Evolution of gases and particles from a savanna fire in South Africa

Peter V. Hobbs, Parikhit Sinha, Robert J. Yokelson, Ted J. Christian, Donald R. Blake, Song Gao, Thomas W. Kirchstetter, Tica Novakov, and Peter Pilewskie

Received 21 March 2002; revised 24 June 2002; accepted 25 July 2002; published 8 March 2003.

[1] Airborne measurements of particles and gases from a 1000-ha savanna fire in South Africa are presented. These measurements represent the most extensive data set reported on the aging of biomass smoke. The measurements include total concentrations of particles (CN), particle sizes, particulate organic carbon and black carbon, light-scattering coefficients, downwelling UV fluxes, and mixing ratios for 42 trace gases and 7 particulate species. The ratios of excess nitrate, ozone, and gaseous acetic acid to excess CO increased significantly as the smoke aged over ∼40–45 min, indicating that these species were formed by photochemistry in the plume. For 17 other species, the excess mixing ratio normalized by the excess mixing ratio of CO decreased significantly with smoke age. The relative rates of decrease for a number of chemical species imply that the average OH concentration in the plume was ∼1.7 × 10^7 molecules cm^-3. Excess CN, normalized by excess CO, decreased rapidly during the first ∼5 min of aging, probably due to coagulation, and then increased, probably due to gas-to-particle conversion. The CO-normalized concentrations of particles <1.5 μm in diameter decreased, and particles >1.5 μm diameter increased, with smoke age. The spectral depletion of solar radiation by the smoke is depicted. The downwelling UV flux near the vertical center of the plume was about two-thirds of that near the top of the plume.

1. Introduction

[2] Biomass burning is a major source of atmospheric trace gases and particles [Crutzen and Andreae, 1990; Fishman et al., 1991]. Savanna fires are the largest source of biomass burning emissions worldwide, and tropical Africa contains about two-thirds of the world’s savanna [Hao and Liu, 1994]. Savanna burning emits a wide variety of species that influence global tropospheric chemistry, including carbon monoxide (CO), nitrogen oxides (NO_x), hydrocarbons, halocarbons, oxygenated organic compounds, and particles [Crutzen and Andreae, 1990; Yokelson et al., 2003]. Smoke aerosols perturb atmospheric radiation through their effects on light extinction and cloud properties [e.g., Hobbs and Radke, 1969; Eagan et al., 1974; Hobbs et al., 1998; Reid et al., 1999]. The photochemical oxidation of CO and organic compounds in the presence of NO_x in smoke produces ozone (O_3) [e.g., Radke et al., 1978; Goode et al., 2000]. Ozone and oxygenated compounds are key precursors of the hydroxyl radical (OH), which is the primary oxidant in the troposphere and is responsible for the removal of reactive pollutants released into the atmosphere by anthropogenic and natural processes [e.g., Seinfeld and Pandis, 1998].

[3] There is a growing body of information on initial emissions from biomass fires [e.g., Stith et al., 1981; Delmas, 1982; Radke et al., 1988; Ward and Hardy, 1991; Hurst et al., 1994; Andreae et al., 1996; Ferek et al., 1998; Sinha et al., 2003; Yokelson et al., 2003], but less is known about the evolution of aging smoke. As smoke ages, it is diluted by mixing with the ambient air, which decreases the mixing ratios of most species emitted by the fire. In addition, some species in the smoke are consumed and others produced by photochemical reactions and other...
processes. Consequently, to assess the regional and global effects of smoke, and to evaluate plume models that include in situ chemical reactions and physical processes, measurements are needed to determine how aging affects the compositions, concentrations, and properties of species in smoke plumes from biomass burning. Changes in the concentrations of species due to in situ chemical and physical processes are revealed, in spite of simultaneous dilution due to mixing with the ambient air, by measuring the change in the ratio of the excess concentration of a species to that of a long-lived tracer for the smoke (such as CO or CO₂).

[5] In studies of smoke from cerrado and rain forest regions of Brazil, Reid et al. [1998] found that the properties of aged gases and particles in regional hazes dominated by biomass burning were significantly different from those of young smoke. For example, as the smoke aged the excess nonmethane hydrocarbons (C < 11) ratioed to excess CO dropped by about one-third, and the aerosol mass to CO ratio increased by about 20–40% with one-third to one-half of the mass growth likely occurring in the first few hours of aging. Changes in particle sizes and compositions during aging had a large impact on the optical properties of the aerosols.

[6] Hobbs et al. [1996] obtained airborne measurements in a smoke plume from a prescribed biomass burn on the Pacific coast of Washington State. Measurable decreases in the CO₂-normalized concentrations of NO and NOₓ were documented over about 35 min of aging. In 1.8 h, the CO₂-normalized concentration of SO₂ decreased by about 60%, and the peak in the CO₂-normalized particle number concentration decreased dramatically while the particle number mode shifted from 0.16 to 0.28 μm and the particle volume mode from 0.25 to 0.38 μm. The mixing ratio of O₃ was below ambient very close to the fire, but it rose quickly and peaked after about a half-hour of aging. Using a high-resolution plume model, Trentmann et al. [2002] were able to reproduce some aspects of the physical evolution of the smoke described by Hobbs et al.

