reef ecosystems. There are strong indications that reef associated benthic algae do also affect reef ecosystem functioning via organic matter release, but all relevant information is lacking. To gain a better understanding of the biogeochemical consequences such phase shifts from corals to algae entail, a series of comparative studies with hermatypic corals and benthic algae were conducted in reefs of the Northern Red Sea during four seasonal expeditions in 2006-2008. These investigations primarily focused on the quantity and quality of the organic matter released by both groups of organisms involving dissolved organic carbon (DOC), particulate organic carbon (POC) and particulate nitrogen (PN). Supplementary mass spectrometric analyses were conducted in order to analyse stable isotope signatures of coral- or algae-derived organic matter. Finally, planktonic and benthic degradation of the respective organic matter were investigated in the field using bottle incubation experiments and stirred benthic chambers, respectively. Our data show clear differences between organic matter release by benthic reef algae or corals for most of the measured parameters, thus, suggest a massive influence of the described phase shifts onto biogeochemical cycles and processes in warm water coral reefs.

## 25-20

**Long-Term, Regional-Scale Patterns in Caribbean Coral Bleaching Responses**

**Allison L. PERRY*[1,2]**, Isabelle M. CÔTÉ[3], John D. REYNOLDS[3], Andrew R. WATKINSON[4,5]

[1]WorldFish Center, Bayan Lepas, Penang, Malaysia, [2]School of Biological Sciences, University of East Anglia, Norwich, United Kingdom, [3]Department of Biological Sciences, Simon Fraser University, Burnaby, BC, Canada, [4]School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom, [5]Tyndall Centre for Climate Change Research, Norwich, United Kingdom

Coral bleaching is one of the most serious and immediate ecological impacts of climate change, with bleaching events increasing in frequency, severity and extent with rising sea surface temperatures (SSTs). Given the geographically widespread nature of this phenomenon, there is a need to understand patterns and drivers of bleaching over multiple spatial and temporal scales. We take a regional-scale approach, and examine long-term trends in the occurrence of coral bleaching in the Caribbean region, and in the SST anomalies associated with bleaching. Using data over a 24-year period, we assess whether corals may be adjusting to rising temperatures, and examine the regional-scale relationship between the geographic extent of bleaching and rising SST anomalies. At both local and regional scales, there is little evidence to support the possibility that Caribbean reefs are keeping pace with rising sea temperatures, while the geographic extent of bleaching in the region is accelerating with rising sea temperatures even more rapidly than previously known. In combination, our results emphasise the particular vulnerability of reefs to climatic warming.

## 25-21

**Right Of Disaster: Understanding, Predicting And Accelerating The Adaptive Response Of Reef Coral Symbioses To Climate Change**

**Andrew BAKER*[1,2]**

[1]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, [2]Marine Program, Wildlife Conservation Society, Bronx

Reef-building coral symbioses are increasingly threatened by the effects of climate change, and it is not yet known whether these organisms will be able to adapt or acclimatize quickly enough to avoid large-scale loss of reef ecosystems. A variety of mechanisms have been identified by which corals, their algal symbionts, and other microbial partners might compensate for these environmental changes. Most research to date has focused on the ability of corals to flexibly associate with diverse algal symbionts ("zooxanthellae" in the genus *Symbiodinium*) whose specific identity results in different environmental optima for the coral host. However, the potential importance of this mechanism is limited by: (1) the timescales over which flexibility might act; (2) ontogenetic restrictions, environmental prerequisites and host systematic constraints on flexibility; and (3) physiological tradeoffs of hosting different symbionts. Despite these considerations, symbiosis flexibility remains the most promising mechanism identified to date by which corals might survive climate change. Consequently, as we move into an era of unavoidable climate impacts, knowledge of symbiosis flexibility might be used to understand declines, forecast future effects, and prioritize species and areas of special conservation. Moreover, despite the limitations on symbiosis flexibility outlined above, artificial manipulation of symbiont communities at the larval or adult coral stages may have conservation benefit and should be attempted. These interventions can be employed to: (1) create stocks of thermally tolerant corals for restoration purposes; (2) protect the largest and oldest corals on reefs of special value; and (3) create species survivorship networks in targeted areas of special concern whose persistence may help preserve ecosystem function. Symbiosis flexibility has probably played a critical role in the evolution and success of reef corals, and triage-based conservation strategies that leverage these natural adaptive mechanisms to mitigate climate change effects should be attempted whenever possible.

## 25-22

**Proliferation Of An Opportunistic Symbiodinium Sp. During The 2005 Eastern Caribbean Mass Coral 'bleaching.'**

**Todd LAJEUNESSE*[1,2]**, Jennifer FINNEY[3], Robin SMITH[4], Hazel OXENFORD[3]

[1]Biology, Florida International University, North Miami, FL, [2]Biology, Pennsylvania State Universtiy, University Park, [3]Center for Resource Management and Environmental Studies, University of the West Indies, Bridgetown, Barbados, [4]Biology, Florida International University, Miami, FL

Corals of the Eastern Caribbean underwent their worst recorded bleaching and mortality in the fall of 2005. The resident dinoflagellate endosymbionts were examined in coral species from Barbados during the summer before signs of stress were evident. Sampling was repeated in early winter one month following a return to normal sea surface temperatures, but before recovery. The reefs were revisited 5 months and two years later to assess the state of Symbiodinium populations. A partial or complete change in the resident population to a putatively stress-tolerant opportunist, Symbiodinium D1a, occurred in colonies of several coral species over the course of this event. Low-abundance resident background populations of D1a were detected using rtPCR before signs of stress were evident and proliferated in many colonies during the late summer and fall. The differential growth and/or persistence of this background symbiont in response to thermal stress 'saved' many colonies from bleaching. Many colonies that bleached experienced partial or total mortality in the months that followed. While the prevalence of Symbiodinium D1a remained high months later, the symbiont populations in most colonies reverted back to their normal symbiont species after two years. The distribution patterns before, during and after this event clearly indicate that Symbiodinium D1a is a weedy species generalized to numerous host taxa and opportunistic during times of physiological stress.

## 25-23

**A Community Change in The Symbionts Of A Scleractinian Coral Following A Natural Bleaching Event: Field Evidence Of Acclimatization**

**Alison JONES*[1]**, Ray BERKELMANS[2], Madeleine VAN OPPEN[2], Jos MIEOG[3], William SINCLAIR[1]

[1]Biosystems and Resources, Central Queensland University, Rockhampton, Australia, [2]Environmental Change and Impacts, Australian Institute of Marine Science, Townsville, Australia, [3]Marine Benthic Ecology and Evolution, University of Groningen, Haren, Netherlands

It has been hypothesized that reef corals can change their Symbiodinium community populations dramatically by up-regulating low levels of more stress tolerant types in their tissue after bleaching. In this study, we quantify the change in symbiont community in colonies of a common reef-builder Acropora millepora after a natural bleaching event in the Keppel Islands (Great Barrier Reef). By late February 2006 when bleaching was at its most intense, the relative difference in bleaching susceptibility between corals predominated by C2 and D was clearly evident, with the former bleaching white and the latter normally pigmented. The symbiont community change in surviving colonies was dramatic (71% changed predominance from C2 to D or C1 (n=58) however selective mortality of C2 colonies also played a substantial role in shifting the symbiont community in the post-bleaching coral population. We suggest that this change in symbiont community structure occurred mainly as a result of background symbionts proliferating in recovered colonies. If these backgrounds symbionts are present in other structurally important coral species, coral reefs may have considerably more acclimatization potential through symbiont shuffling than previously thought.

## 25-24

**Shifts in *symbiodinium* Communities Following Bleaching in The Panamic Eastern Pacific: Insights From Quantitative Pcr**

**Adrienne CORREA*[1,2]**, Andrew BAKER[3], Danielle MCDONALD[3], Peter GLYNN[3]

[1]Ecology, Evolution & Environmental Biology, Columbia University, New York, NY, [2]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, [3]Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL

The extent to which reef corals can adapt and/or acclimatize to increasing sea surface temperatures is highly debated within climate change science. It is hypothesized that physiological differences among the genetically diverse dinoflagellate endosymbionts of corals (*Symbiodinium* spp.) may prove critical to the survival of reefs. This could occur in two ways: (1) the differential proliferation of coral colonies that specifically host thermally tolerant symbionts; and/or (2) shifts favoring heat tolerant *Symbiodinium* in colonies that flexibly host multiple symbiont types. Some shifts in symbiont dominance have already been documented on recently bleached reefs, within individual bleached colonies, and seasonally within healthy colonies. These shifts may be "host-driven", such as when differential host mortality indirectly results in community-wide changes in *Symbiodinium* prevalence; or they could be symbiont-driven, representing the outcome of ecological processes such as competition among symbionts within hosts. We are using quantitative PCR (qPCR) to explore: (1) the prevalence of mixed *Symbiodinium* communities; (2) changes in symbiont community structure; and (3) the potential evidence for symbiont competition within a long-term (1995-2006) dataset of two Panamanian coral species (*Pocillopora damicornis* and *Pocillopora elegans*) in the eastern Pacific, and also within experimentally bleached colonies. This approach allows us to explore the degree to which fine-scale changes occur between years in the average dominant *Symbiodinium* clade on reefs, as well as changes in the relative abundance of *Symbiodinium* clades within individual coral colonies before, during, and after bleaching. Since cryptic diversity may function as a 'safety net' during times of environmental change, *Symbiodinium* community dynamics, especially following disturbance, may be critical to predicting the potential future survival trajectories of coral reefs.

## 25-25

**Can Scleractinians Take Up Exogenous Symbionts After A Bleaching Event?**

**Mary Alice COFFROTH*[1]**, Eleni PETROU[2], Daniel POLAND[2], Lyndsey HOLLAND[1]

[1]Geology, University at Buffalo, Buffalo, NY, [2]Biology, University at Buffalo, Buffalo, NY

With reports of coral bleaching on the rise, it is ever more important to understand how corals will respond to bleaching events and to assess their ability to recover. One large unknown is the manner in which bleached corals recover their symbiont populations. Can corals acquire zooxanthellae from the environment or is recovery dependent on surviving *in hospite* symbionts? Acquisition of symbionts from the environment could be an important mechanism for acclimatization to an altered environment. We examined the ability of *Porites divaricata*, a scleractinian coral found throughout the Caribbean, to secondarily acquire algal symbionts after an experimentally induced bleaching event. *Porites divaricata* colonies in the Florida Keys typically harbor *Symbiodinium* B170 (based on sequence variation in the chloroplast 23S rDNA). Using elevated temperature, colonies of *P. divaricata* were induced to bleach and then exposed to *Symbiodinium* strains not typically found in the adult host (*Symbiodinium* strains A198, B211, B 224 and D206). At 19 d and 38 d after exposure to the atypical strain, most of the colonies only harbored the symbiont type originally found in the host prior to bleaching (i.e. B170). However, after 19d all colonies exposed to strain B224 harbored the non-native strain in addition to the strain normally found in *P. divaricata* (B170). In the other treatments, the inoculated strain was only rarely detected (7% of samples). This suggests that corals may secondarily obtain new symbionts from the environment, but like the primary infection, host-symbiont specificity restricts the plasticity of the symbiosis.

## 25-26

**Environmental Controls on the Establishment and Development of Symbiosis in Corals**

**Vivian CUMBO*[1]**, Andrew BAIRD[2], M.H. VAN OPPEN[3]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [2]ACR Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [3]Australian Institute of Marine Science, Townsville, Australia

The initial establishment of symbiosis is critical for coral that acquire their zooxanthellae via horizontal transmission because it gives them an opportunity to associate with different, more beneficial strains of zooxanthellae. Corals can associate with many different species of zooxanthellae, some which are more tolerant of high temperature. Consequently, one possible way for corals to cope with projected increases in sea surface temperature attributed to global warming is to initially associate with heat tolerant symbionts. This study tested this mechanism by determining whether environmental conditions affect the establishment and development of symbiosis for the coral, *Acropora monticulosa*. Coral larvae were exposed to 25, 28 or 31°C and given either *Symbiodinium* clades A, C or D. Some strains of *Symbiodinium* clade D are known to be heat tolerant, while clade C is generally considered heat sensitive. Symbiosis was established with all clades of zooxanthellae under every temperature treatment. The proportion of larvae infected with clade C decreased as temperatures increased, while the proportion of larvae infected with clade A peaked at 28°C then decreased. In contrast, the proportion of larvae infected with clade D increased as temperature increased. Additionally, the density of zooxanthellae within the larvae decreased significantly for clade A and C but increased for clade D as temperature increased. These results suggest that as seawater temperatures increase, the coral host may be able to shift to more heat tolerant clades of zooxanthellae and potentially aid coral's ability to cope with global warming.