[7] Goode et al. [2000] reported that the ratio of excess O₃ to excess CO rose to as much as 8.9% within 2 h of aging near the top of an Alaskan smoke plume. On the same timescale, the ratio of excess NH₃ to excess CO fell by about two-thirds, and both formic and acetic acid doubled with respect to CO. These observations are mostly consistent with a photochemical model of a smoke plume developed by Mason et al. [2001], which includes oxygenated organic compounds. On longer timescales, measurements of excess O₃/excess CO have been reported for haze layers produced by biomass burning, the ages of which in days were estimated roughly [Wofsy et al., 1992; Andreae et al., 1994; Mauzerall et al., 1996].

[8] In August and September 2000, the University of Washington (UW) Cloud and Aerosol Research Group (CARG), with its Convair-580 research aircraft, participated in the Southern African Regional Science Initiative 2000 (SAFARI 2000) field project. Since one of the goals of SAFARI 2000 is to study the emissions and transformations of smoke from biomass burning, we paid particular attention to obtaining detailed measurements of smoke from ten savanna fires in southern Africa. The measurements obtained in smoke immediately above these fires (i.e., “initial” smoke) are described by Sinha et al. [2003] and Yokelson et al. [2003]. In addition, measurements of particles and gases were made on smoke samples of known ages downwind of several savanna fires. In this paper we describe such measurements for a relatively large prescribed savanna fire that was ignited in the Timbavati game reserve in South Africa on 7 September 2000 (hereafter referred to as the Timbavati fire).

2. Instrumentation and Sampling Techniques

[9] All of the measurements described in this paper were obtained aboard the UW Convair-580 research aircraft. A complete list of the instruments aboard the aircraft is given by P. V. Hobbs in Appendix A of Sinha et al. [2003]. Brief information on each of the instruments used in the present study is given below.

2.1. Continuous Measurements

[10] Ambient air temperatures were measured with an in-house built temperature sensor enclosed in a reverse-flow housing to eliminate dynamic heating. Total temperature was measured with a Rosemount platinum resistance thermometer, and the ambient temperature derived from this by correcting for dynamic heating. The ambient dewpoint temperature, from which the ambient relative humidity (RH) could be derived, was measured with a Cambridge chilled-mirror device.

[11] The NASA Ames Solar Spectral Flux Radiometer (SSFR) was used to measure irradiance over the wavelength range 300–1700 nm [Pilewskie et al., 2003]. Spectral resolution is 9 to 12 nm over the spectra range. The dynamic resolution is 15 bits full range. Integration time was nominally 100 ms and spectral sampling rate was approximately 1 Hz. The SSFR was calibrated for wavelength response, angular response, and absolute spectral power. The SSFR was calibrated before and after flights using a LI-COR field calibration unit, which allowed monitoring of the stability of the SSFR over the duration of the experiment. Absolute accuracy of spectral irradiance was estimated to be 3% across the spectrum. Precision was estimated to be 0.1% over one day and 1% over one month.

[12] Continuous measurements of sulfur dioxide (SO₂) concentrations were made with a Teco 43S pulsed fluorescence analyzer (precision 7%, detection limit 1 ppbv). A TSI 3025A ultrafine condensation particle counter was used to obtain continuous measurements in the smoke plume of the total concentrations of particles (CN), in the size range 0.003–3 μm diameter, with a precision of 10%. Continuous measurements of particle size spectra from 0.5 to 3.0 μm diameter were measured with a TSI 3320 aerodynamic particle sizer. The light-scattering coefficient of particles was measured continuously with an MS Electron nephelometer.
2.2. AFTIR

[13] An airborne Fourier transform infrared spectrometer (AFTIR) was used aboard the Convair-580 aircraft. The AFTIR had a dedicated inlet that directed ram air through a Pyrex multipass cell with an exchange time of 4–5 s. During plume penetrations, the AFTIR was used to grab smoke samples and to detain them for 2–3 min of signal averaging. This allowed measurements of the major reactive and stable trace gases present above 5–20 ppbv. The species measured were water vapor (H2O), carbon dioxide (CO2), CO, nitric oxide (NO), nitrogen dioxide (NO2), methane (CH4), ethene (C2H4), acetylene (C2H2), formaldehyde (HCHO), methanol (CH3OH), acetic acid (CH3COOH), formic acid (HCOOH), ammonia (NH3), nitric acid (HNO3), nitrous oxide (N2O), nitric oxide (NO), nitric dioxide (NO2), nitrogen dioxide (NOF2), methane (CH4), ethene (C2H4), acetylene (C2H2), formic acid (HCOOH), acetic acid (CH3COOH), formaldehyde (HCHO), and hydrogen cyanide (HCN). The AFTIR technique, the precision of the measurements, and many of the results are discussed by Yokelson et al. [2003].

2.3. Filters and Electron Microscope Grids

[14] Particles were collected for specified time periods on quartz filters (Pallflex 2500 QAT-UP), Teflon filters (Gelman Sciences Teflo membrane, 2.0 μm pore size), and on electron microscope (EM) grids. The Teflon filters were weighed before and after particle sampling in a humidity and temperature controlled chamber (RH = 40%, T = 293 K) to determine the masses of dry total particulate matter (TPM) collected on the filters. From control and field blank filters, the uncertainty of the dry TPM was estimated to be ±0.5 μg. By comparison, the typical dry TPM loading for the smoke aerosol samples was always greater than 100 μg.

[15] After gravimetric analysis, the Teflon filters were extracted in deionized water (HPLC grade) and analyzed by a standard ion chromatography system. This analysis yielded mass concentrations of the chloride, nitrate and sulfate (Cl−, NO3 and SO42−, respectively) to a precision of 5%, as well as several organic species (precision within 20%) such as oxalate (C2O42−). An Inductively Coupled Plasma-Atomic Emission Spectrometer was used to measure the mass concentration of the potassium ion (K+) to a precision of 4%. Each of these measurements was accompanied by field blanks to correct for background signals and to estimate measurement uncertainties and detection limits. Further details on the Teflon filter analyses, and results obtained are given by Gao et al. [2003].

[16] Aerosol samples collected intermittently on quartz (Pallflex 2500 QAT-UP) filters were used to determine the concentration of particulate carbon. The quartz filters were baked before use at 800°C for at least 6 h to remove carbonaceous impurities, and then analyzed for total carbon (TC) content using the evolved gas analysis (EGA) method described by Novakov [1981, 1982]. In EGA, a portion of the filter is heated at a constant rate (40°C min−1 in this case) from 50 to 800°C in an oxygen atmosphere. The carbon-containing gases that evolve from the sample are converted to CO2 (over a manganese dioxide catalyst maintained at 800°C) that is subsequently measured with a nondispersive infrared analyzer (Beckman Model 870). A plot of the CO2 concentration versus temperature is called a thermogram. The area under a thermogram is proportional to the TC content of the analyzed sample. The tandem filter method described by Turpin et al. [1994] and Kirchstetter et al. [2001] was used to adjust estimates of TC for the positive sampling artifact that results from the adsorption of organic gases on the quartz filters. Black carbon (BC) concentrations were estimated with an optical transmission technique similar to that described by Rosen and Novakov [1983]. This method compares the attenuation of white light through a loaded filter relative to that of a blank filter. The relationship between optical attenuation (ATN) and the BC concentration (μg cm−2) is given by ATN = σ·BC, where ATN = 100ln(Io/I), and Io and I are the transmitted light intensities through the blank and loaded filters, respectively, and σ is the mass absorption cross section for BC deposited on quartz (m2g−1) [Gundel et al., 1984]. A value of 20 m2g−1 was used for the mass absorption cross section. This value was derived from comparison of light absorption measurements and BC concentrations (measured by thermal EGA) on many samples [Gundel et al., 1984; Kirchstetter et al., 2003]. Further information on the EGA and optical transmission techniques used here, and the results obtained, are given by Kirchstetter et al. [2003].

[17] Since the time that it took the aircraft to cross the width of a smoke plume (~1–2 min) was too short to pass enough smoke through the Teflon filters, quartz filters, and the EM grids for subsequent detailed analyses of the aerosol, a “grab-bag” technique was used. The grab-bag consisted of a 2.5 m3 electrically conducting plastic (Velostat) bag, which could be filled with a sample of smoke in 12 s when exposed to ram air. The sample in the grab-bag was drawn through the various gas and aerosol measuring instruments aboard the aircraft, through the filters, and onto the EM grids, for subsequent analysis. Particle size measurements could also be made using the bag samples. The grab-bag system had an aerosol 50% cut-off diameter of about 4 μm, as larger particles were lost in the inlet and on the walls of the grab bag. When crossing a plume, the grab-bag was also used to obtain samples for SO2 measurements using the Teco 43S pulsed fluorescence analyzer. Grab-bag samples were followed by sampling of the ambient air, allowing determination of excess concentrations of species in a plume.

2.4. Canister Samples

[18] Electropolished stainless steel canisters were filled with air samples from smoke plumes, and ambient air just upwind of the fires, using a stainless steel inlet that passed through the aircraft fuselage. The canister samples coincided with the “grab-bag” samples. A typical sampling time for a canister was 30 s. The canister samples were subsequently analyzed for hydrocarbons, halocarbons, dimethyl sulfide (DMS), and methyl nitrate (CH3ONO2).

[19] For each canister sample, mixing ratios of C2−C9 nonmethane hydrocarbons (NMHC), methyl chloride (CH3Cl), methyl iodide (CH3I), chloroform (CHCl3), methyl bromide (CH3Br), bromoform (CHBr3), chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs) were determined by gas chromatography with flame ionization, electron capture and mass spectrometer detection. The precision of the NMHC, CHCl3, CHBr3 and methyl halide measurements was 3%, and the NMHC detection limit was 3 pptv.
Measurements of the longer-lived CFCs, HCFCs, and HFCs were precise to within 1%. Mixing ratios (precisions in parentheses) of CO2 (3%), CO (5%), and CH4 (0.1%) were determined using separate instrumentation. A detailed description of the analytical procedure for the canister samples, including quantification of the measurement precision for individual compounds, is given by Colman et al. [2001].

3. Definitions of Excess Molar Mixing Ratio, Normalized Excess Molar Mixing Ratio, and Combustion Efficiency

[20] The excess molar (or volume) mixing ratio, \( \Delta X \), of a species X in a smoke plume is defined as:

\[
\Delta X = X_{\text{plume}} - X_{\text{ambient}}
\]

where, \( X_{\text{plume}} \) and \( X_{\text{ambient}} \) are the molar (or volume) mixing ratios of X in the smoke plume and in the ambient air, respectively.