## 25-27

***My Name Is Legion, For We Are Many*: The Ecological And Evolutionary Significance Of Population Structure in Symbiotic Dinoflagellates (*symbiodinium*, Dinophyta)**

**Scott R. SANTOS*[1]**

[1]Department of Biological Sciences, Auburn University, Auburn, AL

*Symbiodinium* represents a genus of unicellular dinoflagellate symbionts that associate with a variety of marine protists and invertebrates. Over the last 15 years, eight divergent clades, designated A to H, with numerous subcladal "types" comprising each lineage, have been recognized within the genus. Although the diversity and phylogenetics of the *Symbiodinium* complex is now well established, there has been surprisingly few data on fine-scale population structure and biogeography in these dinoflagellate symbionts. Since populations represent the fundamental unit of evolution, understanding patterns and processes at this level is paramount toward furthering our knowledge on the basic biology of *Symbiodinium* as well as how anthropogenic-driven global climate change may impact these symbionts and their host associations. Here, I present a synopsis of population-level characteristics for *Symbiodinium* distilled from published and unpublished data. These include: 1) the symbiont population of a host is typically comprised of a multitude of individuals belonging to a single genetic entity or clone; 2) for a given host species, the majority of individuals at a site harbor an identical *Symbiodinium* clone, indicating low symbiont population diversity per host species per site; 3) strong genetic structure is common between symbiont populations of a host species across sites, suggesting low genetic connectivity between populations due to poor dispersal capability of clones, and; 4) all clones associating with a particular host species over a widespread geographic range belong to the same phylogenetic "species", implying high specificity in the pairing of host species and *Symbiodinium*. By unifying these characteristics in a single framework, a series of hypotheses, testable via experiments and/or modeling, are synthesized regarding the ecology and evolution of *Symbiodinium* and their important symbiotic associations.

## 25-28

**Coral Holobiont Community Structure: How Much Have We Missed By Focusing Only in The Coral Host?**

**Juan ORTIZ*[1]**, Maria GOMEZ CABRERA[1]

[1]Centre for Marine Studies, The University of Queensland, St Lucia, Australia

Coral community structure has been studied in depth for the past fifty years. However, the identity of symbiotic dinoflagellates that live within the coral colonies, their life-history, and specificity to different hosts is poorly understood. While the number of identified symbiont types increases, we are left with the task of recognizing functional differences between these groups. Several studies have established the symbiont community structure in individual coral colonies, but little is known about how we should interpret the role of the symbiotic dinoflagellate communities in the ecosystem. The aims of this study is: To quantify the contribution of the symbiont identification to the community response to environmental variables by comparing the response of the coral host community structure and the holobiont community structure to the same environmental gradient. The coral community structure and the symbiont community structure were studied in 5 coves with different environmental conditions along the central coast of Venezuela using photo-transects and ITS2 to identified symbionts. 77 % of the variability of the coral community structure can be explain by distance from the closest reef, while 92% of the variability in holobiont community structure can be explain by a combination of 4 environmental variables. The 15% increases in the proportion of the variability explained by the environmental variables is the contribution of the symbiont identity in the model. Following this analysis a holobiont niche segregation was evident having different hots-simbiont combinations associated to different environmental conditions. This study shows quantitatively for the first time how much information can be gain by including the symbiont ID in classical coral community ecology, demonstrating that the study of coral holobiont community structure is the natural next steep forward in the study of changes in coral communities.

## 25-29

**Prevalence Of Background Populations Of An Opportunistic Symbiodinium Among Caribbean Coral Communities.**

**Robin SMITH*[1]**, Todd LAJEUNESSE[1]

[1]Florida International University, Miami, FL

The ecology of *Symbiodinium D1a* in Caribbean corals is different than other symbionts. Distribution surveys indicate that the prevalence of *Symbiodinium D1a* may increase on reefs experiencing irradiance and/or thermal disturbance. Some species within this lineage demonstrate physiological tolerance of irradiance fluctuations while others display increased thermal tolerance. It is therefore important to delineate the natural distribution patterns of this species to gain a better understanding of the acclimation and/or adaptation potential of coral reefs. The fine spatial distribution of *Symbiodinium D1a* in a wide diversity of coral taxa from Caribbean reefs was evaluated using real-time PCR to detect it's presence as a background population. For comparison, host communities in Hawaii and the eastern Pacific were analyzed. Results show that these *Symbiodinium* spp., namely D1a, exist in many corals in the absence of environmental stress; often in low abundance and below the detection limits of conventional fingerprinting techniques. These findings suggest that the rise of population shifts to D-type *Symbiodinium* following environmental disturbance are most readily explained as the disproportionate growth of resident *Symbiodinium D* populations that otherwise exist at low concentrations. *Symbiodinium D1a* appears to be a globally distributed host-generalist capable of associating with most coral genera as a background population during periods of environmental stability with the potential to become opportunistically dominant during periods of physiological stress.

## 25-30

**Symbiont Specificity Within And Among Soft Coral Genera During The 1998 Gbr Mass Coral Bleaching Event**

**Tamar GOULET*[1]**, Todd LAJEUNESSE[2], Katharina FABRICIUS[3]

[1]Biology, University of Mississippi, University, MS, [2]Biology, Pennsylvania State University, University Park, PA, [3]Australian Institute of Marine Science, Townsville, Australia

Coral bleaching (the loss of symbiotic intracellular dinoflagellates, *Symbiodinium* spp.) is not restricted to scleractinian corals but also occurs in soft corals. In the 1998 mass coral bleaching event, soft coral species were severely affected, with considerable variability in bleaching within and among soft coral taxa. In the midst of the bleaching event on the central Great Barrier Reef (GBR), tissue samples were taken from bleached and unbleached colonies representative of 17 soft coral genera in the order Alcyonacea (Octocorallia: Cnidaria). The *Symbiodinium* types in these samples were determined using PCR-denaturing gradient gel electrophoresis (DGGE) fingerprinting analysis of the internal transcribed spacer (ITS) regions 1 and 2. Alcyonaceans from the GBR exhibited a high degree of symbiont specificity. Nine different *Symbiodinium* clade C types occurred. Clade B (*B1n* and *B36*) symbiont types were only recorded from *Nephthea* sp. and a rare clade D type (*D3*) was found only associated with *Clavularia koellikeri*. *Symbiodinium* clade populations were homogenous in all but one colony. Colonies with a bleached appearance hosted symbiont types that were genetically indistinguishable from those in non-bleached conspecifics. These data suggest that parameters other than the resident endosymbionts play an important role in determining bleaching susceptibility within and among soft coral species.

## 25-31

**Coral Physiology: The Interaction Between Symbiodinium Genotype And Environment**

**Jos MIEOG*[1]**, Madeleine VAN OPPEN[2], Ray BERKELMANS[2], Bette WILLIS[3], Wytze STAM[1], Jeanine OLSEN[1]

[1]University of Groningen, Haren, Netherlands, [2]Australian Institute of Marine Science, Townsville, Australia, [3]James Cook University, Townsville, Australia

The influence of different *Symbiodinium* types on the physiology of corals has been difficult to study as coral host x environment interactions interfere when comparing different coral species or populations harboring different algal types. To address this, offspring of the same *Acropora millepora* parental colonies were infected with three different types of algal symbionts found at the Great Barrier Reef (GBR) of Australia: one rare clade A-type found mostly in cooler areas, one common, generalist clade C-type, and one clade D-type that is common in warm and turbid habitats. All groups were grown out at a warm, turbid (Magnetic Island) and a cold, clear (Keppels Islands) inshore location of the GBR. Their growth and survival was monitored and after seven months their heat-tolerance was determined.

At Magnetic Island, C-corals grew 2-3 times faster and survived 2-4 times better than D-corals. Corals with A either died here or changed to D within the first two months. At the Keppels Islands, growth of C-corals was only slightly better compared to D-corals, while A-corals showed the slowest growth. D-corals survived about 2 times better here than A- or C-corals. A-corals were highly susceptible to heat-stress, while D-corals were the most heat-tolerant at both locations.

This study demonstrates that physiological characteristics can differ strongly between conspecific corals in the same environment harboring different algal types, and that changes in the dominant symbiont type of a coral may represent a trade-off (e.g. growth vs. heat-tolerance). The relative fitness of each coral-algal association (as estimated from growth, survival and heat-tolerance), however, was found to vary with environmental factors.

## 25-32

**Can Hosting Different *symbiodinium* spp. Lead To Thermal Adaptation Within *pocillopora Verrucosa* Around Guam?**

**Lisa CHAU*[1]**, Robert ROWAN[1]

[1]Marine Laboratory, University of Guam, Mangilao, Guam

During moderate bleaching events on Guam coral reefs, caused by increased irradiance and sea temperatures, corals hosting *Symbiodinium* genotype C typically bleach, while corals hosting *Symbiodinium* D do not. *Symbiodinium* D corals are thought to be adapted to high temperatures, whereas *Symbiodinium* C corals, though more common, are thought to be temperature-sensitive. In this study corals were challenged by reciprocally transplanting them between two reefs that varied in mean temperature by 0.5oC. This temperature difference was not extreme enough to cause bleaching but provided enough stress to stimulate a potential change in zooxanthellar community structure. In this year-long field study, transplanted colonies of *Pocillopora verrucosa* with known zooxanthellar genotypes (C, D, or a mixture of C and D) were sampled periodically and examined for genotypic changes in their zooxanthellar populations. Results from PCR and restriction fragment length polymorphisms (RFLPs) showed that 40% of transplants retained the same proportion of genotypes after transplantation to a different temperature regime. However, 20% of corals from both sites changed genotypes from C to D or D to C, and 30% remained mixed proportions of C and D throughout the experiment. Ten percent of our transplants died during the experiment; all contained genotypes that were mixed or had shifted. We showed that *Symbiodinium* populations within some corals have the ability to vary their symbiont community structure with changing sea temperatures. However, this mechanism of change through adaptation, shuffling, or recombination is unknown and poorly studied. The coral-algal symbiosis is a dynamic system that requires more investigation to elucidate the mechanisms of change so that we can comprehend the adaptability of corals to increasing sea surface temperatures.

## 25-34

**Relationship Between Historical Sea-Surface Temperature Variability And Climate Change-Induced Coral Mortality in The Western Indian Ocean**

**Mebrahtu ATEWEBERHAN*[1]**, Tim MCCLANAHAN[1,2]

[1]Coral Reef Conservation Project, Wildlife Conservation Society, Mombasa, Kenya, [2]Marine Programs, Wildlife Conservation Society, New York

Coral reefs have become one of the major casualties of climate change. Many of the world's coral reefs suffered high coral mortality during the 1998 ENSO, with the highest mortality in the western Indian Ocean (WIO). We present results of a meta-analysis of field data on change in coral cover across the 1998 ENSO event for 36 major reef areas in the WIO. Average coral cover declined by ~40 % across the event with the highest mortality in the central and northern regions, with the exception of the Red Sea and Gulf of Aden. Based on multivariate analysis of SST properties, WIO reefs were categorized into 3 major groups of differing coral mortalities. Basin-wide change was highly variable and related to historical sea-surface temperature (SST) variability. Mortality was negatively associated with standard deviation (SD) SST until SD ~2.3, with increasing flatness of the SST frequency distributions. It increased with further increase in SD as the SST distributions became strongly bimodal. The predictable environmental patterns associated with the mortality suggest that future change during a warmer and more variable climate can be predicted and management priorities directed accordingly.

## 25-35

**Corals Resisting Warming – The Importance Of Experience**

**Thomas OLIVER*[1]**, Stephen PALUMBI[2]

[1]Hopkins Marine Station, Stanford University, Pacific Grove, CA, [2]Hopkins Marine Station, Stanford Unveristy, Pacific Grove, CA

Studies have demonstrated that corals hosting certain genotypes of the dinoflagellate symbiont *Symbiodinium sp.* better resist the negative effects of temperature increases. However, the role of these resistant genotypes and the relative importance of other mechanisms of adaptation are little known. Perfomed on Ofu Island, American Samoa, this study compared resistance to temperature stress among groups of the coral *Acropora hyacinthus* that not only hosted distinct symbionts but also were sampled from two distinct habitats –a lagoonal pool with extreme swings in its temperature profile and a more moderate pool. Replicate branches were taken from 32 corals, and housed in either a tank held at ambient temperature, or a tank held ~2.5 degrees C higher. Sublethal effects were monitored using a proxy for the photosynthetic health of the symbionts, the maximum quantum yield (MQY) of PSII, measured before dawn. Visual bleaching was recorded using a color reference card, and mortality was indicated by coral tissue sloughing off the skeleton. The experiment ran until ~50% of corals in the elevated tank experienced mortality (4-6 days), and was repeated 3 times. MQY measurements showed that there was both a genotype and pool effect: corals fared better either if they hosted a resistant genotype, or came from the variable pool. However, with regard to both color loss and mortality, the only discernable effect was higher resistance of the corals from the variable pool. As the coral populations in our experiment were not genetically distinct, these results highlight the importance of acclimatization and suggest that bleaching thresholds can vary considerably depending on a coral's environmental experience.

## 25-36

**The Effect Of Thermal History On The Susceptibility Of Reef-Building Corals To Thermal Stress**

**Rachael MIDDLEBROOK*[1]**

[1]Centre for Marine Studies, University of Queensland, Brisbane, Australia

Thermal stress causes the breakdown of the relationship between corals and their symbionts (bleaching). This symbiosis may acclimate to changes in the environment, thereby potentially modifying the environmental threshold at which they bleach. While a few studies have examined the acclimation capacity of reef-building corals, our understanding of the underlying mechanism is still in its infancy. This research focuses on the role of recent thermal history in influencing the response of both corals and symbionts to thermal stress, using the reef-building corals *A.aspera* and *A.formosa.* Symbionts of *A.aspera* corals that were exposed to 31 ºC for 48 h one or two weeks prior to a six-day simulated bleaching event (when corals were exposed to 34 ºC) were found to have more effective photoprotective mechanisms. These mechanisms included changes in non-photochemical quenching and xanthophyll cycling. These differences in photoprotection were correlated with decreased loss of symbionts, with those corals that were not prestressed performing significantly worse, loosing over 40% of their symbionts and having a greater reduction in photosynthetic efficiency. Significant differences were also found in the performance and short-term recovery of *A.formosa* corals exposed to a rapid and a slow progressive heating rate. A slow build up in temperature induced acclimation seen through lipid concentrations, symbiont densities, respiration and photoprotective mechanisms. These results are important as they show that thermal history, in addition to light history, can influence the response of reef-building corals to thermal stress and therefore have implications for the modeling of bleaching events. However, whether acclimation is capable of modifying the thermal threshold of corals sufficiently to cope as sea temperatures increase in response to global warming has not been explored fully.

## 25-37

**Bleaching, El Nino, And El Nina: 13 Years Of Seasonal Analysis Of Reef-Building Corals in Florida, The Bahamas, And The Caribbean**

**William FITT*[1]**, Dusty KEMP[1], Xavier HERNANDEZ-PECH[2], Roberto IGLESIAS-PRIETO[2], Jennifer MCCABE[1], Tom SHANNON[1], Brigitte BRUNS[3], Gregory SCHMIDT[3]

[1]Odum School of Ecology, University of Georgia, Athens, GA, [2]Universidad Nacional Autónoma de México, Puerto Morelos, Mexico, [3]Plant Sciences, University of Georgia, Athens, GA

Six species of coral were monitored approximately every three months for 13 years in the Florida Keys, 11 years in the Bahamas, and 4 years in Puerto Morelos , Mexico. Generally all species exhibited peaks in ash-free dry weight (AFDW) and density of zooxanthellae (Symbiodinium) during the winter/spring and lowest values in the late summer.

Certain generalities include: shallow water (1-4 m) species showed higher AFDW and densities of symbionts compared to deep water populations (13 m). Many of the species of corals had one type of Symbiodinium in shallower colonies, and a different type of Symbiodinium in deeper colonies. The trends of AFDW of the tissues from corals follow the density of Symbiodiinium, some three-months later.

Each species of coral appears to have a minimum value of AFDW, below which the coral tends to die. For instance, the AFDW of 2 mg/cm2 appears to be a minimum for Acropora cervicornis, with two populations dying when they went below this level in the Bahamas, compared with one population that is alive and above the minimum AFDW.

During the 1997/8 El Niño the AFDW and symbiont densities were extremely low, but the next winter (1999) there was a spike in the density of symbionts followed by a slow recovery in AFDW. There were smaller spikes after the El Niño's of 2002 and 2005. During La Niña the temperature extremes were less than normal, and the corals showed values for AFDW and density of Symbiodinium well above the minimum levels. Visible bleaching was only observed for a few of the coral species, occurring at the end of El Niño events.

## 25-38

**The Future Of Specific Symbioses Within The Reef Coral Pocillopra in The Eastern Pacific: Investigating The Impacts Of Thermal Anomalies in Western Mexico**

**Mark WARNER*[1]**, Todd LAJEUNESSE[2], Hector REYES-BONILLA[3], Matt ASCHAFFENBURG[1], Mike MCGINLEY[1], Robin SMITH[4], Tye PETTAY[4]

[1]University of Delaware, Lewes, DE, [2]Pennsylvania State University, University Park, PA, [3]University of Southern Baja California, La Paz, Mexico, [4]Florida International University, Miami, FL

Many sources have pointed to the endosymbiotic dinoflagellates within the genus *Symbiodinium* as a primary cellular target of damage during coral bleaching. However, the genetic and physiological diversity of these symbionts, coupled with the fact that some corals may harbor multiple symbiont types, has led to the idea that such plasticity could provide an axis for acclimatization or adaptation to climate change if corals can retain and/or acquire thermally tolerant algae. In particular, it is thought that symbionts within the "D" lineage may serve this role, yet our knowledge of the ecological distribution and physiological detail of this and other groups of *Symbiodinium* is largely incomplete. The eastern Pacific provides an excellent venue to test these ideas of symbiont change and coral resilience, as it encompasses regions that have been differentially impacted by thermal anomalies and coral bleaching. Here we present the initial findings of a three year study that is investigating the distribution of "C" and "D" *Symbiodinium* within the coral *Pocillopora* in several regions of western Mexico. In addition, the impact of short-term thermal stress experiments on the photobiology, as well as long-term analysis of bleaching recovery, coral growth and fitness in *Pocillopora* harboring dominant populations of either "C" or "D" *Symbiodinium* in the southern Gulf of California will be presented. Initial results from experimental bleaching suggest that D1 symbionts may possess a slightly higher degree of tolerance to elevated temperature and/or light as compared to type C1b-c algae, yet significant damage to photosystem II can result. The long-term implications for recovery and response to future warming events in the northeastern Pacific will be addressed.

## 25-39

**Annual Summer Mass Bleaching Of A Multi-Species Coral Community in American Samoa**

**Douglas FENNER*[1]**, Scott HERON[2]

[1]Marine & Wildlife Resources, American Samoa Government, Pago Pago, American Samoa, [2]Coral Reef Watch, NOAA, Townsville, Australia

Widespread annual summer mass coral bleaching has been predicted to begin in about 30-50 years, due to increasing global temperatures. Annual mass bleaching has been reported for two individual coral species, one in the Mediterranean and one in Florida, but this study is the first known annual bleaching report for a multi-species coral community. Bleaching levels have been recorded in two back-reef pools on Tutuila, American Samoa on a biweekly to monthly basis since late 2003. Mass bleaching of several species has occurred in all four summers during this period. Most *Acropora*, one of two species of *Millepora*, and one small area of *Porties cylindrica* have repeatedly bleached but little mortality has been observed so far. During this period, there was little or no bleaching on the reef slopes. The back-reef pools have limited circulation, and get hotter on sunny summer days than the adjacent ocean, with sea surface temperature (SST) reaching about 32°C in these pools. The two summers previous to the start of recording were reported to have bleaching on reef slopes. About 50% of all staghorns in the pools were dead at the start of observations, which likely were caused by the more intense bleaching in those 2 years. This suggests that bleaching has occurred every summer for at least 6 years in a row. The record of the intensity of bleaching in the pools over the 4 years follows SST's quite closely. This appears to be the first detailed record of the time course of repeated multi-species bleaching available. Ongoing annual mass bleaching of a multi-species community provides a window into the future and an opportunity for examining the effects on corals of climate change.

## 25-40

**Bleaching Damage And Recovery Potential Of Coral Reefs in Dubai, Uae**

John BURT[1,2], **Andrew BAUMAN*[3]**, Aaron BARTHOLOMEW[4], Peter SALE[5,6]

[1]Natural Science and Public Health, Zayed University, Dubai, United Arab Emirates, [2]Department of Biological Sciences, University of Windsor, Windsor Ontario, Canada, [3]International Network on Water, Environment and Health, United Nations University, Dubai, United Arab Emirates, [4]Department of Biology and Chemistry, American University of Sharjah, Sharjah, United Arab Emirates, [5]Department of Biological Sciences, University of Windsor, Windsor, ON, Canada, [6]International Network on Water, Environment and Health, United Nations University, Windsor, Canada

Documenting long-term changes to coral reef communities following large-scale bleaching events is necessary for predicting changes to coral community composition and their recovery potential to climate change. Such information is necessary to successfully predict how bleaching events may affect the composition and recovery potential of coral communities. In the Arabian Gulf increasing frequencies of elevated sea surface temperatures (1996, 1998, and 2002) have caused extensive coral reef mortality in Dubai United Arab Emirate. Here, we surveyed coral communities within Dubai, examining the composition of the coral assemblages present in 2007, and compared this with information on coral community composition from 1996. We characterized five distinct coral communities in 2007 and compared with previously published accounts of the same communities. In 1996, extensive coral mortality in Dubai, primarily affected *Acropora* dominated communities, reducing their abundance by almost 90%. Our research showed that within the same areas, *Acropora* communities had nearly doubled in abundance, from 22% to 42%. Despite this strong recovery of *Acropora* communities, both *Faviid* and *Poritid* assemblages, which only suffered negligible mortality in 1996, dominated remaining communities. However, minimal change in percent coral cover of both *Faviid* and *Poritid* between 1996 and 2007 suggested assemblages were shifting towards *Acropora* dominated pre-bleaching communities. We also investigated the recovery potential of coral communities by surveying coral recruitment. Recruitment densities were consistently low throughout coral assemblages, with community composition highly dependent on the surrounding adult communities. However, the prevalence of relatively fast growing *Acropora* juveniles throughout communities indicated that recovery of *Acropora* dominated communities was occurring. This study shows that despite recurring mass coral bleaching events, coral communities throughout Dubai are able to rapidly recover suggesting that these assemblages may be acclimatized to the extreme conditions found throughout the Arabian Gulf.

## 25-41

**Can Symbiont Diversity Help Coral Reefs Survive Climate Change?**

**Marissa BASKETT*[1]**, Steven GAINES[2], Roger NISBET[2]

[1]National Center for Ecological Analysis and Snythesis, University of California, Santa Barbara, Santa Barbara, CA, [2]Ecology, Evolution and Marine Biology, University of California, Santa Barbara, Santa Barbara, CA

Given climate change, thermal stress-related mass coral bleaching events present one of the greatest anthropogenic threats to coral reefs. While corals and their symbiotic algae may respond to future temperatures through adaptation and shifts in community compositions, the climate may change too rapidly for coral response. Here we develop a model of coral and symbiont ecological dynamics and symbiont evolutionary dynamics. Model results without variation in symbiont thermal tolerance predict coral reef collapse within decades under multiple future climate scenarios, consistent with previous threshold-based predictions. However, model results with genetic or community-level variation in symbiont thermal tolerance can predict coral reef persistence into the next century, provided low enough greenhouse gas emissions occur. Therefore, the level of greenhouse gas emissions will have a significant effect on the future of coral reefs, and accounting for biodiversity and biological dynamics is vital to estimating the size of this effect.

## 25-42

**Factors Affecting The Evolution Of Bleaching Resistance in Corals**

**Julian CALEY*[1]**, Troy DAY[2,3], Laura NAGEL[4], Madeleine VAN OPPEN[1]

[1]Australian Institute of Marine Science, Townsville, Australia, [2]Dept. of Mathematics and Statistics, Queen's University, Kingston, ON, Canada, [3]Dept. of Biology, Queen's University, Kingston, Canada, [4]Dept. of Biology, Queen's University, Kingston, ON, Canada

We present a mathematical model of coevolutionary interactions between partners in a coral-algae mutualistic symbiosis. Our goal is to better understand factors affecting the potential evolution of bleaching resistance in corals, in response to increased average sea temperatures. We explore the evolutionary consequences of four factors: (i) tradeoffs among fitness components, (ii) different proximate mechanisms of coral bleaching, (iii) the genetic determination of bleaching resistance, and (iv) the mode of sexual reproduction. We show that traits in mutualistic symbioses, such as thermal tolerance in corals, are potentially subject to novel kinds of evolutionary constraints, and that these constraints are mediated by ecological dynamics. We also show that some proximate mechanisms of bleaching yield faster evolutionary responses to temperature stress, and that the nature of interspecific control of bleaching resistance and the mode of sexual reproduction interact to strongly influence the rate of spread of resistance alleles. These qualitative theoretical results highlight important future directions for empirical research in order to quantify the potential for coral reefs to evolve resistance to thermal stress.