[21] The normalized excess molar mixing ratio of a species X is the excess molar mixing ratio of X in the smoke divided by the excess molar mixing ratio of a simultaneously measured reference gas (such as CO or CO2). For example, a normalized excess molar emission ratio of species X relative to CO is \( \Delta X/\Delta CO \). It is common to refer to this as the excess molar emission ratio. However, we prefer to use this wording only when \( \Delta X \) and \( \Delta CO \) are measured very close to a fire, as described by Sinha et al. [2003]. Since CO is a biomass burning product with a lifetime of \( \sim 1 \) month in the ambient, tropical troposphere, most of the decrease in the excess molar mixing ratio of CO in the smoke plume, at least in the first few hours, is due to mixing with the ambient air. Therefore, by dividing \( \Delta X \) by \( \Delta CO \), the effects of dilution of \( \Delta X \) due to mixing with the ambient air are largely removed, so that other physical and chemical processes that change \( \Delta X \) in the plume can be isolated.

[22] The combustion efficiency (CE) is the molar ratio of excess carbon (C) emitted as CO2 from a fire to the total excess carbon emitted [Ward and Hardy, 1991]:

\[
CE = \frac{\Delta C_{CO_2}}{\Delta C_{CO_2} + \Delta C_{CO} + \Delta C_{CH_4} + \Delta C_{NMOC} + \Delta C_{PC}}
\]

where NMOC and PC indicate nonmethane organic compounds and particulate carbon, respectively. Thus, CE is the fraction of fuel carbon emitted that is completely oxidized to CO2.

[23] Although CE is a useful quantity for fire models, it is often difficult to measure all of the individual carbon species in the emissions from a fire. As will be shown below, the emission of CO is closely linked to the emission of CH4, NMOC, and PC. Therefore, in this study we have chosen to use the modified combustion efficiency (MCE) as the principal quantity to describe the relative amounts of flaming and smoldering combustion [Ward and Hao, 1992; Ward and Radke, 1993], which is defined as:

\[
MCE = \frac{\Delta C_{CO_2}}{\Delta C_{CO_2} + \Delta C_{CO}}
\]

Since CH4, NMOC, and PC are emitted in small quantities relative to CO2 and CO, the difference between CE and MCE is typically only a few percent.

[24] Both CE and MCE are useful as indicators of the relative amounts of flaming and smoldering combustion that generate emissions. In laboratory studies, Yokelson et al. [1996] found that pure flaming combustion has an MCE near 0.99 and pure smoldering combustion an MCE near 0.8. Therefore, an MCE < 0.9 roughly indicates >50% smoldering combustion, and an MCE > 0.9 suggests >50% flaming combustion.

4. Vegetation and Fire

[25] The Timbavati fire was a carefully controlled and monitored fire in the lowveld of South Africa (T. Land-
mann, personal communication, 2002). In this region of the lowveld the vegetation varies from south Zambezian undifferentiated woodland to Tongaland-Pondoland bushland [White, 1981, 1983]. The fuel for the Timbavati fire was mainly grass, with litter (leaves and twigs) constituting only about 1% of the fuel. The fuel load was $\approx 4800$ kg/ha and $\approx 1000$ ha were ignited. Since $\approx 80\%$ of the fuel exposed to fire was combusted, $\approx 3.8 \times 10^6$ kg of biomass was burned (T. Landmann, personal communication, 2002). The fire was $\approx 2$ km in width.

The main fire was ignited at 0801 UTC (1001 local time) and the flames reached $\approx 2$ m in height. A downwind backfire ignited at 0730 UTC had flames that reached $\approx 0.3–0.5$ m in height. Prior to 1100 UTC the fire was predominantly flaming; thereafter, smoldering combustion dominated. The fire was extinct by 1130 UTC, after smoldering samples of wood were put out near the edge of the plot.

Figure 1 shows an image of the fire taken at 0829 UTC from the NASA ER-2 aircraft flying at an altitude of $\approx 20$ km. The locations of the head fire, back fire, and the ignition point can be seen in Figure 1. Figure 2 shows a photograph of the fire 7 min later, which was taken from the Convair-580 as it approached the fire from upwind.

5. Flight Track

Measurements of the smoke from the Timbavati fire were acquired aboard the Convair-580 from 0842 to 1036 UTC, which was during the predominantly flaming stage of the fire. Figure 3 shows a simplified schematic of the flight track of the Convair-580 during this period. From about 0842 to 1036 UTC samples of smoke were obtained in a series of passes perpendicular to the axis of the plume at various distances and altitudes downwind of the head fire. During these passes, the pilot was instructed to fly the aircraft across the width of the plume.

Table 1 summarizes the times and locations of the plume samples, and some of the parameters measured. Using the average wind speed measured aboard the aircraft ($11.3 \pm 0.9$ m $s^{-1}$), and the distances downwind from the

a Samples 1–5 were collected in canisters and analyzed by gas chromatography. Samples 6–k were measured by AFTIR.

b Derived from an average measured wind speed of $11.3 \pm 0.9$ m $s^{-1}$.
head fire of the various samples, the age of the smoke in each sample was estimated (see Table 1). Environmental conditions for each sample (e.g., pressure, temperature, RH, UV flux, etc.) are also given in Table 1. Samples 1–5 in Table 1 were collected in stainless steel canisters and on Teflon and quartz filters. Samples a–k in Table 1 were analyzed by AFTIR.