## 25-43

**Estimating Potential For Adaptation Of Corals To Climate Change**

**Nikolaus CSÁSZÁR*[1,2]**, Peter RALPH[1], Richard FRANKHAM[3,4], Ray BERKELMANS[2], Madeleine VAN OPPEN[2]

[1]Department of Environmental Sciences, University of Technology, Sydney, Sydney, Australia, [2]Australian Institute of Marine Science, Townsville, Australia, [3]Macquarie University, Sydney, Sydney, Australia, [4]Australian Museum, Sydney, Sydney, Australia

Climate models predict rising global sea-surface temperatures accompanied by increasing frequencies of coral mortalities and shifts in ecosystem structure throughout the 21st century. Today, it is well known that geographically different coral populations display substantial intra-specific variation in thermal tolerance. This suggests local adaptation to different temperature regimes. The ability of the coral/algal symbiosis to adapt to further increasing sea-surface temperatures in an evolutionary sense will depend on the extent of the underlying genetic variation in thermal tolerance. We investigated the genetic- and environmental variation in two phenotypic traits that are directly linked to thermal tolerance in corals. A controlled temperature experiment was conducted on a predominantly clade D zooxanthellae harbouring population of the widely abundant scleractinian coral species *Acropora millepora* from the Great Barrier Reef, Australia.

Under sub-bleaching (31 ºC) and bleaching (32 ºC) conditions, the proportion of the observed phenotypic variation that was due to genetic factors (i.e. the heritability in the broad-sense; $h^2$) was high for both traits: the decrease in maximum capacity of photosystem II (Fv/Fm) for *in hospite* zooxanthellae, and the increase in coral growth rates. Under control conditions (27 ºC), however, the phenotypic performance of these traits was determined to a lesser extent by genetic factors. This suggests that under high temperatures, there is an underlying heritable component for both the maximum efficiency of photosystem II in the zooxanthellae, and coral growth rates. Additional thermal-stress related phenotypic traits for this particular population are currently under investigation.

This is the first study to show that thermal tolerance in corals has an underlying genetic component, and provides direct insight into the evolutionary potential of this species to adapt to climate change.

## 25-44

**Coral Mortality From Bleaching: Pre-Adaptation Of Host Corals To Increased Seawater Temperatures With Dependence Upon Rapidly Adapting Zooxanthellae**

**Kevin STRYCHAR*[1]**, Paul SAMMARCO[2]

[1]Texas A&M University - Corpus Christi, Corpus Christi, TX, [2]Louisiana Universities Marine Consortium, Chauvin, LA

Bleaching in corals is the loss of obligate symbiotic zooxanthellae (required for growth and survival) from their tissue. Increased sea-surface temperatures (SSTs) associated with climate change have caused mass coral bleaching on a global basis. This in turn has caused widespread coral mortality, increasing in frequency through time. Some studies suggest that the host 'ejects' the symbiont during these stressful periods, but the mechanism(s) by which this occurs is still unknown. Recent evidence suggests that processes of cell death, apoptosis and necrosis, associated with zooxanthellae cells increase within host tissues as temperatures increase and may be the primary causes of zooxanthellar loss. The host response to increased temperatures is not known, however, nor is the fact of "who releases whom" during the bleaching process. Here we determine whether the host coral or the zooxanthellae symbionts are more temperature-sensitive and which is being subjected to higher selection pressure due to temperature. Assessment of two types of cell death, apoptosis and necrosis, of cell and tissue states was done by flow cytometry, fluorescent microscopy, and transmission electron microscopy. We examined the temperature resistance properties of three scleractinian coral hosts - Acropora hyacinthus, Porites solida, and Favites complanata - and their zooxanthellae by exposing them to experimental temperatures of 28, 30, 32, and 34C for 48 hrs. Coral host cells did not exhibit any signs of apoptosis until exposed to temperatures of 34C. Zooxanthellae cells, however, exhibited apoptosis at temperatures as low as 30C, and this effect increased markedly in the symbionts as temperature increased. These findings suggest that the host corals are pre-adapted to temperature increases and not suffering mortality from this stress but from the loss of their zooxanthellar endosymbionts – a process driving natural selection in Symbiodinium and necessitating their rapid adaptation to a changing environment.

## 25-45

**Climate Change Can Supersensitise Corals To Natural Levels Of Ultra Violet Radiation**

**Ruth REEF*[1]**, Sophie DOVE[1], Maya CARMI[1], Ann MOONEY[1], Paulina KANIEWSKA[1], Oren LEVY[1], Ove HOEGH-GULDBERG[1]

[1]Centre for Marine Studies, The University of Queensland, St Lucia QLD, Australia

Corals are exceptional for their ability to tolerate ultra violet radiation (UVR) intensities that can be lethal to many reef organisms. Their sessile nature combined with their obligatory symbiosis with the photosynthetic dinoflagellate Symbiodinium means exposure to solar radiation, five percent of which is harmful UVR, is high. While some of the UVR protection associated with corals comes from the previously documented UVR screening compounds in the tissue, we find that this is complemented by unique properties of the coral skeleton that reduce the intensity of UVR in the overlying tissue. This property becomes even more important during heat stress, when we demonstrate that a vast and rapid reduction in the UVR screening ability of the tissue occurs and that this leads to a significant increase in the amount of UVR induced DNA damage in the cells. However, when grown under high levels of carbon dioxide (and hence low concentrations of carbonate ions) some of the ability of the skeleton to reduce the levels of UVR in the overlying tissue is lost. Thus, the remarkable ability of corals to thrive in the UVR levels of shallow tropical waters might be greatly lessened by the predicted changes to sea surface temperature and carbon dioxide levels. This research therefore indicates yet another subtlety associated with the change in environmental conditions surrounding coral reefs associated with rapid anthropogenic climate change.

## 25-46

**Analysis of Fish Abundance in the Gulf of California, and Projection of Changes by Global Warming**

**Arturo AYALA BOCOS*[1]**, Hector REYES BONILLA[1]

[1]Biologia Marina, Universidad Autonoma de Baja California Sur, La Paz, Mexico

The Gulf of California is considered as a key area for conservation worldwide, and has high endemism and diversity of its reef fish fauna. This group might be affected by global warming, because they are ectotherms and temperature may increase several degrees by 2100. This study analyze the latitudinal patterns of abundance of the 20 most abundant reef fishes in the Gulf of California, and evaluate possible changes caused by the temperature increment. Stationary censuses of fishes (N= 147) were done in six regions, from Los Angeles Bay (28°N) to Los Cabos (22°N). For each region we obtained the following information: mean, minimum and maximum surface temperature, photosynthetic pigments, and nitrate, phosphate and silicate concentrations. These factors were included in stepwise regressions to evaluate its influence on each species, and the equations were used to project change in numbers as a result of warming, by changing the coefficients linked to mean temperature in 1°, 2° and 3° C. The results of the models indicated that as temperature increases, four species reduce their abundance, fourteen became very similar in numbers along the gulf, and two were unaffected. Ten species will extend its range to areas where they are currently absent. Finally, richness and diversity (H´) of the "future" communities will increase significantly; the highest value occurred in the 1°C increase model, but afterwards the values reduce gradually. Our conclusions are: a) the Gulf of California reef fish fauna will not react homogeneously to temperature increase; b) some species may change their distribution; c) ecological indices reflect the predicted qualitative shift in assemblage composition; and d) the differential responses of the species may cause an ecological imbalance in teleost assemblages of the gulf in following decades.

## 25-47

**Climate Change And The Future For Coral Reef Fishes**

**Philip MUNDAY*[1,2]**, Geoffrey JONES[2,3], Morgan PRATCHETT[3], Ashley WILLIAMS[4]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Towwnsville, Australia, [2]School of Marine and Tropical Biology, James Cook University, Townsville, Australia, [3]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [4]Fishing and Fisheries Research Centre, James Cook University, Townsville, Australia

We review and predict the likely impacts of climate change on coral reef fishes. Changes to ocean temperature, pH, currents, and extreme weather events will affect reef fishes through impacts on individual performance, trophic linkages, recruitment dynamics, population connectivity and other ecosystem processes. The most immediate and identifiable impacts will be changes in the composition of reef fish communities and loss of biodiversity as a result of coral bleaching. Coral-dependant fishes suffer the most rapid declines in abundance following coral bleaching. However, we predict that many other species will exhibit longer-term declines due to loss of settlement habitat and erosion of the structural complexity of reef habitats. Continued degradation of coral reefs from climate change will lead to impoverished reef fish communities. Increased ocean temperature will affect the physiological performance and behaviour of reef fishes, especially during the larval phase. Small increases in temperature might tend to favour larval survival, but this could be counteracted by negative effects on reproduction. We predict that already variable recruitment will become more unpredictable, with more good recruitment events and more recruitment failures, especially in locations where food supply is patchy or unreliable. A substantial number of species could exhibit range shifts, with potential implications for extinction risk of small-range species near reef margins. Finally, the potential for adaptation to climate change needs more consideration. Many coral-reef fishes have geographical ranges spanning a wide temperature gradient and many have short generation times. These characteristics are conducive to acclimation and local adaptation to climate change, and provide some hope that resilient species might adapt to climate change if immediate action is taken to stabilise Earth's climate.

## 25-48

**Increased Predation Rates On Coral-Dwelling Fishes Associated With Bleached Coral Hosts**

**Darren COKER*[1]**, Morgan PRATCHETT[1], Philip MUNDAY[1]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia

Climate-induced coral bleaching frequently leads to declines in the abundance and diversity of coral associated fishes, though the proximate causes of these declines remain largely unknown. More specifically, it is unclear why coral-dwelling fishes rapidly disappear from bleached coral hosts, even though these corals continue to provide effective physical habitat structure. The purpose of this study was to test whether fishes that remain on bleached coral hosts are more susceptible to predation. Using controlled aquaria-based experiments, we compared predation rates on coral-dwelling fishes (*Dascyllus aruanus, Pomacentrus moluccensis*) associated with i) healthy, ii) bleached, iii) dead and iv) algal covered colonies of the coral, *Pocillopora damacornis*. Experiments were conducted by placing two prey fish of each species with one of the four different habitat types in large glass aquaria. After 1 hour, a single predator (*Pseudochromis fuscus*) was introduced and survivorship of prey was recorded over 75 hours. This study revealed a 75% survivorship of coral-dwelling damselfishes in tanks with healthy coral colonies, wheras only 67% and 63% of damselfishes survived in tanks with bleached versus dead coral hosts, respectively and 58% with algal covered corals. It is possible therefore that the loss of coral healthy coral tissue and pigmentation influenced the ability of prey to elude predation.

It is apparent therefore, that as coral habitat degrades from healthy to algal cover, survivorship of associated fish decreases by 17% due to predation. It is apparent therefore that healthy coral plays an important role in moderating predation interactions among coral reef fishes. We conclude that increasing susceptibility to predation may provide significant motivation for coral-dwelling fishes to rapidly vacate recently bleached coral hosts. Moreover, increased predation may contribute greatly to declines in abundance of coral-dwelling damselfishes following widespread coral bleaching.

## 25-49

**Effects of climate-induced coral bleaching on coral reef fishes.**

**Morgan PRATCHETT*[1]**, Philip MUNDAY[1], Shaun WILSON[1], Nicholas GRAHAM[2], Joshua CINNER[1], David BELLWOOD[1], Geoff JONES[1], Nicholas POLUNIN[2], Tim MCCLANAHAN[3]

[1]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [2]School of Marine Science & Technology, University of Newcastle, Newcastle-upon-Tyne, United Kingdom, [3]Wildlife Conservation Society, New York, NY

Global climate change is having devastating effects on habitat structure in coral-reef ecosystems, owing to extreme environmental sensitivities and consequent bleaching of reef-building scleractinian corals. Coral bleaching and loss of live coral may also lead to longer-term declines in topographic complexity. This review identifies coral cover and topographic complexity as critical and distinct components of coral-reef habitats that shape communities of coral-reef fishes. Coral loss has the greatest and most immediate effect on fishes that depend on live corals for food or shelter, and many such fishes may face considerable risk of extinction with increasing frequency and severity of bleaching. Coral loss may also have longer-term consequences for fishes that require live corals at settlement, which are compounded by devastating effects of declining topographic complexity. Topographic complexity moderates major biotic factors, such as predation and competition, contributing to the high diversity of fishes on coral reefs. Many coral-reef fishes that do not depend on live coral are dependent on the topographic complexity provided by healthy coral growth and will be adversely affected by long-term degradation of coral reef habitats following severe coral bleaching. Urgent action on the fundamental causes of climate change and appropriate management of critical elements of habitat structure (coral cover and topographic complexity) are key to ensuring long-term persistence of coral-reef fishes.

## 25-50

**Sublethal Response Of Reef Fishes To Low Coral Cover**

**David FEARY*[1]**, Mark MCCORMICK[2], Geoffrey JONES[2]

[1]United Nations University-INWEH, Dubai, United Arab Emirates, [2]James Cook University, Townsville, Australia

Although the global decline in coral reef health is likely to have profound effects on reef associated fishes, these effects are poorly understood. While declining coral cover can reduce the abundance of reef fishes through direct effects on recruitment and/or mortality, recent evidence suggests that individuals may survive in disturbed habitats, but may experience sublethal reductions in their condition. To test this, we examined the response of 2 coral associated damselfishes (Pomacentridae), Chrysiptera parasema and Dascyllus melanurus, to varying levels of live coral cover. Growth, persistence and the condition of individuals were quantified on replicate coral colonies in 3 coral treatments: 100 % live coral (control), 50 % live coral (partial) and 0 % live coral (dead). The growth rates of both species were directly related to the percentage live coral cover, with individuals associated with dead corals exhibiting the slowest growth, and highest growth on control corals. Differences in the growth of individuals between treatments occurred after 29 days. There was no significant difference in the numbers of fishes persisting or the condition of individuals between different treatments on this time-scale. We argue that slower growth in disturbed habitats will delay the onset of maturity, reduce lifetime fecundity and increase vulnerability to gape-limited predation. Hence, immediate effects on recruitment and survival may underestimate the longer-term impacts of declining coral on the structure and diversity of the coral-associated reef fish communities.

## 25-51

**Climate Warming And The Ocean-Scale Integrity Of Coral Reef Ecosystems**

**Nick GRAHAM*[1]**, Tim MCCLANAHAN[2], Aaron MACNEIL[3], Shaun WILSON[4], Nick POLUNIN[5], Simon JENNINGS[6], Pascale CHABANET[7], Susan CLARK[8], Mark SPALDING[9], Yves LETOURNEUR[10], Lionel BIGOT[11], Rene GALZIN[12], Marcus OHMAN[13], Kajsa GARPE[13], Alasdair EDWARDS[5], Charles SHEPPARD[14]

[1]School of Marine Science & Technology, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]Wildlife Conservation Society, New York, NY, [3]Panama City Laboratory, NOAA, Panama City Beach, FL, [4]James Cook University, Townsville, Australia, [5]Newcastle University, Newcastle upon Tyne, United Kingdom, [6]Centre for Environment, Fisheries and Aquaculture Science, Lowestoft, United Kingdom, [7]Institut de Recherche pour le Developpement, Noumea, New Caledonia, [8]Natural England, Newcastle upon Tyne, United Kingdom, [9]The Nature Conservancy, Newmarket, United Kingdom, [10]Universite de la Mediterranee, Marseille, France, [11]Universite de La Reunion, Saint-Denis, Reunion, [12]Universite de Perpignan, Perpignan, France, [13]Stockholm University, Stockholm, Sweden, [14]University of Warwick, Coventry, United Kingdom

Coral reefs have emerged as one of the ecosystems most vulnerable to climate variation and change. While the contribution of climate warming to the loss of live coral cover has been well documented across large spatial and temporal scales, the associated effects on fish have not. Such information is important as coral reef fish assemblages are the most species dense vertebrate communities on earth, contribute critical ecosystem functions and provide crucial ecosystem services to the burgeoning human societies in tropical countries. Here we assess the impacts of the 1998 mass bleaching event on coral cover, reef structural complexity, and the functionality and abundance of reef fishes across the Indian Ocean. Using Bayesian meta-analysis we show changes in the size structure, diversity and trophic composition of the reef fish community have followed coral declines. Furthermore, using Bayesian predictive intervals we predict how different components of the fish community will respond to any future changes to coral cover across the region. Although ocean scale integrity of these coral reef ecosystems has been lost, it is positive to see the effects are spatially variable at various scales with impacts and vulnerability affected by geography, oceanography and management regime. Existing no-take marine protected areas still support high biomass of fish, however they had no positive affect on the response of the ecosystem to large-scale disturbance. This suggests that it is imperative that future planning identifies regional refugia from climate change as priorities for protection.

## 25-52

**Relating Patterns in Coral Bleaching And The Extrinsic Environment Over Multiple Scales: Opportunities For Prioritizing Resource Management in Florida in Response To Climate Change**

**Eric MIELBRECHT*[1]**, Daniel WAGNER[2], Alex SCORE[3], Lara HANSEN[4]

[1]Emerald Coast Environmental Consulting, Washington, DC, [2]Biological Sciences, Florida Institute of Technology, Melbourne, FL, [3]World Wildlife Fund, Marathon, FL, [4]World Wildlife Fund, Washington, DC

Coral reefs were one of the first ecosystems where the effects of climate change were readily apparent. As a result of their high vulnerability to climate change, Florida's stakeholders and decision-makers urgently need targeted research, clear communications, and accessible tools to better understand the impacts of climate change and coral bleaching to the Florida Keys National Marine Sanctuary so they can develop and implement successful management efforts. The Climate Change: Linking Environmental Analysis to Decision Support (LEADS) initiative brought together scientists and stakeholders to analyze patterns in coral resilience to climate change and transform these findings into effective management strategies. Quantitative landscape ecology techniques were combined with GIS tools to perform a multi-scale meta-analysis of the relationships between extrinsic environmental factors, coral community structure and bleaching response to suggest patterns of resilience within the Florida Keys National Marine Sanctuary. Data from a wide range of coral surveys, water quality monitoring and other environmental monitoring efforts were obtained through 2007 from institutions cooperating with the Florida Reef Resilience Program and validated for use in testing relationships at both ecological and bleaching event temporal and spatial scales. Resulting patterns of potential resilience provide a new way of prioritizing management efforts in order to respond to climate change within the Florida Keys National Marine Sanctuary.

## 25-53

**Using Climate Information To Improve Coral Reef Management**

**Elizabeth MCLEOD*[1]**, Rodney SALM[1], Axel TIMMERMANN[2], Russell MOFFITT[3]

[1]The Nature Conservancy, Honolulu, HI, [2]International Pacific Research Center, School of Ocean and Earth Science and Technology, University of Hawaii, Honolulu, HI, [3]JIMAR/Univ. of Hawaii & NOAA Pacific Islands Fisheries Science Center, Honolulu, HI

Climate change is challenging marine protected area (MPA) managers to build adaptability into their conservation strategies. Managers need tools to identify coral communities at low risk of succumbing to thermal stress both to protect existing MPA investments, and to guide decisions about the location and design of new MPAs. We used available data from remote sensing and other monitoring systems to generate maps of the Coral Triangle indicating reefs of higher and lower thermal stress now and projected into the future. Using 4 km Pathfinder 5.0 Sea Surface Temperature data, we analyzed intra- and inter-annual variation in sea surface temperature and identified reef areas with reliably stable conditions and others that are more likely to suffer anomalous temperature increases leading to thermal stress. Weekly Pathfinder SST composites from 1985 through the present were compared to 1° C over the expected summertime maximum, recording those that exceeded this level and tallying accumulated Degree Heating Weeks. The analysis determined which locations sustained levels of high potential thermal stress ("hot spots") or little to no thermal stress ("cool spots") and compared those to known bleaching events. We used Coupled General Circulation models (CGCM) to provide estimates of future climate change at a global scale. These models used different climate forcing scenarios from the Intergovernmental Panel on Climate Change. For regional estimates, the CGCM simulations disagree considerably, hence we used a probabilistic multi-model ensemble forecasting approach for future climate change. This approach allowed us to identify areas in the Coral Triangle which are "optimal" in a probabilistic sense which helps decision makers and planners to include uncertainty estimates in their planning efforts. Maps of reef vulnerability provide marine conservation planners with a tool to help identify coral reefs for conservation purposes that are well positioned to survive climate-related increases in temperature.

## 25-54

**Incorporating Anticipated Patterns Of Coral Bleaching Into The Design Of Marine Protected Areas**

**Will WHITE*[1]**, Louis BOTSFORD[1], Philip MUNDAY[2], Jeffrey MAYNARD[3], Geoffrey JONES[2]

[1]Dept. of Wildlife, Fisheries, and Conservation Biology, University of California - Davis, Davis, CA, [2]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Australia, [3]Climate Change Response Programme, Great Barrier Reef Marine Park Authority, Townsville, Australia

Networks of marine protected areas (MPAs) can ensure the persistence of fish and invertebrate populations on coral reefs by providing spatial refuges from overexploitation and habitat destruction. However, MPAs do not afford reefs any protection against coral bleaching. Moreover, if corals inside an MPA do not recover from an intense bleaching event, the ensuing coral mortality can drastically reduce the diversity and complexity of habitats inside that MPA. Since many fished species rely on complex reef habitats for shelter, especially as juveniles, bleaching can impair the ability of MPAs to safeguard the persistence of those species. Prior theoretical work has shown that the success of MPA networks hinges on maintaining a size and spacing among protected habitat patches that is sufficient to sustain population connectivity. Several authors have noted the need to set aside larger reef areas in MPAs in order to buffer against habitat losses caused by bleaching, but none have offered quantitative guidelines for doing so. We address this need by incorporating spatially and temporally autocorrelated patterns of coral bleaching (inferred from recent satellite-derived estimates of sea surface temperate on the Great Barrier Reef) into models of fish metapopulation dynamics within marine reserve networks. By explicitly accounting for the expected spatial pattern of habitat loss, we are able to evaluate the relative performance of MPA networks with different spatial configurations. Our results suggest guidelines for incorporating the possibility of bleaching into sizing and spacing guidelines for marine reserve design in order to minimize the detrimental impact of future bleaching events.

## 25-55

**Quantifying The Synergistic Interaction Between Thermal Stress And Water Quality in Determining The Differential Bleaching Susceptibility Of Coral Communities On The Gbr**

**Scott WOOLDRIDGE*[1]**, Terry DONE[1]

[1]Australian Institute of Marine Science, Townsville, Australia

In this presentation, the potential for the ambient water quality regime at a particular reef site to act as a 'preconditioning' determinant of coral bleaching susceptibility is considered for the 1998 and 2002 mass bleaching events on the Great Barrier Reef, Australia. In the first instance, a simple empirical approach is utilised to highlight the strong spatial coherence that exists between zones of known water quality and the differential bleaching susceptibility (per unit temperature increase) of the resident coral communities. In particular, reef areas that are regularly exposed to terrestrial runoff events with high inorganic nitrogen loads are shown to display enhanced susceptibility (~ factor 2) to thermal stress. To test the robustness of this relation, a mechanistic model is developed which implicitly captures the biological attribute of bleaching 'resistance' to thermal stress. Again, poor regional water quality is shown to be a strong determinant of bleaching resistance – potentially lowering the thermal bleaching thresholds by 1 -1.5$^{o}$C compared to reefs in highly oligotrophic waters. The implications for siting of no-take areas and for water-quality protection initiatives are discussed

## 25-56

**Are Refugia Based on Triage Principles the Last Hope for Reef Systems?**

**Donald POTTS*[1]**

[1]Institute of Marine Sciences, University California, Santa Cruz, Santa Cruz, CA

Current human population growth and industrialization ensure that climatic, oceanographic and other changes affecting reef systems will continue accelerating, and probably lead to major reef degradation and species extinctions within decades. Because coral reefs exist at land-sea-air interfaces, they are exposed simultaneously to direct and indirect impacts of many atmospheric, oceanographic and terrigenous factors. While research tends to concentrate on primary impacts (e.g. coral bleaching from heating; declining calcification with ocean acidification), the same factors often have secondary effects on many other physiological and ecological processes (e.g. larval development and survival may be particularly sensitive to pH). When multiple factors with multiple effects act simultaneously but at different rates, on different scales, and with variable time-lags, they are likely to generate non-linear, synergistic interactions with cumulative impacts much greater than the sum of the individual processes, and which may reach disaster levels much earlier than the primary effect alone.

The rapidity of projected environmental changes suggests time available for averting the worst impacts is very limited. Nevertheless, impacts should vary in space and time, creating opportunities to maximize chances of persistence of some reef systems by focusing resources on the most sustainable systems. This will require three goals for research and managerial planning.

1. Identification of refugia (geographic, ecological, or genetic) where ecosystems and individual species are most resistant to environmental changes.

2. Development of science-based management for longterm maintenance of refugia as geographic, ecological and genetic reservoirs to provide eventual sources for re-establishing reef viability elsewhere.

3. Application of triage principles holistically to entire reefs and systems to determine priorities and urgency for research and management of reefs.

This paper outlines criteria for identifying sustainable refugia, proposes some management goals, and compares examples of marginal oceanic (Midway Atoll) and central continental (Great Barrier Reef) sites as potential refugia.

## 26-1

**The Marine Biodiversity of Cuba**

Rodolfo CLARO[1], Pedro ALCOLADO[1], **Kenyon LINDEMAN*[2]**

[1]Instituto de Oceanologia, CITMA, La Habana, Cuba, [2]Dept. of Marine and Environ. Systems, Florida Institute of Technology, Melbourne, FL

The marine biodiversity of Cuba is highly influenced by coral reefs; however, a comprehensive summary of the main attributes of Cuban marine biodiversity has been unavailable. The objective of this work was to produce a book-length digital compendium that summarizes and integrates primary knowledge of the biodiversity of Cuban reefs and associated ecosystems. This study is based on analyses by over 30 authors of the existing bibliographical information (published or in archives) and recent unpublished data from diverse studies. Primary focal points included the identification of main marine resources, current and potential stressors, key indicators of conservation status, and options for improved management. The results are presented in a digital book available by CD and the World Wide Web that summarizes and integrates fundamental knowledge about organismal diversity and ecological processes of coastal Cuba. The book includes: a paleogeographic analysis of the origin and evolution of primary regions, habitats and biota; ecological and biogeographic evaluations of coastal and ocean systems; and summaries of ecological and economic resource importance. The substantial Cuban marine protected area system is also described. Existing information is collated by phylum and lower systematic categories for all groups of fauna, flora, and microorganisms. All recorded marine species are listed: approximately 7300 in 23 lists from bacteria to mammals. The species total includes 5700 and 1030 species of invertebrates and fishes, respectively. Prominent goods and services of Cuban marine biological diversity are also described (fisheries, tourism, bio-products, etc). Significant threats are identified and institutional management frameworks are outlined. Major gaps in knowledge and coordinated research needs are identified. A substantial array of hierarchical actions is summarized for the conservation, rehabilitation, and sustainable use of the marine biological diversity of Cuba.