The time interval between crossing the plume and 30.1 km downwind of the head fire was 110 min. Therefore, the average speed of the aircraft along the length of the plume was 4.5 m s\(^{-1}\), compared to the average wind speed of 11.3 ± 0.9 m s\(^{-1}\). Hence, the first and last samples were not exactly Lagrangian pairs. However, as mentioned previously, the fire was predominantly flaming and moving into fresh fuel during this period of time (as indicated also by the MCE values in Table 1). Therefore, variations in the excess mixing ratio of a species with age of the smoke should primarily reflect effects that occurred downwind.

6. Results and Discussion

6.1. Vertical Profiles Upwind of the Fire and Transects Through the Smoke Plume

Figure 4 shows vertical profiles of temperature, relative humidity, and SO\(_2\) concentration measured upwind of the Timbavati fire from 0829 to 0840 UTC.

![Figure 4](image)

Figure 4. Vertical profiles of temperature, relative humidity, and SO\(_2\) concentration measured upwind of the Timbavati fire from 0829 to 0840 UTC.

[30] Shown in Figures 5 and 6 are the light-scattering coefficient due to particles and CN concentrations measured in horizontal tracks across the width of the smoke plume and at various distances downwind of the fire. At 0.2 km downwind, where the width of the plume was 3–4 km, the peak values of the light-scattering coefficient and CN were 0.0022 m\(^{-1}\) and 7 × 10\(^5\) cm\(^{-3}\), respectively. The

Figure 5. Particle light-scattering coefficient across the width of the Timbavati smoke plume at various distances downwind of the fire.
corresponding values at 26.2 km downwind, where the width of the plume was \( \sim 10-15 \) km, were \( 0.0004 \) m \(^{-1}\) and \( 0.5 \times 10^5 \) cm \(^{-3}\).

### 6.2. Attenuation of Solar Radiation by Smoke

[33] Since photochemical reactions in the smoke will depend on the intensity of UV radiation, we show in Figure 7 the downwelling UV irradiance in the wavelength band 300–390 nm, measured by the SSFR aboard the Convair-580, in the Timbavati plume from 0842 to 1036 UTC. Generally, the aircraft was flown at about the vertical center of the plume, but for a brief period of time it was near the top of the plume. Near the center of the plume, the UV flux was about two-thirds of that near the top of the plume.

[34] Figure 8a shows SSFR-measured upwelling and downwelling irradiance spectra at 0939 UTC (solid curve) and at 1021 UTC (dashed curve), near plume top and approximately 1000 m below plume top, respectively. Both sets of measurements were obtained 20–25 km downwind of the fire. Figure 8b shows the fractional absorption (obtained by normalizing the absorbed solar radiation in

The solid curve was obtained at 0939 UTC near plume top, and the dashed curve at 1021 UTC at \( \sim 1000 \) m below plume top. (b) Fractional absorption between plume top and \( \sim 1000 \) m below plume top.
by gas chromatography (GC/C) and filters (F/GB) and which were considered to derive from biomass burning by the significant correlation of their excess mixing ratios with the excess mixing ratio of CO or CO2 ($r^2 \geq 0.5$). Table 3 lists the excess mixing ratios of gases measured in the smoke plume by AFTIR.

[38] It can be seen from Tables 2 and 3 that the mixing ratios of many chemical species in the plume changed with distance from the fire. This could be due to chemical reactions, which may produce or consume a species with time. However, even for a species that is not affected by chemical reactions, the mixing ratio in the plume will generally decrease with increasing distance from a fire due to mixing of the smoke with the ambient air. As discussed in section 3, the dilution of a species due to mixing with the ambient air can be removed in large part, at least for the first few hours of travel, by dividing the excess molar mixing ratio of the species by the excess molar mixing ratio of CO.

[39] Isoprene has a daytime lifetime in the ambient tropical atmosphere of only $\sim 60$ min due to its reaction with OH [Mauzerall et al., 1998]. Consequently, decreases in the excess mixing ratios of isoprene in young smoke should reflect both its reaction with OH and dilution due to mixing with ambient air. Figure 10 shows $\Delta$Isoprene/ΔCO as a function of the age of the smoke in the Timbavati plume. Both quantities decline to ambient levels at approximately the same rate, which indicates that chemical reactions were dominant in decreasing the concentration of isoprene in the plume.

[40] Figure 11 shows a plot similar to Figure 10 but for ethene, which has a significantly longer lifetime than isoprene. In this case, $\Delta$C2H4/ΔCO decreases only slightly with age (over $\sim 40$ min), but $\Delta$C2H4 ratio falls off more rapidly (due to mixing with the ambient air).

### 6.3.2. Photochemistry

[41] A value of $\Delta X/\Delta CO$ measured before any significant postemission transformations is the emission ratio of compound X for the fire. Changes in $\Delta X/\Delta CO$ as smoke ages reveal the rate of photochemical and heterogeneous processes in the plume. Tables 4 and 5 show $\Delta X/\Delta CO$ values for many samples of various ages in the smoke from the Timbavati fire. While $\Delta X/\Delta CO$ decreases with the age of the smoke for various hydrocarbons, due to reactions with OH (or more slowly with O3), it should increase for photochemical products. For example, Figure 12 shows $\Delta X/\Delta CO$ for acetic acid (CH3COOH), O3, and nitrate increasing as the smoke ages. After 40 min of aging, $\Delta$CH3COOH/ΔCO is about three times its initial value (Figure 12a). By contrast, it took $> 2$ h for this ratio to double in Alaskan smoke plumes [Goode et al., 2000].