## 26-2

**Rhodolith Beds Diversity in A Gradient From 3 To 60 Meters Depth At The Brazilian Continental Shelf**

**Gilberto AMADO-FILHO*[1]**

[1]Programa Zona Costeira, Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

Rhodoliths beds are one of the most extensive benthic communities of the Brazilian continental shelf, but their structure and associated communities are poorly known. In this work we described the structure of rhodoliths beds along the Espírito Santo and Bahia State coast. The study areas were 3 to 45 kilometers offshore. Samples were obtained by SCUBA diving in three depths zones: 4 to 18 m, 25 to 30 m and 50 to 55 m during the years of 2005-2007. Transect lines and video images were used to determine rhodoliths density. Diameters and sphericity were measured from at least 60 individuals from each zone. Rhodoliths size increased (5.1 ± 0.2 cm to 10.9 ± 4.1 cm), and density decreased (125 ± 86 to 32 ± 12 rhodoliths.m2) from the shallow to the deeper zone. Spheroidal was the typical shape throughout the depth zones. Ten rhodolith forming coralline species were identified belonging to the genera: Hydrolithon, Lithophyllum, Lithothamnion, Mesophyllum, Neogoniolithon, Spongites and Sporolithon. One species of kelp Laminaria abyssalis is associated to rhodolith beds at the depth of 50-55 m. A flora of 160 macroalgae species were identified in studied area. Epibenthic biomass seasonal changes over rhodoliths from summer (116 ± 68 g.m2) to winter season (62 ± 25 g.m2) were seen and can be related to the instability caused to the beds by the higher frequency of typical storm disturbance in the winter period. Although rhodoliths beds are subject to movement caused by water motion and bioturbation the obtained results indicates that the studied rhodoliths beds present a similar benthic diversity to that found in Atlantic tropical reef forming communities.

## 26-3

**Reef And Mangrove Sponge Fauna: A Systematic Comparison, And An Evolutionary Hypothesis.**

**Maria C. DIAZ*[1]**, Klaus RUETZLER[2]

[1]Department of Research, Museo Marino de Margarita, Boca del Rio, Venezuela, [2]Invertebrate Zoology, National Museum of Natural history, Smithsonian Institution, Washigton D.C., VA

Comparing sponge communities from reefs and offshore mangrove islands at various Caribbean sites we find that, despite similar geographic distribution, they are strikingly different in systematic composition and biological properties. Taxonomically we find that families that flourish in one ecosystem are absent or rare in the other. Such is the case within the species-rich order Haplosclerida where the family Petrosiidae (genera Xestospongia, Petrosia) dominates on the reef, while the family Chalinidae (Haliclona , Chalinula) prevails in the mangroves. At least eight other Demospongiae families and two orders reflect this disjunct pattern of occurrence; these taxa represent approximately 50 % of the sponge diversity known from the two systems. Morphologically, we find a separation in terms of shape and size among the major representatives of the group, with much larger sizes on the reef, dominated by tube-, vase-, rod-shaped, or massive amorphous sponges. On Mangroves, thin or thick crusts and some massive-amorphous shapes predominate, although any shape can be found, except it is restricted to small size categories. Regarding sexual reproduction, a prevalence of oviparous broadcasters is found on the reef, viviparous brooders are common in the mangrove. Ecologically, we find certain symbiotic consortia common on reefs but practically absent in mangroves. We correlate the distribution of these important biological traits with the physical properties of the reef and mangrove environments. A hypothesis is presented of how these two sponge faunas are historically related and how they interact at the present time. We discuss how taxonomy enlightens the ecological and evolutionary connectivity of these faunas and make recommendations for future study and environmental evaluation.

## 26-4

**Diversity Of Soft Corals (Octocorallia) in Kenya And The Adjacent Pemba Island (Tanzania) With Reference To Other South Equatorial East African Reefs**

**Yehuda BENAYAHU*[1]**, Michael H. SCHLEYER[2], Shimrit PERKOL-FINKEL[1], Alex SHLAGMAN[1]

[1]Zoology, Tel Aviv University, Tel Aviv, Israel, [2]Oceanographic Research Institute, Durban, South Africa

The coral reefs of East Africa are of particular biogeographical interest and some of them are known for their flourishing soft coral communities. Intrigued by the lack of taxonomic and ecological reports on the soft corals from Kenya and Pemba Island (4-50S), we conducted comprehensive soft coral surveys at various sites there. We investigated their species diversity, also in comparison to previously studied south equatorial East African reefs. Collecting trips were conducted during 2000-2005 and approximately 900 samples were obtained. The distributional patterns of the different taxa on the reefs were determined and in some areas their live coverage was measured. Overall, the collections yielded 85 species belonging to 28 genera. Some of the Nephtheidae are still being examined, as are several new species that have yet to be described. The most specious genera on the surveyed reefs were *Sinularia* (26 species), *Sarcophyton* (10) *Cladiella, Lemnalia* and *Lobophytum* (5 each). Interestingly, some genera of the family Xeniidae that were represented by only one or two species (i.e., *Cespitularia, Efflatounaria* and *Sympodiu*m) monopolized large reef areas locally. The reef habitats richest in soft corals were found below 7-8 m depth, including steep walls (25-35 m). The soft coral assemblages growing on sea-grass beds in shallow lagoons and aggregations of *Studeriotes* on silt bottoms are of special interest. The studied reefs display a higher soft coral diversity compared to Mafia Is. (Tanzania, $7^0$S), the northern coast of Mozambique (12-$16^0$S), Bazaruto Is. (Mozambique, $21^0$S) and KwaZulu-Natal (South Africa, $28^0$S). The current findings further demonstrate the distinct latitudinal diversity pattern on south equatorial African reefs, with the highest diversity found on the near-equator reefs. The findings also reinforce the need to implement effective conservation policies and management programs in order to promote preservation of these diverse soft coral communities.

## 26-5

**Soft Coral Biodiversity And Distribution In The Western Indian Ocean: Gradients, Function And Significance**

**Michael SCHLEYER*[1]**, Yehuda BENAYAHU[2]

[1]Oceanographic Research Institute, Durban, South Africa, [2]Department of Zoology and The Porter School of Environmental Studies, Tel Aviv, Israel

Soft corals (Octocorallia: Alcyonacea) constitute important reef benthos in the WIO, yet relatively little is known of their distributional gradients, function or significance. Integrated results of published surveys and of material recently collected as far afield as the Chagos Archipelago manifest interesting gradients in their diversity, abundance and apparent function. Reef disturbance may result in them becoming dominant, eliciting an alternative stable state in some coral communities. While certain tropical taxa attenuate from north to south, others attain their highest abundance at high latitude; the latter appears to be related to their ability to tolerate more swell-driven turbulence. Once established, soft corals appear to be persistent and long-lived, a characteristic also reported in the literature. A long-term monitoring study has nevertheless revealed that they appear to be vulnerable to climate change.

## 26-6

**Vagile Coelobites Of Eastern Pacific Coral Reefs: Structurally Homogenous Reef Environments And The Importance Of Substrate in Shaping Community Composition**

**Ian ENOCHS*[1]**, Gena HOCKENSMITH[1]

[1]Marine Biology and Fisheries, University of Miami, Miami, FL

Coral reef framework structures are complex three-dimensional habitats occupied by diverse taxa. The term cryptofauna (coelobites) specifically applies to those organisms that live within the interstices of coral reef framework. The remarkably diverse assemblage of cryptic biota is poorly understood relative to that of the epibenthic and nektonic reef species. It has been postulated that the biomass of this cryptic component of the reef ecosystem is extremely high, possibly exceeding that of the surface biota, and it is likely that coelobites are integral to reef nutrient dynamics. Furthermore, cryptic animals that inhabit reef pore spaces may degrade coral skeletons, playing an important role in bioerosion; the biogenic loss of reef framework. Thus, evaluating the interaction of nutrient dynamics, bioerosion, habitat structure, cryptic biomass and biodiversity is essential to understanding coral reef community responses to a changing climate. Previously, the strong dependence of cryptic community composition on the size and shape of the void-space habitat has limited extrapolation of studies to the "whole reef" level. *Pocillopora* reefs of the eastern Pacific are structurally complex yet relatively homogenous across a horizontal plane. This unique physical composition allows for the possibility of replicate sampling of the coelobite community and a subsequently broader scale analysis. In order to evaluate the dependency of cryptic community structure on the nature of the substrate it occupies, both living and dead *Pocillopora* colonies were defaunated and returned to the reef. After one year *in situ*, associated coelobites were identified, weighed, and counted. Substrate preference (live vs. dead coral) was found to be species specific. Biomass and abundance of vagile coelobites was significantly higher in living coral colonies when compared to dead coral framework. These findings have important implications for how reef communities may respond to coral mortality.

## 26-7

**Coastal Fish Communities of the Socotra Archipelago: "Pseudo-Reefal" Diversity and Ecology Without Coral Reefs.**

**Uwe ZAJONZ*[1]**, Dr. Friedhelm KRUPP[1]

[1]Ichthyology, Senckenberg Research Institute and Natural History Museum, Frankfurt a.M, Germany

Between 1999 and 2007 shallow water fish communities of the Socotra Archipelago (Gulf of Aden, NW Indian Ocean) were studied with the objective of assessing patterns of diversity and abundance, community composition, trophic structure and biogeographic affinities. The Archipelago hosts very diverse, varied and biogeographically unique coral and fish communities. About 730 fish species in 110 families have been recorded from the Archipelago as yet. The structure of the dominant shallow water fish community types, as inferred from species composition, trophic analysis and correlation analysis of fish and benthic communities, is comparable with typical "reef fish" assemblages of the Western Indian Ocean. Despite the fact that the Archipelago has only few biogenic reefs, the species numbers within certain reef fish taxa exceed those known from the entire neighbouring Red Sea. Research on tropical marine communities typically focus on reef habitats with high cover of scleractinian corals and the presence of so-called "reef-associated" fish species, based on the postulate that these are dominating factors in determining coastal diversity in the tropics. Results of the present study suggest that, besides classical coral reef assemblages, equally diverse benthic and associated fish communities can evolve, if the local "mix" of abiotic and biotic variables is suitable. These include mesoscale habitat heterogeneity and complexity, i.e. availability, connectivity among these habitats and among wider biogeographic units, and probably productivity. Being exposed to a harsh monsoon regime, Socotra's coastal ecosystems are heterogeneous and dynamic in space and time, giving rise to a great variety of ecological niches and thus supporting corals and fishes from many different 'walks of life'. Consequently, more consideration needs to be given to studying population dynamics, connectivity and biogeography of such marginal "pseudo-reefal" communities.

## 26-8

**Molecular Data Suggest An Indo-Pacific Origin Of The Invasive Snowflake Coral (Carijoa Riisei) in The Hawaiian Archipelago And Refute A Caribbean Introduction**

**Gregory CONCEPCION*[1]**, Samuel KAHNG[2], Marc CREPEAU[1], Erik FRANKLIN[1], Steve COLES[3], Robert TOONEN[1]

[1]Hawaii Institute of Marine Biology, University of Hawaii at Manoa, Kaneohe, HI, [2]Oceanography, University of Hawaii at Manoa, Honolulu, HI, [3]Natural Sciences, Bishop Museum, Honolulu, HI

The first published report of the invasive snowflake coral in Hawaii comes from Pearl Harbor in 1972. Subsequent identification of this species as the Caribbean octocoral *Carijoa riisei* led to the general conclusion that it was introduced via contemporary maritime vectors. In an attempt to confirm the source of the Hawaiian population, we used mitochondrial ($h$ = 0.8379; $\pi$ = 0.0022) and nuclear (H = 0.8904; $\pi$ = 0.0299) data to compare Hawaiian specimens with *Carijoa* samples collected worldwide (n=248). In addition, vessel traffic patterns for the Pacific Ocean were examined for 1940-1979 to determine maritime connectivity to and from Hawaii during the assumed time of introduction. Combined mitochondrial and nuclear data show both higher and considerable unique genetic diversity within the Indo-Pacific compared to samples from throughout the Caribbean-Atlantic, suggesting that the species is native to the Indo-Pacific. Further, isolation-by-distance (IBD) analysis indicates a significant correlation between genetic and geographic distance in both the Indo-Pacific and Hawaii, but not for the Atlantic, and coalescent estimates for the Atlantic are the lowest of the three populations. Finally, *C. riisei* sampled from throughout Hawaii (n=96) share none of the Caribbean mtDNA haplotypes (29 unique haplotypes) and only a single nDNA allele (of 29 unique alleles), indicating that the Hawaiian populations derive from Indo-Pacific rather than Caribbean-Atlantic origins. Despite an active commercial vessel route between Hawaii and the Panama Canal, we find no evidence to support a maritime introduction of *Carijoa riisei* from the Caribbean-Atlantic.

**Biodiversity Of Reefs: Inferring From Sparse Data**

**Daphne FAUTIN*[1]**

[1]University of Kansas, Lawrence, KS

Data on occurrences of a particular organism from publications and museum specimens can be used to infer occurrence of members of that species in places where sampling has not been done and at times in the past and future. Programs to make such inferences are based on knowledge of the habitat correlates of the species and determining where else in the world those habitat parameters occur. Precision of such an inference depends on 1) accurate and precise knowledge of the species' habitat requirements, 2) detailed spatially-explicit environmental data, and 3) comprehensive taxonomic and nomenclatural information. Such inferential tools can be important in understanding biogeographic consequences of climate change, in predicting where invasive species might persist, and in recognizing invasive species.

## 26-10

**Standardized Sampling And Molecular Approaches For Assessing Marine Biodiversity Of Coral Reefs**

**Laetitia PLAISANCE*[1]**, Christopher MEYER[2], Gustav PAULAY[3], Russell BRAINARD[4], Amy HALL[4], Julian CALEY[5], Nancy KNOWLTON[1]

[1]Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA, [2]University of Berkeley, Berkeley, CA, [3]Florida Museum of Natural History, University of Florida, Gainesville, FL, [4]Joint Institute for Marine and Atmospheric Research, University of Hawaii, Honolulu, HI, [5]Australian Institute of Marine Science, Townsville, Australia

Coral reefs are the most diverse and among the most threatened of all marine ecosystems. Unfortunately, we lack the taxonomic expertise and the time needed to characterize this diversity, as well as the extent of biodiversity loss related to human impacts, using traditional methods. However, the revolution in molecular genetics dramatically changes the potential for reef scientists to make progress in this area, particularly in poorly characterized groups for which taxonomic expertise is limited (e.g. very small cryptic organisms). As exhaustive inventories of reef-associated fauna are impractical, standardized sampling methods are the best option for estimating and comparing patterns of diversity for these communities. In this study, we employed a DNA barcode approach (cytochrome oxidase subunit I) to characterize the biodiversity of marine crustaceans associated with coral reefs in Moorea (French Polynesia), the northern Line Islands, French Frigate Shoals (Hawaii) and Lizard Island (Australia). We sampled the small cryptic fauna in two different habitats: in dead Pocillopora heads (most sites) and Autonomous Reef Monitoring Structures (ARMS) deployed for one year at four sites around French Frigate Shoals. Results to date suggest that current estimates greatly underestimate reef biodiversity as rarefaction curves reveal that they will increase significantly with additional sampling. Moreover, comparison of crustacean diversity between Moorea and the Line Islands showed little overlap, as only 11 OTUs (Operational Taxonomic Unit) out of 135, were found in both localities, 44% of the total diversity being singletons and 33% being found only in one locality. Moreover, none of the Moorea taxa matched at the species level with any record in GenBank. Nevertheless, these methods have great potential when they are globally deployed with adequate replication, something that is now possible given the ease of obtaining sequence data.

## 26-11

**Autonomous Reef Monitoring Structures (Arms): A Tool For Monitoring Indices Of Biodiversity**

**Amy HALL*[1]**, Russell BRAINARD[2], Julian CALEY[3], Scott GODWIN[4], Leslie HARRIS[5], Nancy KNOWLTON[6], Tito LOTUFO[7], Joel MARTIN[5], Kaylyn MCCOY[8], Megan MOEWS[1], Russell MOFFITT[1], Gustav PAULAY[9], Laetitia PLAISANCE[10]

[1]JIMAR Univeristy of Hawaii, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [2]NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [3]Australian Institute of Marine Science, Queensland, Australia, [4]Hawaii Institute of Marine Biology, Kaneohe, HI, [5]Natural History Museum of Los Angeles County, Los Angeles, CA, [6]Smithsonian Institution, National Museum of Natural History, Washington, DC, [7]Instituto de Ciencias do Mar, Laboratorio de Ecologia Animal, Fortaleza, Brazil, [8]State of Hawaii, Division of Aquatic Resources, Honolulu, HI, [9]Florida Museum of Natural History, Gainesville, FL, [10]Scripps Institution of Oceanography, La Jolla, CA

Coral reefs are high diversity ecosystems, but methods to assess this diversity can be problematic, particularly for small and cryptic organisms. Autonomous Reef Monitoring Structures (ARMS) have been developed and are being tested as a standard method to mimic the structural complexity of coral reef habitats and attract colonizing non-coral invertebrates. It is currently difficult to find non-subjective methods of assessing invertebrate biodiversity on coral reefs. With an increasing scarcity of trained invertebrate taxonomists globally, ARMS will enable researchers to obtain indices of invertebrate biodiversity utilizing molecular techniques that would otherwise be challenging and time consuming using traditional morphological analyses alone. In October 2006, ARMS were deployed in a preliminary study at French Frigate Shoals in the Papahanaumokuakea Marine National Monument, Northwestern Hawaiian Islands, and subsequently recovered and analyzed in October 2007. ARMS were deployed at sites selected on the basis of habitat characterization: a backreef site, a lagoon patch reef site, and two forereef sites, from 1 to 14 m. Analyses were designed to look at the effectiveness of the instruments across the range of habitats and taxa collected. ARMS were most productive in sampling molluscs (28%), ascidians (24%), crustaceans (19%), and bryozoans (11%) in forereef and lagoon patch reef habitats. In addition, DNA barcode analyses were conducted to characterize crustacean biodiversity associated with ARMS in comparison to dead *Pocillopora* heads from other sites in the Pacific. These results suggest that coupling ARMS with taxonomic and molecular analyses can be an effective method to assess and monitor understudied coral reef invertebrate biodiversity. Additional ARMS deployments occurring around the Hawaiian Islands, Pacific remote island areas, American Samoa, Australia, Brazil, and Panama will enhance our ability to monitor coral reef ecosystem change globally and build capacity for ecosystem-based management.

## 26-12

**Biodiversity Census at French Frigate Shoals, A Baseline Diversity Study**

**Russell MOFFITT*[1]**, Russell BRAINARD[2], Julian CALEY[3], Scott GODWIN[4], Amy HALL[1], Leslie HARRIS[5], Elizabeth KEENAN[6], Nancy KNOWLTON[7], Tito LOTUFO[8], Jim MARAGOS[9], Joel MARTIN[5], Sea MCKEON[10], Megan MOEWS[1], Gustav PAULAY[10], Cory PITTMAN[11], Alison SHERWOOD[12], John STARMER[13], Brian ZGLICZYNSKI[1]

[1]Coral Reef Ecosystem Division, JIMAR/Univ. of Hawaii & NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [2]Coral Reef Ecosystem Division, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, [3]Australian Institute of Marine Science, Townsville, Australia, [4]Hawaii Institute of Marine Biology, Kaneohe, HI, [5]Natural History Museum of Los Angeles County, Los Angeles, CA, [6]NOAA/NOS/PMNM, Honolulu, HI, [7]Dept. of Invertebrate Zoology, Smithsonian Institution, National Museum of Natural History, Washington, DC, [8]Laboratorio de Ecologia Animal, Instituto de Ciencias do Mar, Fortaleza, Brazil, [9]USFWS, Honolulu, HI, [10]Florida Museum of Natural History, University of Florida, Gainesville, FL, [11]Camp Olowalu, Lahaina, HI, [12]Botany Department, University of Hawaii at Manoa, Honolulu, HI, [13]CNMI Coastal Resources Management Office, Saipan, Northern Mariana Islands

With increasing concerns about climate change, there is clear danger that much coral reef diversity could be lost before it is documented and managers will be left with a limited understanding of undisturbed reef communities on which to base future decisions. To effectively manage and conserve these ecosystems, it is first necessary to obtain baseline data of existing biodiversity and enhance understanding of changes over time. As part of the Census of Coral Reef Ecosystems (CReefs) of the Census of Marine Life, a multi-institutional team of taxonomists surveyed cryptic, poorly known, and understudied organisms, particularly invertebrate, algal and microbial species at French Frigate Shoals in the relatively pristine Papahanaumokuakea Marine National Monument in the Northwestern Hawaiian Islands. This open atoll has the highest reported shallow coral reef biodiversity in the Hawaiian Archipelago and has been hypothesized to be a diversity pathway for the spread of species from three directions, most notably Johnston Atoll. During a 16-day field survey, 15 diverse habitat types were sampled utilizing an array of methods designed to target key ecological niches and minimize ecological impacts, including hand collecting, rubble extraction, rubble brushing, sand sampling, Yabbie pump, microbial collections, algal collections, suction/vacuum, baited traps, Ekman grabs, sand dredges, plankton tows, and Autonomous Reef Monitoring Structures. At least 1600 morphospecies were documented and photographed, including >100 new species and/or regional records. New records include 7 species of algae, 33 decapod crustaceans, 48 opistobranch molluscs, and 1 family of ascidians. Greater than 20% of the known Hawaiian marine invertebrate diversity was encountered, reflecting on the effectiveness of methods and the poorly known nature of tropical reef biodiversity. In addition 1,279 DNA subsamples, representing 40% of the overall specimens, were collected to sequence for inclusion in the Barcode of Life.

## 26-13

**Age And Origin Of Hawaiian Endemic Fishes in The Papahânaumokuâkea Marine National Monument**

Zoltan SZABO[1], John RANDALL[1], Randall KOSAKI[2], **Brian BOWEN*[3]**

[1]Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, HI, [2]Papahânaumokuâkea Marine National Monument, Honolulu, HI, [3]University of Hawaii, Hawaii Institute of Marine Biology, Kaneohe, HI

The Hawaiian Archipelago has one of the highest levels of marine endemism (25% for fishes) and is among the most isolated reef habitats in the world. In this research program, we are examining the age and source of colonization events that enhance Hawaiian biodiversity, especially in the new Papahânaumokuâkea Marine National Monument. Three of these Hawaiian endemics (HE) are blennies with an unambiguous sister species in the Indo-West Pacific (IWP) which allowed us to resolve the age of colonization events. Based on a 659 bp fragment of mitochondrial cytochrome b, we observed approximately d = 7% sequence divergence between Cirripectes vanderbilti (HE) and C. variolosus (IWP) and about the same level of divergence between Plagiotremus ewaensis (HE) and P. rhinorhynchos (IWP). Between Plagiotremus goslinei (HE) and P. tapeinosoma (IWP) we observed d = 0.3% (2 bp differences) indicating a very recent arrival. A conventional molecular clock for fishes places the first two colonization events at approximately 3.5 million years ago, and the third event at approximately 150,000 years ago. Ongoing research will indicate whether Johnston Atoll, 800 km south of Hawaii, is the essential gateway into the archipelago, and whether a pulse of colonization occurred at 3.5 million years before present. Our finding for P. goslinei may prompt a re-examination of taxonomic status.

## 26-14

**How Useful Is Panbiogeography in Deconstructing Philippine Coral Reef Biogeography?**

**Benjamin VALLEJO JR*[1]**

[1]Institute of Environmental Science and Meteorology, University of the Philippines, Quezon City, Philippines

The Philippines is considered at the center of global coral reef biodiversity. Recent studies indicate that the Verde Island Passage in Southwestern Luzon has extremely high taxonmic diversity per unit area. More recent research indicate that several areas in the central Philippines have similar levels of taxonomic richness most notably in molluscs. The existence of several diversity massings within archipelagic seas or basins in the Philippines is a major biogeographic pattern that strenthens the theory that these seas are important biogeographic regions. These patterns are coincident with major tectonic features. As island integration seems to be the most parsimonious theory to explain Philippine biogeography, this necessitates a more integrative theory to explain these spatial patterns of marine biodiversity. A panbiogeographic hypothesis is thus presented.