[42] In minutes-old smoke from the Timbavati fire the O3 mixing ratio was below ambient due to reaction with NO and particles, but $\Delta$O3/ΔCO rose to as much as 9% within 30 min (Figure 12b). In comparison, $\Delta$O3/ΔCO rose more slowly to only $\sim 1.5\%$ in 30 min in a smoke plume in the Pacific Northwest of the United States [Hobbs et al., 1996], and required $\sim 2$ h to reach 9% in an Alaskan smoke plume [Goode et al., 2000]. These initial bursts of O3 production may account for a significant portion of the total O3 production in smoke plumes, since Yokelson et al. [2003] report $\Delta$O3/ΔCO of 22% in biomass burning haze several

HOBBS ET AL.: EVOLUTION OF GASES AND PARTICLES SAF 21 - 9
alkenes, which react quickly with OH and more slowly with O₃ (of at least 95%). Most of the hydrocarbons in Table 6 are organic compounds and NOx. Listed in Table 6, and shown in Figures 12–15, are those gases for which ΔX/ΔCO either increased or decreased significantly with aging when modeled as a linear process. (“Significant” refers to a statistical confidence level of at least 95%.) The species in Table 6 are similarly linked. For example, photolysis of NO₂ yields O₃. Thus, Table 6 shows that during the first 40 min in the Timbavati plume the average concentration of OH in the smoke as it ages over the time interval t.

6.3.3. Estimates of OH Concentrations in the Smoke

The rate-limiting step for loss of many chemical species in the atmosphere is reaction with the OH radical. We can use this fact to estimate the average concentration of OH in the relatively young smoke from the Timbavati fire. The ratio ΔNO₂/ΔCO decreased while ΔO₃/ΔCO increased. The ratio ΔNO₂/ΔCO decreased to roughly one-third of its initial value in ~40 min. However, this measurement should not be viewed as quantitative, since all of the downwind NO₂ mixing ratios were near or below the detection limit of the AFTIR. Nitrogen dioxide can also react with OH to yield gas phase HNO₃, which can then be converted to particulate nitrate; ΔNO₃/ΔCO increased by a factor of 2.5 in 39 min in the Timbavati plume.

6.3.3. Estimates of OH Concentrations in the Smoke

The rate-limiting step for loss of many chemical species in the atmosphere is reaction with the OH radical. We can use this fact to estimate the average concentration of OH in the relatively young smoke from the Timbavati fire. The ratio ΔNO₂/ΔCO decreased while ΔO₃/ΔCO increased. The ratio ΔNO₂/ΔCO decreased to roughly one-third of its initial value in ~40 min. However, this measurement should not be viewed as quantitative, since all of the downwind NO₂ mixing ratios were near or below the detection limit of the AFTIR. Nitrogen dioxide can also react with OH to yield gas phase HNO₃, which can then be converted to particulate nitrate; ΔNO₃/ΔCO increased by a factor of 2.5 in 39 min in the Timbavati plume.

Figure 10. Excess volume mixing ratio of isoprene (squares), and the excess volume mixing ratio of isoprene normalized with respect to CO (circles), versus age of the smoke in the Timbavati plume.

days old off the coast of Namibia, and Andreae et al. [1994] measured a range of ΔO₃/ΔCO values from 20% to 88% in biomass burning haze estimated to be about 10 days old over the South Atlantic Ocean. Hence, for some species ΔX/ΔCO can increase significantly after emission, but the rate of change depends on the species and on local conditions. As expected, faster photochemistry is observed in sub tropical Africa than at higher latitudes. Photochemistry should be faster near the top of a plume where ultraviolet light is more intense. The ΔO₃/ΔCO values we measured high in the Timbavati plume (i.e., samples e, f and g in Figure 7) lie above the slope in Figure 12b that gives the average formation rate.

[45] If the rate of decrease in the CO-normalized excess mixing ratio of species X in a smoke plume is dominated by its reaction with OH, we can write:

$$\frac{\Delta X}{\Delta CO}t = \left[\frac{\Delta X}{\Delta CO}\right]_0 \exp\{-k_\text{OH}|t\}$$

where $\Delta X/\Delta CO$ and $(\Delta X/\Delta CO)_h$ are the CO-normalized excess mixing ratios of X immediately over the fire (t = 0) and after the smoke has aged for time t, respectively, and $k_\text{OH}$ is the rate coefficient for X reacting with OH. If equation (4) is applied to two species X₁ and X₂, the following is obtained:

$$\ln\left(\frac{\Delta X_1}{\Delta X_2}\right)_t = -[OH](k_1 - k_2)t + \ln\left(\frac{\Delta X_1}{\Delta X_2}\right)_0$$

where, $k_1$ and $k_2$ are the rate coefficients for $X_1$ and $X_2$, respectively, reacting with OH. Hence, a plot of $\ln(\Delta X_1/\Delta X_2)$ versus $(k_1 - k_2)t$ will have slope $-|OH|$, where $|OH|$ is the average concentration of OH in the smoke as it ages over the time interval t.