## 26-15

**Atlantic Reef Fish Biogeography And Evolution**

**Sergio FLOETER*[1]**, Luiz ROCHA[2], Ross ROBERTSON[3]

[1]Ecologia e Zoologia, UFSC, Florianopolis, Brazil, [2]HIMB, University of Hawaii, Kaneohe, HI, [3]Smithsonian Tropical Research Institute, Panama, Panama

How and when areas of endemism of the tropical Atlantic Ocean were formed? How do they relate to each other? What are the spatio-temporal components of diversification? We tried to shed light into these questions by analyzing the distributions of 2605 reef fishes in 25 areas of the Atlantic and southern Africa and a collection of 27 recently published phylogenies of various Atlantic reef fish taxa. Phylogenetic (proportion of sister species) and distributional patterns (number of shared species) are generally concordant with recognized biogeographic provinces. The highly uneven distribution of species in certain genera appears to be related to their origin, with highest species richness in areas with the greatest phylogenetic depth. Diversity buildup in the Atlantic involved (1) diversification within each province, (2) isolation as a result of biogeographic barriers, and (3) stochastic accretion via dispersal between provinces. The timing of cladogenesis is not concordant among taxonomic groups, indicating that no single vicariant event explains the observed divergences. The three soft (non-terrestrial) inter-regional barriers (mid-Atlantic, Amazon, and Benguela) clearly act as "filters" by restricting dispersal but at the same time allowing occasional crossings that eventually become new species. Fluctuations in the effectiveness of these filters, combined with ecological differences among provinces, apparently provide a mechanism for much of the recent diversification of reef fishes in the Atlantic. Fish life history attributes like spawning mode, body size and depth range are differentially affected by the soft barriers as revealed by the analyses of trans-barrier species. Our dataset indicates that both historical events (e.g. Tethys closure) as well as relatively recent dispersal (with or without further speciation) have had a strong influence on Atlantic tropical marine biodiversity and have contributed to the biogeographic patterns we observe today, however, examples of the latter process outnumber the former.

## 26-16

**A Regional Scale Diversity-Environment Relationship For Pacific Coral Reef Fish Communities**

**Laurent VIGLIOLA*[1,2]**, Serge ANDREFOUET[3,4], Michel KULBICKI[5], Christine KRANENBOURG[6], Pierre LEGENDRE[7], Pierre LABROSSE[2,8], Samasoni SAUNI[2,9], Pierre BOBLIN[2]

[1]Institut de Recherche pour le Développement (IRD), Plouzane, France, [2]Secretariat of the Pacific Community (SPC), Noumea, New Caledonia, [3]Institut de Recherche pour le Développement (IRD), Noumea, New Caledonia, [4]Institute for Marine Remote Sensing (IMaRS), St. Petersburg, [5]Institut de Recherche pour le Développement (IRD), Perpignan, France, [6]Institute for Marine Remote Sensing (IMaRS), St. Petersburg, FL, [7]Université de Montréal, Montreal, QC, Canada, [8]Institut Mauritanien de Recherches Océanographiques et des Pêches (IMROP), Nouadhibou, Mauritania, [9]Pacific Islands Forum Fisheries Agency (FFA), Honiara, Solomon Islands

Predicting the response of biodiversity to ongoing global and local changes in the environment is a challenging, yet necessary step to identify the most effective schemes for conservation and sustainable use. The present study combines *in situ* and remotely sensed data across 10 Pacific Island Countries and estimates a diversity-environment relationship for coral reef fish communities across this 5500 km longitude by 2500 km latitude region. Reef fish diversity and 32 associated environmental variables were recorded by underwater visual censuses following a stratified sampling design. The environmental matrix was augmented with an additional 40 variables derived from remotely sensed geomorphologic maps. Measurements were made within a moving window, effectively collecting information at multiple spatial scales. A general linear model revealed that the combination of nine environmental variables accounted for 69% of species richness variability. Fish diversity increased with depth, habitat complexity, reef diversity at 200-m scale, and variation in reef composition at 20-km scale. Diversity was greater on reef slopes than on flats and decreased with the amount of land within a 2 $km^2$ area, reef connectivity at 2-km scale, variation in reef composition within a 200 $km^2$ area, and the distance to the Indo-Australian centre of biodiversity. Contemporary distribution patterns of biodiversity are a function of species origin, dispersal, and survival. By combining proxies of these factors at multiple spatial scales, this study indicates that good predictions of biodiversity can be made for coral reef fishes of the Pacific region.

## 26-17

**Commonness, Rarity, And Biodiversity On Indo-Pacific Coral Reefs**

**Sean CONNOLLY*[1,2]**, Maria DORNELAS[2,3], Terry HUGHES[2], David BELLWOOD[1,2]

[1]School of Marine and Tropical Biology, James Cook University, Townsville, QLD, Australia, [2]ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, QLD, Australia, [3]Gatty Marine Laboratory, University of St Andrews, St Andrews, Fife, United Kingdom

Patterns in the commonness and rarity of species are a fundamental characteristic of ecological assemblages, and are frequently used to test alternative models of biodiversity. However, attempts to test between alternative models for such patterns often lead to inconclusive results, leading to calls for a greater diversity of approaches to testing species-abundance models. Here, we examine patterns of commonness and rarity in tropical reef fishes and corals from a 10,000-km transect across the Pacific Ocean, and we assess their concordance with species-abundance models based on lognormal, gamma, and neutral model distributions. To overcome problems with previous analyses, we develop a new goodness-of-fit test that explicitly treats individuals, rather than species, as the units that are sampled. We find that the lognormal provides substantially better fit to patterns of commonness and rarity than the alternatives, deviates from the data by less than 1%, on average, and produces far better estimates of metacommunity diversity than the alternatives. Neutral and gamma-based alternatives perform poorly because our data exhibit a combination of many very rare species and a few highly abundant species, which these models cannot simultaneously capture. It is likely that interspecific differences, such as those implicit in models generating lognormal distributions, will be required to explain this kind of heterogeneity in species abundances.

## 26-18

**Coral Species Abundance Distribution: Patterns Of Commonness And Rarity**

**Maria DORNELAS*[1]**, Sean CONNOLLY[1]

[1]ARC Centre of Excellence for Coral Reef Studies, Townsville, Australia

Species abundance distributions portray the patterns of species rarity and commonness in ecological communities, and therefore are important measures of biodiversity. However, the abundances of rare species, which are often particularly important for conservation, require large samples to be confidently estimated. Here, we present the species abundance distribution for a sample of >40,000 coral colonies from a single bay in Lizard Island. This exceeds existing samples of coral assemblages by over an order of magnitude. Although species abundance distributions are widely accepted to follow a lognormal distribution, our data have a multimodal distribution. Three different model selection procedures all indicate that the underlying community abundance distribution has at least three modes. Thus, the multiple modes in our data are a real feature of community abundance distributions, rather than stochastic sampling effects. We hypothesize that this pattern may be caused by variability in species spatial distributions.

## 26-19

**The Stability Of Clonal Lineages Over Space And Time**

**Daniel PETTAY*[1]**, Todd LAJEUNESSE[1], Dustin KEMP[2]

[1]Pennsylvania State University, University Park, PA, [2]University of Georgia, Athens, GA

Recent use of molecular techniques has revealed that the dinoflagellate genus *Symbiodinium*, once believed to be one pandemic species, includes many highly divergent clades, each containing numerous species or "types" (based on rDNA ITS1 & 2 fingerpinting). While much research has been conducted to determine the specificity between host and symbiont, little is known about the clonality of a particular symbiont "type" over a single colony and within a colony over time. To examine the clonal diversity of clade B types over space and time, nine polymorphic microsatellite loci were amplified and sequenced to yield a multilocus genotype. While certain host and symbiont taxa appear to be more flexible in their ability to associate with numerous partners, a majority of the data indicate strong specificity between host and symbiont. Even the Caribbean coral *Montastrea faveolata*, which can associate with symbionts belonging to clades A through D, shows specificity for only a small subset of subcladal types that correlate with both bathymetry and geography. Hosts like the coral *Meadrina meandrites* epitomize this specificity by associating with only one ITS2 type throughout the Caribbean. Analyzing samples collected from hosts like the two described above enable comparisons to be made between both symbioses which appear to be more flexible and symbioses which are quite specific. Host species known to display a range of specificity (i.e. low specificity = *M. faveolata*, high specificity = *M. meandrites*) were sampled repeatedly to determine clonal diversity spatially. To examine the longevity of clonal lineages, a subset of colonies were also sampled seasonally. To date, the data indicate that a majority of the colonies host a single symbiont lineage over the entire colony. Continued research in this area will also allow species boundaries to be determined and provide insight into the evolutionary processes of *Symbiodinium*.

## 26-20

**Diversity Dynamics Of Reefs And Level-Bottom Communities Compared: Paleontological Evidence For Reefs As Sources Of Biodiversity Over The Last 240 Myr**

**Wolfgang KIESSLING*[1]**

[1]Museum of Natural History, Humboldt University, Berlin, Germany

The fossil record of Mesozoic-Cenozoic reefs is used to evaluate the role of evolutionary origin versus ecological maintenance in the biodiversity of living and ancient reefs. Data from the Paleobiology Database (http://paleodb.org) were analyzed to compare the diversity dynamics of taxa with a statistically significant preference for reefs with those having a preference for non-reef marine habitats.

After standardizing for different sample sizes (reef data are more limited than other data) the results suggest that reefs have significantly greater rates of speciation than level-bottom communities. Except for mass extinction episodes, in which reef taxa are more substantially affected than level-bottom taxa, there is no evidence for generally greater or smaller extinction rates of reef taxa. Therefore reefs can be viewed as cradles of evolution over long stretches of time, whereas there is no evidence for reefs preserving diversity better than other ecosystems.

Although these results strictly apply to only those taxa that are readily fossilized (corals, hypercalcified sponges, bivalves, gastropods, echinoderms and brachiopods), there is no reason to assume that other taxa should not follow the same basic trends.

## 26-21

**Diversity And Diversification in The Southwest Indian Ocean (Program Anr Biotas)**

**J. Henrich BRUGGEMANN*[1]**, Gustav PAULAY[2], François MICHONNEAU[2], Nicolas HUBERT[1], Mireille M.M. GUILLAUME[1,3]

[1]ECOMAR, Université de la Réunion, Saint-Denis, Reunion, [2]Florida Museum of Natural History, University of Florida, Gainesville, FL, [3]Milieux et Peuplements Aquatiques, UMR 5178 CNRS UPMC MNHN, Muséum National d'Histoire Naturelle, Paris, France

Biological diversity is unevenly distributed across the world. Both species richness and endemism vary greatly across land and sea and often show localized peaks in geographically restricted "hotspots". Eight of 10 marine hotspots lie adjacent to terrestrial hotspots, suggesting that similar processes may be responsible for their origin and/or maintenance. The Southwest Indian Ocean (SWIO) region is both a marine and terrestrial biodiversity hotspot. It represents a varied terrain for evolutionary processes, encompassing old as well as young island groups (e.g. Madagascar, the Mascarenes, Seychelles and Comoros). We are examining patterns of diversity, differentiation, and diversification in this region using integrative taxonomy and phylogenetic analysis of rapidly evolving DNA markers in marine (invertebrates and fish) as well as terrestrial organisms. Field work begun on Reunion Island, where new collections include ~400 species of molluscs, ~250 crustaceans, ~100 echinoderms, ~250 reef fishes, and ~100 species in other phyla. Approximately 30% of species collected are new records for Reunion. An estimate based on echinoderms suggests that >5% represent new species. About 60% of the species collected at Reunion are also represented by the same form or sister species in recent collections from Pacific Oceania, allowing fauna-level comparisons of differentiation on the scale of ocean basins. Species that show differentiation on this scale will be subjected to detailed phylogeographic analysis within the SWIO. Such a taxonomically-wide approach allows us to test what factors are associated with different types and levels of differentiation.

## 26-22

**Patterns Of Diversity, Endemism, Origination And Extinction On Coral Reefs: Stomatopod Crustaceans**

**Marjorie REAKA*[1]**

[1]Biology, University of Maryland, College Park, MD

Reef-dwelling stomatopods show roughly similar contours of Indo-Pacific diversity as corals, reef fishes and cowries, having a very strongly accentuated peak in the Indonesian area of the Indo-Australian Archipelago but also high diversity along the western Indian Ocean shelf and especially Madagascar. The degree to which endemism corresponds to this pattern depends upon the scale examined, with local endemics occurring everywhere but regional endemics occurring disproportionately in the Indo-Australian Archipelago and on the periphery of the wider Indian and Pacific Ocean realms. Like the greatest proportion of coral reef organisms, the size frequency distribution of reef-dwelling stomatopods is skewed toward small body sizes with restricted reproductive output, dispersal and geographic range sizes. Small species, speciation and extinction are concentrated in the central "hotspot" but also at the periphery of the regions, supporting a "Merry Go Round" rather than a "Cradle" or a "Museum" hypothesis for the generation and maintenance of Indo-Australian Archipelago diversity. However, the areas of high diversity in the Indo-Australian Archipelago and in the western Indian Ocean also contain species of large body size with greatly enhanced reproductive output, dispersal potential and sizes of geographic ranges. The West to Central Pacific region appears to operate as a "Sink", where extinction likely outpaces origination, leading to declining diversity but considerable endemism.

## 26-23

**Are Echinoderms From Mars? Insights Into Diversification And Biogeography From The "most Bizarre" Animal Phylum.**

**Gustav PAULAY*[1]**

[1]Florida Museum of Natural History, University of Florida, Gainesville, FL