[46] Results for the average OH concentrations derived in this way using combinations of the five best species (propene, ethene, 1-butene, ethane and CO) that have various reaction rates with OH but negligible competing loss rates due to O₃, are shown in Table 7; example plots are shown in Figure 16. The average derived concentration of OH, using room temperature rate constants, during the first ~40 min in the Timbavati plume is $(1.7 \pm 0.2) \times 10^7$ molecules cm⁻³.

[47] Noontime, cloud-free, surface OH concentrations at the latitude and in the season of this study were modeled to be only $(3–4) \times 10^6$ molecules cm⁻³ [Logan et al., 1981], or ~4–6 times lower than our estimated value for the OH concentrations in the Timbavati plume. Other models and measurements (including those of polluted urban air) yield maximum OH concentrations ranging from ~$(2–10) \times 10^6$ molecules cm⁻³ [Finlayson-Pitts and Pitts, 2000]. The photochemical model of a smoke plume developed by Mason et al. [2001] predicts OH levels a little greater than $1 \times 10^6$ molecules cm⁻³ during the first hour of plume evolution when initialized with oxygenated organic compounds and ΔNOₓ/ΔCO of 0.02 (S. Mason, personal communication, 2002). An important implication

Figure 11. As for Figure 10 but for ethene.
of the high average OH concentration that we have derived from the Timbavati plume is that the lifetime of reactive species in biomass-burning plumes is much shorter than suggested by 24-h average lifetimes calculated for ambient conditions.

[48] The short lifetimes of many fire emissions are evident in the data for the Timbavati fire (Table 4). For example, Δ1-butene/ΔCO decreased to 35% of its initial value in 31 min; much faster than implied by the average tropical lifetime of 2.2 h calculated by Mauzerall et al. [1998] using a 24-hour average OH concentration of $2.7 \times 10^6$ molecules cm$^{-2}$. The Δisoprene/ΔCO ratio fell by a factor of 2 in only 7 min, and ΔC$_2$H$_4$/ΔCO fell by 30% in 39 minutes. These changes are also much faster than implied by

study, particularly as these young plumes are a major global source of trace gases and particles.

6.3.4. Transformations of Particles

[50] The concentrations of CN and accumulation-mode particles (0.1–3 μm diameter) changed as the smoke from the Timbavati fire aged.

[51] Figure 17a shows the excess CN concentrations measured as the Convair-580 flew along the length of the plume between 0950 and 0955 UTC. The concentrations were high (~500,000 cm⁻³) in the immediate vicinity of the fire but fell off sharply (to 50,000 cm⁻³) within about 5.5 km and remained near this value to about 23 km downwind. However, even at 23 km downwind the excess CN concentrations were well over an order of magnitude greater than in the ambient air. To compensate for the effects of plume dilution on the excess CN concentrations, we show in Figure 17b ΔCN/ΔCO along the length of the plume. The normalized excess CN concentrations decrease for about 10 min, but thereafter show an overall increase with aging. We attribute the initial decrease to coagulation of the highly concentrated particles. If we assume monodispersed particles with a diameter of 0.01 μm, the estimated e-folding time for decreasing CN concentrations by particle coagulation is ~9 min up to about 3 km from the fire, but at ~20 km from the fire it is ~170 min. Changing the diameter of the assumed monodispersed particles to 0.003 and 0.1 μm changes the e-folding time up to 3 km from the fire to 2.5 and 70 min, respectively. The increase in the normalized excess CN concentrations beyond ~10 min, seen in Figure 17b, could be due to gas-to-particle (g-to-p) conversion dominating over coagulation. The production of new particles by g-to-p conversion, as opposed to condensation onto

![Figure 12](image)

Figure 12. Excess mixing ratios normalized with respect to CO as a function of age of smoke in the Timbavati plume of (a) acetic acid and (b) ozone. The ratio of particulate nitrate (in μg m⁻³) normalized by the excess volume mixing ratio of CO (in ppmv) is shown in (c).

the lifetimes calculated by Mauzerall et al. [1998] of 1 and 12 h, respectively.

[50] We conclude that the photochemical environment in young biomass burning plumes differs considerably from ambient or average conditions and requires specialized

*See Tables 2 and 3 for measurement techniques. “Significant” refers to a statistical confidence level = 95%.
Figure 13. As for Figure 12 but for (a) nitrogen dioxide (NO₂), (b) ethene (C₂H₄), (c) propene (C₃H₆), (d) 1,2-pentene (C₅H₁₀), (e) 2-methyl-2-butene (C₇H₁₄), and (f) 1-pentene (C₅H₁₀).
existing particles, is favored by smaller surface area concentrations of particles; the aerosol surface area concentration in the Timbavati plume decreased by a factor of about five from 0 to 10 km downwind of the fire. Discussions by Gao et al. [2003] on g-to-p conversion of some organic species support this interpretation.

Figure 14. As for Figure 12 but for (a) 2-methyl-1-pentene (C₆H₁₂), (b) 1,3-butadiene (C₄H₆), (c) 1-butene (C₄H₈), (d) isoprene (C₅H₈), (e) benzene (C₆H₆), and (f) t-2-butene (C₄H₈).
smoke samples 0 and 39 min old in the Timbavati plume. The effects of dilution on the particle concentrations due to mixing with the ambient air have been removed from the curves shown in Figure 18 by dividing the concentrations by CO. For particles less than about 1.5 μm in diameter, the particle concentrations decreased as the smoke aged, whereas for larger particles the concentrations were greater in the smoke that was 39 min old than in the smoke.
initially emitted from the fire. These results are consistent with the smaller particles coagulating to form the larger particles.

Sample 5 (see Table 1) was the oldest sample (39 min) for which both the excess mixing ratio of CO and the excess mass of particulate nitrate were measured. From the data in Table 2, we can compute the excess mass of nitrate (per m$^3$ of the smoke) in sample 5, which can then be converted to the number of excess NO$_3^-$ molecules per cubic meter of smoke ($8 \times 10^{16}$) using the molecular mass of nitrate (62) and Avogadro’s number ($6.022 \times 10^{23}$ molecules mol$^{-1}$). We can also compute the number of excess CO molecules per cubic meter of smoke in sample 5 ($2 \times 10^{19}$) from its excess volume-mixing ratio of 0.88 ppmv. These calculations imply that the ratio of excess NO$_3^-$ molecules to excess CO molecules in sample 5 is $\sim 0.004$. This ratio is higher than the initial $\Delta$NH$_3$/\Delta$CO ratio in the smoke ($\sim 0.002$; see Table 5 samples a and b).

$^a$Rate coefficients for the reactions were taken from Finlayson-Pitts and Pitts [2000].

**Figure 16.** Plots of equation (5) based on measurements in the Timbavati plume. The slope provides an estimate of the average OH concentration in the plume during the first $\sim$40 min of smoke aging.
Therefore, not all of the nitrate can be present as ammonium nitrate. This suggests that some of the NO$_3^-$ may be paired with K$^+$ or other positive ions rather than ammonium (NH$_4^+$). Potassium nitrate was observed in older smoke samples by Li et al. [2003] using electron microscopy. The $\Delta$NO$_3^-$/$\Delta$CO ratio of 0.004 for sample 5 can also be compared to the initial $\Delta$NO$_x$/$\Delta$CO ratio (see Table 5 samples a and b) of $\sim$0.04. The comparison

---

**Figure 17.** (a) Running mean concentration of condensation nuclei (CN) along the length of the Timbavati smoke plume. (b) Excess concentration of CN normalized by excess concentration of CO along the length of the Timbavati smoke plume. The ambient concentration of CN was $\sim$1000 cm$^{-3}$. The excess concentrations of CO were obtained by interpolating canister measurements.
implies that up to ~10% of the initial NOx was converted to particle nitrate in ~40 min. Much of the rest of the NOx was probably converted to gas-phase reservoir species, such as PAN, HNO3(g), alkyl nitrates, etc. (In extratropical fires, the initial NH3/CO and NOx/CO ratios are more nearly equal, which may favor the production of relatively more particle ammonium nitrate [Goode et al., 2000].) A similar analysis for sulfur species suggests that ~10% of the initial SO2 was converted to SO42− in ~40 min.

Four papers in this Special Issue of Journal of Geophysical Research provide additional information on the effects of aging on particles in the plume from the Timbavati fire. Magi and Hobbs [2003] show that the change in the light-scattering coefficient of the smoke, as the relative humidity was increased from 30 to 80%, was less for smoke aged over 40 min than for smoke just over the fire. Transmission electron microscopy (TEM) was used to study individual particles in the smoke from the Timbavati fire [Li et al., 2003; Pósfai et al., 2003]. In the initial smoke just above the fire, potassium chloride (KCl) particles with organic coatings dominated, with lesser amounts of calcium-bearing particles, tar balls, organic particles, sea salt, mineral dust, and minor amounts of soot. The most obvious effect of aging of the smoke was a transformation from KCl particles to potassium sulfate and nitrate particles. The relative number concentration of organic particles was largest in the young smoke, whereas tar balls were dominant in the more aged smoke. Gao et al. [2003] discuss the secondary formation of inorganic and organic species in smoke from the Timbavati and other fires. It was found that secondary formation of sulfate, nitrate, levoglucosan, and several organic acids occurred during the initial aging of smoke aerosols, presumably due to condensation.

7. Conclusions

In this paper we have described airborne measurements of the emissions and initial evolution of particles and gases from a 1000-ha prescribed burn of savanna vegetation in South Africa. These measurements represent the most extensive and quantitative data yet reported on the effects of aging on biomass smoke.

This study has provided:
1. Excess mixing ratios and downwind changes in normalized excess mixing ratios for 42 trace gases, total particulate matter, organic carbon, black carbon, and particulate Cl−, NO3−, SO42− and K+ (Tables 2–5).
2. An estimate of the average OH concentration in the young smoke plume (Table 7 and Figure 16).
3. Downwelling and upwelling UV fluxes (300–390 nm) within the smoke along the length of the plume (Table 1 and Figure 7), and the spectral depletion of solar radiation by the smoke (Figures 8 and 9).
4. Measurements of the light-scattering coefficient, and condensation nucleus (CN) concentrations across the width of the smoke plume at various distances downwind of the fire (Figures 5 and 6), CN measurements along the length of the plume (Figure 17), and the evolution of the particle size spectra during ~40 min of aging (Figure 18).

Figure 18. Aerosol size distributions of smoke over fire (0 min) and after aging for 39 min. The excess particle concentrations are divided by excess CO concentrations to eliminate the effects of mixing of the smoke with the ambient air.
